This volume is dedicated to AMIA, the principal professional association for the editors. Born as the American Medical Informatics Association in 1990, AMIA is now preferentially known simply by its acronym and has grown to include some 5500 members who are dedicated to all aspects of biomedical informatics. AMIA and this textbook have evolved in parallel for four decades, and we thank the organization and its members for all they have done for the field and for health care and biomedicine. May both AMIA and this volume evolve and prosper in parallel for years to come.

## Foreword

---

Health and biomedicine are in the midst of revolutionary change. Health care, mental health, and public health are converging as discovery science reveals these traditional “silos” share biologic pathways and collaborative management demonstrates better outcomes. Health care reimbursement is increasingly framed in terms of paying for outcomes achieved through value-based purchasing and population health management. Individuals are more engaged in their health and wellness decisions, using personal biomedical monitoring devices and testing services and engaging in citizen science. Systems biology is revealing the complex interactions among a person’s genome, microbiome, immune system, neurologic system, social factors, and environment. Novel biomarkers and therapeutics exploit these interactions.

These advances are fueled by digitization and generation of data at an unprecedented scale. The volume of health care data has multiplied 8 times since 2013 and is projected to grow at a compound annual rate of 36% between 2018 and 2025<sup>1</sup>. The rate of growth of biomedical research data is comparable<sup>2</sup>. When you consider recent estimates that socioeconomic, health behaviors, and environment—factors outside of the domain of health care and biomedicine—contribute as much as 80% to health outcomes<sup>3</sup>, the variety and scale of health-related data are breathtaking.

Biomedical informatics provides the scientific basis for making sense of these data—methods and tools to structure, mine, visualize, and reason with data and information. Biomedical informatics also provides the scientific basis for incorporating data and information into effective workflows—techniques to link people, process, and technology into systems; methods to evaluate systems and technology components; and methods to facilitate system-level change.

Biomedical informatics grew out of efforts to understand biomedical reasoning<sup>4</sup>, such as artificial intelligence; to develop medical systems, such as multiphasic screening<sup>5</sup>; and to write computer programs to solve clinical problems, such as diagnosis and treatment of acid-base disorders<sup>6</sup>. By the late 1970s, “medical informatics” was used interchangeably with “computer applications in medical care”. As computer programs were written for various allied health disciplines, nursing informatics, dental informatics, and public health informatics emerged. The 1980s saw the emergence of computational biology for applications such as scientific visualization and bioinformatics to support tasks such as DNA sequence analysis.

*Biomedical Informatics: Computer Applications in Health Care and Biomedicine* provided the first comprehensive guide to the field with its first edition in 1990. That edition and the subsequent three have served as the core syllabus for introductory courses in informatics and as a reference source for those seeking advanced training or working in the field. The fifth edition carries on the tradition with new topics, comprehensive glossary, reading lists, and citations.

I encourage people who are considering formal education in biomedical informatics to use this book to sample the field. The book's framework provides a guide for educators from junior high to graduate school as they design introductory courses in biomedical informatics. It is the basic text for students entering the field.

With digitization and data driving change across the health and biomedicine ecosystem, everyone in the ecosystem will benefit from reading *Biomedical Informatics* and using it as a handbook to guide their work. The following is a sample of questions readers can turn to the book to explore:

- **Practicing health professionals**—How do I recognize an information need? How do I quickly scan and filter information to answer a question? How do I sense the fitness of the information to answer my question? How do I configure my electronic health record to focus my attention and save time? How do I recognize when to override decision support? How do I analyze data from my practice to identify learning and improvement opportunities? How do I engage with patients outside of face-to-face encounters?
- **Quality improvement teams**—How might we detect if the outcome we are trying to improve is changing in the desired direction? Are data available in our operational systems that are fit for that purpose? What combination of pattern detection algorithm, workflow process, decision support, and training might work together to change the outcome? How can we adapt operational processes and systems to test the change and to scale if it proves effective?
- **Discovery science teams**—How do data about biological systems differ from data about physical systems? How do we decide when to use integrative analytic approaches and when to use reductionist approaches? How much context do we need to keep about data we create and how do we structure the metadata? How do we optimize compute and storage platforms? How might we leverage electronic health record-derived phenotype to generate hypotheses?
- **Artificial intelligence researchers or health “app” developers**—What health outcome am I trying to change? Do I need a detection, prediction, or classification algorithm? What sources of data might be fit for that purpose? What type of intervention might change the outcome? Who would be the best target for the intervention? What is the best place in their workflow to incorporate the intervention?
- **Health system leaders**—How do we restructure team roles and electronic health record workflows to reduce clinician burnout and improve care quality? How do we take advantage of technology-enabled self-management and virtual visits to increase adherence and close gaps in care? How do we continuously evaluate evidence and implement or de-implement guidelines and decision support across our system? How do we leverage technology to deploy context-sensitive just-in-time learning across our system?
- **Health policy makers**—How might we enhance health information privacy and security and reduce barriers to using data for population

health, health care quality improvement, and discovery? To what degree is de-identification a safeguard? What combination of legislative mandate, executive action, and industry-driven innovation will accelerate health data interoperability and business agility? How might federal and state governments enable communities to access small area data to inform their collective action to improve community health and well-being?

You have taken the first step in exploring these frontiers by picking up this book. Enjoy!

## Preface to the Fifth Edition

---

The world of biomedical research and health care has changed remarkably in the 30 years since the first edition of this book was published. So too has the world of computing and communications and thus the underlying scientific issues that sit at the intersections among biomedical science, patient care, public health, and information technology. It is no longer necessary to argue that it has become impossible to practice modern medicine, or to conduct modern biological research, without information technologies. Since the initiation of the Human Genome Project three decades ago, life scientists have been generating data at a rate that defies traditional methods for information management and data analysis.

Health professionals also are constantly reminded that a large percentage of their activities relates to information management—for example, obtaining and recording information about patients, consulting colleagues, reading and assessing the scientific literature, planning diagnostic procedures, devising strategies for patient care, interpreting results of laboratory and radiologic studies, or conducting case-based and population-based research. Artificial intelligence, “big data,” and data science are having unprecedented impact on the world, with the biomedical field a particularly active and visible component of such activity.

It is complexity and uncertainty, plus society’s overriding concern for patient well-being, and the resulting need for optimal decision making, that set medicine and health apart from many other information-intensive fields. Our desire to provide the best possible health and health care for our society gives a special significance to the effective organization and management of the huge bodies of data with which health professionals and biomedical researchers must deal. It also suggests the need for specialized approaches and for skilled scientists who are knowledgeable about human biology, clinical care, information technologies, and the scientific issues that drive the effective use of such technologies in the biomedical context.

### Information Management in Biomedicine

---

The clinical and research influence of biomedical-computing systems is remarkably broad. Clinical information systems, which provide communication and information-management functions, are now installed in essentially all health care institutions. Physicians can search entire drug indexes in a few seconds, using the information provided by a computer program to anticipate harmful side effects or drug interactions. Electrocardiograms (ECGs) are typically analyzed initially by computer programs, and similar techniques are being applied for interpretation of pulmonary-function tests and a variety of laboratory and radiologic abnormalities. Devices with embedded processors routinely monitor patients and provide warnings in critical-care settings, such as the

intensive-care unit (ICU) or the operating room. Both biomedical researchers and clinicians regularly use computer programs to search the medical literature, and modern clinical research would be severely hampered without computer-based data-storage techniques and statistical analysis systems. Machine learning methods and artificial intelligence are generating remarkable results in medical settings. These have attracted attention not only from the news media, patients, and clinicians but also from health system leaders and from major corporations and startup companies that are offering new approaches to patient care and health information management. Advanced decision-support tools also are emerging from research laboratories, are being integrated with patient-care systems, and are beginning to have a profound effect on the way medicine is practiced.

Despite this extensive use of computers in health care settings and biomedical research, and a resulting expansion of interest in learning more about biomedical computing, many life scientists, health-science students, and professionals have found it difficult to obtain a comprehensive and rigorous, but nontechnical, overview of the field. Both practitioners and basic scientists are recognizing that thorough preparation for their professional futures requires that they gain an understanding of the state of the art in biomedical computing, of the current and future capabilities *and* limitations of the technology, and of the way in which such developments fit within the scientific, social, and financial context of biomedicine and our health care system. In turn, the future of the biomedical-computing field will be largely determined by how well health professionals and biomedical scientists are prepared to guide and to capitalize upon the discipline's development.

This book is intended to meet this growing need for such well-equipped professionals. The first edition appeared in 1990 (published by Addison-Wesley) and was used extensively in courses on medical informatics throughout the world (in some cases with translations to other languages). It was updated with a second edition (published by Springer) in 2000, responding to the remarkable changes that occurred during the 1990s, most notably the Human Genome Project and the introduction of the World Wide Web with its impact on adoption and acceptance of the Internet. The third edition (again published by Springer) appeared in 2006, reflecting the ongoing rapid evolution of both technology and health- and biomedically related applications, plus the emerging government recognition of the key role that health information technology would need to play in promoting quality, safety, and efficiency in patient care. With that edition the title of the book was changed from *Medical Informatics* to *Biomedical Informatics*, reflecting (as is discussed in ► Chap. 1) both the increasing breadth of the basic discipline and the evolving new name for academic units, societies, research programs, and publications in the field. The fourth edition (published by Springer in 2014) followed the same conceptual framework for learning about the science that underlies applications of computing and communications technology in biomedicine and health care, for understanding the state of the art in computer applications in clinical care and biology, for critiquing existing systems, and for anticipating future directions that the field may take.

In many respects, the fourth edition was very different from its predecessors, however. Most importantly, it reflected the remarkable changes in computing and communications that continued to occur, most notably in communications, networking, and health information technology policy, and the exploding interest in the role that information technology must play in systems integration and the melding of genomics with innovations in clinical practice and treatment. Several new chapters were introduced and most of the remaining ones underwent extensive revision.

In this fifth edition, we have found that two previous single-chapter topics have expanded to warrant two complementary chapters, specifically Cognitive Science (split into *Cognitive Informatics* and *Human-Computer Interaction, Usability, and Workflow*) and Consumer Health Informatics and Personal Health Records (split into *Personal Health Informatics* and *mHealth and Applications*). There is a new chapter on precision medicine, which has emerged in the past 6 years as a unique area of special interest. Those readers who are familiar with the first four editions will find that the organization and philosophy are essentially unchanged (although bioinformatics, as a set of methodologies, is now considered a “recurrent theme” rather than an “application”), but the content is either new or extensively updated.<sup>1</sup>

This book differs from other introductions to the field in its broad coverage and in its emphasis on the field’s conceptual underpinnings rather than on technical details. Our book presumes no health- or computer-science background, but it does assume that you are interested in a comprehensive domain summary that stresses the underlying concepts and that introduces technical details only to the extent that they are necessary to meet the principal goal. Recent specialized texts are available to cover the technical underpinnings of many topics in this book; many are cited as suggested readings throughout the book, or are cited in the text for those who wish to pursue a more technical exposure to a topic.

## Overview and Guide to Use of This Book

---

This book is written as a text so that it can be used in formal courses, but we have adopted a broad view of the population for whom it is intended. Thus, it may be used not only by students of medicine and of the other health professions but also as an introductory text by future biomedical informatics professionals, as well as for self-study and for reference by practitioners, including those who are pursuing formal board certification in clinical informatics (as is discussed in more detail later in this

---

1 As with the first four editions, this book has tended to draw both its examples and its contributors from North America. There is excellent work in other parts of the world as well, although variations in health care systems, and especially financing, do tend to change the way in which systems evolve from one country to the next. The basic concepts are identical, however, so the book is intended to be useful in educational programs in other parts of the world as well.

“Preface”). The book is probably too detailed for use in a 2- or 3-day continuing-education course, although it could be introduced as a reference for further independent study.

Our principal goal in writing this text is to teach *concepts* in biomedical informatics—the study of biomedical information and its use in decision making—and to illustrate them in the context of descriptions of representative systems that are in use today or that taught us lessons in the past. As you will see, biomedical informatics is more than the study of computers in biomedicine, and we have organized the book to emphasize that point. ▶ Chapter 1 first sets the stage for the rest of the book by providing a glimpse of the future, defining important terms and concepts, describing the content of the field, explaining the connections between biomedical informatics and related disciplines, and discussing the forces that have influenced research in biomedical informatics and its integration into clinical practice and biological research.

Broad issues regarding the nature of data, information, and knowledge pervade all areas of application, as do concepts related to optimal decision making. ▶ Chapters 2 and 3 focus on these topics but mention computers only in passing. They serve as the foundation for all that follows. ▶ Chapters 4 and 5 on cognitive science issues enhance the discussions in ▶ Chaps. 2 and 3, pointing out that decision making and behavior are deeply rooted in the ways in which information is processed by the human mind. Key concepts underlying system design, human-computer interaction, patient safety, educational technology, and decision making are introduced in these chapters.

▶ Chapter 6 introduces the central notions of software engineering that are important for understanding the applications described later. We have dropped a chapter from previous editions that dealt broadly with system architectures, networking, and computer-system design. This topic is more about engineering than informatics, it changes rapidly, and there are excellent books on this subject to which students can turn if they need more information on these topics.

▶ Chapter 7 summarizes the issues of standards development, focusing in particular on data exchange and issues related to sharing of clinical data. This important and rapidly evolving topic warrants inclusion given the evolution of the health information exchange, institutional system integration challenges, federal government directives, and the increasingly central role of standards in enabling clinical systems to have their desired influence on health care practices.

▶ Chapter 8 addresses a topic of increasing practical relevance in both the clinical and biological worlds: natural language understanding and the processing of biomedical texts. The importance of these methods is clear when one considers the amount of information contained in free-text notes or reports (either dictated and transcribed or increasingly created using speech-understanding systems) or in the published biomedical literature. Even with efforts to encourage structured data entry in clinical systems, there will likely always be an important role for techniques that allow computer systems to extract meaning from natural language documents.

▶ Chapter 9 recognizes that bioinformatics is not just an application area but rather a fundamental area of study. The chapter introduces

many of the concepts and analytical tools that underlie modern computational approaches to the management of human biological data, especially in areas such as genomics and proteomics. Applications of bioinformatics related to human health and disease later appear in a chapter on “Translational Bioinformatics” (► Chap. 26).

► Chapter 10 is a comprehensive introduction to the conceptual underpinnings of biomedical and clinical image capture, analysis, interpretation, and use. This overview of the basic issues and imaging modalities serves as background for ► Chap. 22, which deals with imaging applications issues, highlighted in the world of radiological imaging and image management (e.g., in picture archiving and communication systems).

► Chapter 11 considers personal health informatics not as a set of applications (which are covered in ► Chap. 19), but as introductory concepts that relate to this topic, such as notions of the digital self and the digital divide, patient-generated health data, and how a focus on the patient (or on healthy individuals) affects both the person and the field of biomedical informatics.

► Chapter 12 addresses the key legal and ethical issues that have arisen when health information systems are considered. Then, in ► Chap. 13, the challenges associated with technology assessment and with the evaluation of clinical information systems are introduced.

► Chapters 14–28 (which include two new chapters in this edition, including one on mHealth and another on precision medicine) survey many of the key biomedical areas in which informatics methods are being used. Each chapter explains the conceptual and organizational issues in building that type of system, reviews the pertinent history, and examines the barriers to successful implementations.

► Chapter 29 reprises and updates a chapter that was new in the fourth edition, providing a summary of the rapidly evolving policy issues related to health information technology. Although the emphasis is on US government policy, there is some discussion of issues that clearly generalize both to states (in the USA) and to other countries.

The book concludes in ► Chap. 30 with a look to the future—a vision of how informatics concepts, computers, and advanced communication devices one day may pervade every aspect of biomedical research and clinical practice. Rather than offering a single point of view developed by a group of forward thinkers, as was offered in the fourth edition, we have invited seven prominent and innovative thinkers to contribute their own views. We integrate these seven future perspectives (representing clinical medicine, nursing, health policy, translational bioinformatics, academic informatics, the information technology industry, and the federal government) into a chapter where the editors have synthesized the seven perspectives after building on how an analysis of the past helps to inform the future of this dynamic field.

## **The Study of Computer Applications in Biomedicine**

---

The actual and potential uses of computers in health care and biomedicine form a remarkably broad and complex topic. However, just as you do not need to understand how a telephone or an ATM machine works

to make good use of it and to tell when it is functioning poorly, we believe that technical biomedical-computing skills are not needed by health workers and life scientists who wish simply to become effective users of evolving information technologies. On the other hand, such technical skills are of course necessary for individuals with career commitment to developing information systems for biomedical and health environments. Thus, this book will neither teach you to be a programmer nor show you how to fix a broken computer (although it might motivate you to learn how to do both). It also will not tell you about every important biomedical-computing system or application; we shall use an extensive bibliography included with each chapter to direct you to a wealth of literature where review articles and individual project reports can be found. We describe specific systems only as examples that can provide you with an understanding of the conceptual and organizational issues to be addressed in building systems for such uses. Examples also help to reveal the remaining barriers to successful implementations. Some of the application systems described in the book are well established, even in the commercial marketplace. Others are just beginning to be used broadly in biomedical settings. Several are still largely confined to the research laboratory.

Because we wish to emphasize the concepts underlying this field, we generally limit the discussion of technical implementation details. The computer-science issues can be learned from other courses and other textbooks. One exception, however, is our emphasis on the details of decision science as they relate to biomedical problem solving (► Chaps. 3 and 24). These topics generally are not presented in computer-science courses, yet they play a central role in the intelligent use of biomedical data and knowledge. Sections on medical decision making and computer-assisted decision support accordingly include more technical detail than you will find in other chapters.

All chapters include an annotated list of “Suggested Readings” to which you can turn if you have a particular interest in a topic, and there is a comprehensive set of references with each chapter. We use **boldface** print to indicate the key terms of each chapter; the definitions of these terms are included in the “Glossary” at the end of the book. Because many of the issues in biomedical informatics are conceptual, we have included “Questions for Discussion” at the end of each chapter. You will quickly discover that most of these questions do not have “right” answers. They are intended to illuminate key issues in the field and to motivate you to examine additional readings and new areas of research.

It is inherently limiting to learn about computer applications solely by reading about them. We accordingly encourage you to complement your studies by seeing real systems in use—ideally by using them yourself. Your understanding of system limitations and of what *you* would do to improve a biomedical-computing system will be greatly enhanced if you have had personal experience with representative applications. Be aggressive in seeking opportunities to observe and use working systems.

In a field that is changing as rapidly as biomedical informatics is, it is difficult ever to feel that you have knowledge that is completely current.

However, the conceptual basis for study changes much more slowly than do the detailed technological issues. Thus, the lessons you learn from this volume will provide you with a foundation on which you can continue to build in the years ahead.

## The Need for a Course in Biomedical Informatics

---

A suggestion that new courses are needed in the curricula for students of the health professions is generally not met with enthusiasm. If anything, educators and students have been clamoring for *reduced* lecture time, for more emphasis on small group sessions, and for more free time for problem solving and reflection. Yet, in recent decades, many studies and reports have specifically identified biomedical informatics, including computer applications, as an area in which new educational opportunities need to be developed so that physicians and other health professionals will be better prepared for clinical practice. As early as 1984, the Association of American Medical Colleges (AAMC) recommended the formation of new academic units in biomedical informatics in our medical schools, and subsequent studies and reports have continued to stress the importance of the field and the need for its inclusion in the educational environments of health professionals.

The reason for this strong recommendation is clear: *The practice of medicine is inextricably entwined with the management of information.* In the past, practitioners handled medical information through resources such as the nearest hospital or medical-school library; personal collections of books, journals, and reprints; files of patient records; consultation with colleagues; manual office bookkeeping; and (all-too-often flawed) memorization. Although these techniques continue to be variably valuable, information technology is offering new methods for finding, filing, and sorting information: online bibliographic retrieval systems, including full-text publications; personal computers, laptops, tablets, and smart phones, with database software to maintain personal information and commonly used references; office-practice and clinical information systems and EHRs to capture, communicate, and preserve key elements of the health record; information retrieval and consultation systems to provide assistance when an answer to a question is needed rapidly; practice-management systems to integrate billing and receivable functions with other aspects of office or clinic organization; and other online information resources that help to reduce the pressure to memorize in a field that defies total mastery of all but its narrowest aspects. With such a pervasive and inevitable role for computers in clinical practice, and with a growing failure of traditional techniques to deal with the rapidly increasing information-management needs of practitioners, it has become obvious to many people that an essential topic has emerged for study in schools and clinical training programs (such as residencies) that train medical and other health professionals.

What is less clear is how the subject should be taught in medical schools or other health professional degree programs, and to what extent it should be left for postgraduate education. We believe that top-

ics in biomedical informatics are best taught and learned in the context of health-science training, which allows concepts from both the health sciences and informatics science to be integrated. Biomedical-computing novices are likely to have only limited opportunities for intensive study of the material once their health-professional training has been completed, although elective opportunities for informatics rotations are now offered to residents in many academic medical centers.

The format of biomedical informatics education has evolved as faculty members have been hired to carry out informatics research and to develop courses at more health-science schools, and as the emphasis on lectures as the primary teaching method continues to diminish. Computers will be used increasingly as teaching tools and as devices for communication, problem solving, and data sharing among students and faculty. Indeed, the recent COVID-19 pandemic has moved many traditional medical teaching experiences from the classroom to online teaching environments using video conferencing and on-demand access to course materials. Such experiences do not teach informatics (unless that is the topic of the course), but they have rapidly engaged both faculty and students in technology-intensive teaching and learning experiences. The acceptance of computing, and dependence upon it, has already influenced faculty, trainees, and curriculum committees. This book is designed to be used in a traditional introductory course, whether taught online or in a classroom, although the “Questions for Discussion” also could be used to focus conversation in small seminars and working groups. Integration of biomedical informatics topics into clinical experiences has also become more common. The goal is increasingly to provide instruction in biomedical informatics whenever this field is most relevant to the topic the student is studying. This aim requires educational opportunities throughout the years of formal training, supplemented by continuing-education programs after graduation.

The goal of integrating biomedicine and biomedical informatics is to provide a mechanism for increasing the sophistication of health professionals, so that they know and understand the available resources. They also should be familiar with biomedical computing’s successes and failures, its research frontiers, and its limitations, so that they can avoid repeating the mistakes of the past. Study of biomedical informatics also should improve their skills in information management and problem solving. With a suitable integration of hands-on computer experience, computer-mediated learning, courses in clinical problem solving, and study of the material in this volume, health-science students will be well prepared to make effective use of computational tools and information management in health care delivery.

## **The Need for Specialists in Biomedical Informatics**

---

As mentioned, this book also is intended to be used as an introductory text in programs of study for people who intend to make their professional careers in biomedical informatics. If we have persuaded you that a course in biomedical informatics is needed, then the requirement for

trained faculty to teach the courses will be obvious. Some people might argue, however, that a course on this subject could be taught by a computer scientist who had an interest in biomedical computing, or by a physician or biologist who had taken a few computing courses. Indeed, in the past, most teaching—and research—has been undertaken by faculty trained primarily in one of the fields and later drawn to the other. Today, however, schools have come to realize the need for professionals trained specifically at the interfaces among biomedicine, biomedical informatics, and related disciplines such as computer science, statistics, cognitive science, health economics, and medical ethics.

This book outlines a first course for students training for careers in the biomedical informatics field. We specifically address the need for an educational experience in which computing and information-science concepts are synthesized with biomedical issues regarding research, training, and clinical practice. It is the *integration* of the related disciplines that originally was lacking in the educational opportunities available to students with career interests in biomedical informatics. Schools are establishing such courses and training programs in growing numbers, but their efforts have been constrained by a lack of faculty who have a broad familiarity with the field and who can develop curricula for students of the health professions as well as of informatics itself.

The increasing introduction of computing techniques into biomedical environments requires that well-trained individuals be available not only to teach students but also to design, develop, select, and manage the biomedical-computing systems of tomorrow. There is a wide range of context-dependent computing issues that people can appreciate only by working on problems defined by the health care setting and its constraints. The field's development has been hampered because there are relatively few trained personnel to design research programs, to carry out the experimental and developmental activities, and to provide academic leadership in biomedical informatics. A frequently cited problem is the difficulty a health professional (or a biologist) and a technically trained computer scientist experience when they try to communicate with one another. The vocabularies of the two fields are complex and have little overlap, and there is a process of acculturation to biomedicine that is difficult for computer scientists to appreciate through distant observation. Thus, interdisciplinary research and development projects are more likely to be successful when they are led by people who can effectively bridge the biomedical and computing fields. Such professionals often can facilitate sensitive communication among program personnel whose backgrounds and training differ substantially.

Hospitals and health systems have begun to learn that they need such individuals, especially with the increasing implementation of, and dependence upon, EHRs and related clinical systems. The creation of a *Chief Medical Information Officer (CMIO)* has now become a common innovation. As the concept became popular, however, questions arose about how to identify and evaluate candidates for such key institutional roles. The need for some kind of suitable certification process became clear—one that would require individuals to demonstrate both formal training and the broad skills and knowledge that were required. Thus,

the American Medical Informatics Association (AMIA) and its members began to develop plans for a formal certification program. For physicians, the most meaningful approach was to create a formal medical subspecialty in clinical informatics. Working with the American Board of Preventive Medicine and the parent organization, the American Board of Medical Specialties (ABMS), AMIA helped to obtain approval for a subspecialty board that would allow medical specialists, with board certification in any ABMS specialty (such as pediatrics, internal medicine, radiology, pathology, preventive medicine) to pursue subspecialty board certification in clinical informatics. This proposal was ultimately approved by the ABMS in 2011, and the board examination was first administered in 2013<sup>2</sup>. After a period during which currently active clinical informatics physician experts could sit for their clinical informatics boards, board eligibility now requires a formal fellowship in clinical informatics. This is similar to the fellowship requirement for other subspecialties such as cardiology, nephrology, and the like. Many health care institutions now offer formal clinical informatics fellowships for physicians who have completed a residency in one of the almost 30 ABMS specialties. These individuals are now often turning to this volume as a resource to help them to prepare for their board examinations.

It is exciting to be working in a field that is maturing and that is having a beneficial effect on society. There is ample opportunity remaining for innovation as new technologies evolve and fundamental computing problems succumb to the creativity and hard work of our colleagues. In light of the increasing sophistication and specialization required in computer science in general, it is hardly surprising that a new discipline should arise at that field's interface with biomedicine. This book is dedicated to clarifying the definition and to nurturing the effectiveness of that discipline: biomedical informatics.

2 AMIA is currently developing a Health Informatics Certification program (AHIC) for individuals who seek professional certification in health-related informatics but are not physicians or are otherwise not eligible to take the ABMS board certification exam. ► <https://www.amia.org/ahic> (Accessed June 10, 2020).

## Acknowledgments

---

In the 1980s, when I was based at Stanford University, I conferred with colleagues Larry Fagan and Gio Wiederhold, and we decided to compile the first comprehensive textbook on what was then called medical informatics. As it turned out, none of us predicted the enormity of the task we were about to undertake. Our challenge was to create a multiauthored textbook that captured the collective expertise of leaders in the field yet was cohesive in content and style. The concept for the book was first developed in 1982. We had begun to teach a course on computer applications in health care at Stanford's School of Medicine and had quickly determined that there was no comprehensive introductory text on the subject. Despite several published collections of research descriptions and subject reviews, none had been developed to meet the needs of a rigorous introductory course. The thought of writing a textbook was daunting due to the diversity of topics. None of us felt that he was sufficiently expert in the full range of important subjects for us to write the book ourselves. Yet we wanted to avoid putting together a collection of disconnected chapters containing assorted subject reviews. Thus, we decided to solicit contributions from leaders in the pertinent fields but to provide organizational guidelines in advance for each chapter. We also urged contributors to avoid writing subject reviews but, instead, to focus on the key conceptual topics in their field and to pick a handful of examples to illustrate their didactic points.

As the draft chapters began to come in, we realized that major editing would be required if we were to achieve our goals of cohesiveness and a uniform orientation across all the chapters. We were thus delighted when, in 1987, Leslie Perreault, a graduate of our informatics training program, assumed responsibility for reworking the individual chapters to make an integral whole and for bringing the project to completion. The final product, published in 1990, was the result of many compromises, heavy editing, detailed rewriting, and numerous iterations. We were gratified by the positive response to the book when it finally appeared, and especially by the students of biomedical informatics who have often come to us at scientific meetings and told us about their appreciation of the book.

As the 1990s progressed, however, we began to realize that, despite our emphasis on basic concepts in the field (rather than a survey of existing systems), the volume was beginning to show its age. A great deal had changed since the initial chapters were written, and it became clear that a new edition would be required. The original editors discussed the project and decided that we should redesign the book, solicit updated chapters, and publish a new edition. Leslie Perreault by this time was a busy Director at First Consulting Group in New York City and would not have as much time to devote to the project as she had when we did the first edition. With trepidation, in light of our knowledge of the work that would be involved, we embarked on the new project.

As before, the chapter authors did a marvelous job, trying to meet our deadlines, putting up with editing changes that were designed to

bring a uniform style to the book, and contributing excellent chapters that nicely reflected the changes in the field during the preceding decade.

No sooner had the second edition appeared in print in 2000 than we started to get inquiries about when the next update would appear. We began to realize that the maintenance of a textbook in a field such as biomedical informatics was nearly a constant, ongoing process. By this time I had moved to Columbia University and the initial group of editors had largely disbanded to take on other responsibilities, with Leslie Perreault no longer available. Accordingly, as plans for a third edition began to take shape, my Columbia colleague Jim Cimino joined me as the new associate editor, whereas Drs. Fagan, Wiederhold, and Perreault continued to be involved as chapter authors. Once again the authors did their best to try to meet our deadlines as the third edition took shape. This time we added several chapters, attempting to cover additional key topics that readers and authors had identified as being necessary enhancements to the earlier editions. We were once again extremely appreciative of all the authors' commitment and for the excellence of their work on behalf of the book and the field.

Predictably, it was only a short time after the publication of the third edition in 2006 that we began to get queries about a fourth edition. We resisted for a year or two, but it became clear that the third edition was becoming rapidly stale in some key areas and that there were new topics that were not in the book and needed to be added. With that in mind we, in consultation with Grant Weston from Springer's offices in London, agreed to embark on a fourth edition. Progress was slowed by my professional moves (to Phoenix, Arizona, then Houston, Texas, and then back to New York) with a very busy 3-year stint as President and CEO of the American Medical Informatics Association. Similarly, Jim Cimino left Columbia to assume new responsibilities at the NIH Clinical Center in Bethesda, MD. With several new chapters in mind, and the need to change authors of some of the existing chapters due to retirements (this too will happen, even in a young field like informatics), we began working on the fourth edition, finally completing the effort with publication in early 2014.

Now, seven years later, we are completing the fifth edition of the volume. It was not long after the publication of the fourth edition that we began to get requests for a new edition that would include many of the new and emerging topics that had not made it into the 2014 publication. With the introduction of new chapters, major revisions to previous chapters, and some reordering of authors or introduction of new ones, we have attempted to assure that this new edition will fill the necessary gaps and engage our readers with its currency and relevance. As Jim Cimino (now directing the Informatics Institute at the University of Alabama in Birmingham) and I considered the development of this edition, we realized that we were not getting any younger and it would be wise to craft a succession plan so that others could handle the inevitable requests for a sixth and subsequent editions. We were delighted when Michael Chiang agreed to join us as an associate editor, coauthoring three chapters and becoming fully involved in the book's philosophy and the editing tasks involved. Michael was a postdoctoral informatics

trainee at Columbia when we were both there on the faculty. A well-known pediatric ophthalmologist, he is now balancing his clinical career with an active set of research and academic activities in biomedical informatics. We believe that Michael will be a perfect person to carry the book into the future as Jim and I (both of whom view the book as a significant component of our professional life's work) phase out our own involvement after this edition. I should add that, in mid-2020, Michael was named director of the National Eye Institute at NIH, which offers further evidence of his accomplishments as a ophthalmologist, researcher, and informatician.

For this edition we owe particular gratitude to Elektra McDermott, our developmental editor, whose rigorous attention to detail has been crucial given the size and the complexity of the undertaking. At Springer we have been delighted to work once again with Grant Weston, Executive Editor in their Medicine and Life Sciences division, who has been extremely supportive despite our missed deadlines. And I want to offer my sincere personal thanks to Jim Cimino, who has been a superb and talented collaborator in this effort for the last three editions. Without his hard work and expertise, we would still be struggling to complete the massive editing job associated with this now very long manuscript.

# About the Future Perspective Authors (Chapter 30)

---

## **David Blumenthal, MD, MPP**

became President and CEO of the Commonwealth Fund, a national health care philanthropy based in New York City, in January, 2013. Previously, he served as Chief Health Information and Innovation Officer at Partners Health System in Boston, MA, and was Samuel O. Thier Professor of Medicine and Professor of Health Care Policy at Massachusetts General Hospital/ Harvard Medical School. From 2009 to 2011, Dr. Blumenthal was the National Coordinator for Health Information Technology under President Barack Obama. In this role he was charged with building an interoperable, private and secure nationwide health information system and supporting the widespread, meaningful use of health IT. Prior to that, Dr. Blumenthal was a practicing primary care physician, director of the Institute for Health Policy, and professor of medicine and health policy at Massachusetts General Hospital/Partners Healthcare System and Harvard Medical School. As a renowned health services researcher and national authority on health IT adoption, Dr. Blumenthal has authored over 300 scholarly publications, including the seminal studies on the adoption and use of health information technology in the United States. Dr. Blumenthal received his undergraduate, medical, and public policy degrees from Harvard University and completed his residency in internal medicine at Massachusetts General Hospital.

## **Patricia Flatley Brennan, RN, PhD, FAAN, FACMI**

is the Director of the National Library of Medicine (NLM) and Adjunct Investigator in the National Institute of Nursing Research's Advanced Visualization Branch at the National Institutes of Health (NIH). As the world's largest biomedical library, NLM produces digital information resources used by scientists, health professionals, and members of the public. A leader in research in computational health informatics, NLM plays a pivotal role in translating research into practice. NLM's research and information services support scientific discovery, health care, and public health. Prior to joining

NLM, Dr. Brennan was the Lillian L. Moehlman Bascom Professor at the School of Nursing and College of Engineering at the University of Wisconsin–Madison. Dr. Brennan is a pioneer in the development of innovative information systems and services such as ComputerLink, an electronic network designed to reduce isolation and improve self-care among home care patients. She directed HeartCare, a web-based information and communication service that helps home-dwelling cardiac patients recover faster and with fewer symptoms, and also directed Project HealthDesign, an initiative designed to stimulate the next generation of personal health records. Her professional accomplishments reflect her background, which unites engineering, information technology, and clinical care to improve public health and ensure the best possible experience in patient care. A past president of the American Medical Informatics Association, Dr. Brennan was elected to the National Academy of Medicine in 2001. She is a fellow of the American Academy of Nursing, the American College of Medical Informatics, and the New York Academy of Medicine. In 2020, Dr. Brennan was inducted into the American Institute for Medical and Biological Engineering (AIMBE). The AIMBE College of Fellows is among the highest professional distinctions accorded to a medical and biological engineer.

#### **Mark Frisse, MD, MS, MBA**

is an Emeritus Professor in the Department of Biomedical Informatics at Vanderbilt University Medical Center. Until July 2020, he held the Accenture Endowed Chair within the Department. His interests are directed toward the potential contribution to economically sustainable health care through more effective use of informatics and information technology. In addition to his teaching and research responsibilities at the Vanderbilt Medical School, he also directed the Masters of Management in Health Care graduate program at Vanderbilt's Owen Graduate School of Management and led a health information technology course for the executive Masters of Health Care Delivery Science program at Tuck School of Business, Dartmouth College. Previously, Dr. Frisse has held leadership positions at Washington University, Express Scripts, and the First Consulting Group.

At Express Scripts, he was Chief Medical Officer and was responsible for their Practice Patterns Science division and helped found RxHub. At First Consulting, he led engagements in vendor selection, quality governance, physician information technology leadership development, and clinician governance. A board-certified internist with fellowship training in medical oncology, he obtained his bachelor's degree from the University of Notre Dame in 1974 and his MD from Washington University in 1978. He received a master's degree in medical information science from Stanford University in 1987 and an MBA from Washington University in 1997. He is a fellow of the American College of Physicians, the American College of Medical Informatics, and the New York Academy of Medicine. He is an elected member of the National Academy of Medicine.

#### **Eric Horvitz**

is a technical fellow at Microsoft, where he serves as the company's first Chief Scientific Officer. He previously served as director of Microsoft Research Labs. He has pursued principles and applications of AI with contributions in machine learning, perception, natural language understanding, and decision making. His research centers on challenges with uses of AI amidst the complexities of the open world, including uses of probabilistic and decision-theoretic representations for reasoning and action, models of bounded rationality, and human-AI complementarity and coordination. His efforts and collaborations have led to fielded systems in healthcare, transportation, ecommerce, operating systems, and aerospace. He received the Feigenbaum Prize and the Allen Newell Prize for contributions to AI. He was inducted into the CHI Academy for contributions at the intersection of AI and human-computer interaction. He has been elected fellow of the American College of Medical Informatics (ACMI), National Academy of Engineering (NAE), Association of Computing Machinery (ACM), Association for the Advancement of AI (AAAI), the American Association for the Advancement of Science (AAAS), the American Academy of Arts and Sciences, and the American Philosophical Society. He has served as president of the AAAI, and on advisory commit-

tees for the NSF, NIH, and the U.S. Department of Defense. He currently serves on the Board of Regents of the National Library of Medicine and on the scientific advisory board of the Allen Institute for AI. He earned his Bachelors in biophysics at Binghamton University and a PhD in biomedical informatics and his MD at Stanford University.

**Judy Murphy, RN, FACMI, FHIMSS, FAAN**

is a nursing executive with a long history in health informatics. She was Chief Nursing Officer for IBM Global Healthcare, where she was strategic advisor regarding provider IT solutions to achieve the quadruple aim. Prior to working at IBM, she was Deputy National Coordinator for Programs and Policy at the ONC in Washington D.C. where she led federal efforts to assist healthcare providers in adopting health IT to improve care and to promote consumers' understanding and use of health IT for their own health. She came to ONC with 25 years of health informatics experience at Aurora Health Care in Wisconsin, a large integrated delivery network. As Vice President-EHR Applications, she led their EHR program since 1995, when Aurora was an early adopter of technology. She publishes and lectures nationally and internationally. She served on the AMIA and HIMSS Board of Directors and is a Fellow in the American Academy of Nursing, the American College of Medical Informatics and HIMSS. She has received numerous awards, including the HIMSS 2018 Most Influential Women in Health IT, the AMIA 2014 Don Eugene Detmer Award for Health Policy Contributions in Informatics, the HIMSS 2014 Federal Health IT Leadership Award, and the HIMSS 2006 Nursing Informatics Leadership Award.

**Peter Tarczy-Hornoch, MD**

is Professor and Chair of the Department of Biomedical Informatics and Medical Education at the University of Washington (UW). His background includes computer science, bioengineering, biomedical informatics, medicine (Pediatrics and Neonatology) with undergraduate and medical degrees from Stanford, Residency at the University of Minnesota, Fellowship at the University of Washington. He has played a key role in establishing and growing the biomedical informatics research, teaching and practice activities at UW

for over two decades. The unifying theme of his research has been data integration of electronic biomedical data (clinical and genomic) both for a) knowledge discovery and b) in order to integrate this knowledge with clinical data at the point of care for decision support. His current research focuses on a) secondary use of electronic medical record (EMR) for translational research including outcomes research, learning healthcare systems, patient accrual and biospecimen acquisition based on complex phenotypic eligibility criteria, b) the use of EMR systems for cross institutional comparative effectiveness research, and c) integration of genomic data into the EMR for clinical decision support. Key past research has included data integration and knowledge base creation for genomic testing. He has served in a number of national leadership roles including founding chair of the AMIA Genomics (now Genomics and Translational Bioinformatics) working group.

#### **Robert M. Wachter, MD**

is Professor and Chair of the Department of Medicine at the University of California, San Francisco. He is author of 300 articles and 6 books and is a frequent contributor to the *New York Times* and *Wall Street Journal*. He coined the term “hospitalist” in 1996 and is often considered the “father” of the hospitalist field, the fastest growing specialty in the history of modern medicine. He is past president of the Society of Hospital Medicine and past chair of the American Board of Internal Medicine. In the safety and quality arenas, his book, *Understanding Patient Safety*, is the world’s top selling safety primer. In 2004, he received the John M. Eisenberg Award, the nation’s top honor in patient safety. Twelve times, *Modern Healthcare* magazine has ranked him as one of the 50 most influential physician-executives in the U.S.; he was #1 on the list in 2015. His 2015 book, *The Digital Doctor: Hope, Hype and Harm at the Dawn of Medicine’s Computer Age*, was a *New York Times* science best-seller. In 2016, he chaired a blue-ribbon commission advising England’s National Health Service on its digital strategy. He is an elected member of the National Academy of Medicine.

## About the Editors

---

### Edward H. Shortliffe

is Chair Emeritus and Adjunct Professor in the Department of Biomedical Informatics at Columbia University's Vagelos College of Physicians and Surgeons. Previously he served as President and CEO of the American Medical Informatics Association. He was Professor of Biomedical Informatics at the University of Texas Health Science Center in Houston and at Arizona State University. A board-certified internist, he was Founding Dean of the University of Arizona College of Medicine – Phoenix and served as Professor of Biomedical Informatics and of Medicine at Columbia University. Before that he was Professor of Medicine and of Computer Science at Stanford University. Honors include his election to membership in the National Academy of Medicine (where he served on the executive council for 6 years and has chaired the membership committee) and in the American Society for Clinical Investigation. He has also been elected to fellowship in the American College of Medical Informatics and the American Association for Artificial Intelligence. A Master of the American College of Physicians (ACP), he held a position for 6 years on that organization's Board of Regents. He is Editor Emeritus of the *Journal of Biomedical Informatics* and has served on the editorial boards for several other biomedical informatics publications. In the early 1980s, he was recipient of a research career development award from the National Library of Medicine. In addition, he received the Grace Murray Hopper Award of the Association for Computing Machinery in 1976, the Morris F. Collen Award of the American College of Medical Informatics in 2006, and was a Henry J. Kaiser Family Foundation Faculty Scholar in General Internal Medicine. He has served on the oversight committee for the Division on Engineering and Physical Sciences (National Academy of Sciences), the National Committee on Vital and Health Statistics (NCVHS), and on the President's Information Technology Advisory Committee (PITAC). Dr. Shortliffe has authored over 350 articles and books in the fields of biomedical computing and artificial intelligence.

### James J. Cimino

is a board-certified internist who completed a National Library of Medicine informatics fellowship at the Massachusetts General Hospital and Harvard University and then went on to an academic position at Columbia University College of Physicians and Surgeons and the Presbyterian Hospital in New York. He spent 20 years at Columbia, carrying out clinical informatics research, building clinical information systems, teaching medical informatics and medicine, and caring for patients, rising to the rank of full professor in both Biomedical Informatics and Medicine. His principal research areas there included desiderata for controlled terminologies, mobile and Web-based clinical information systems for clinicians and patients, and a context-aware form of clinical decision support called “infobuttons.” In 2008, he moved to the National Institutes of Health, where he was the Chief of the Laboratory for Informatics Development and a Tenured Investigator at the NIH Clinical Center and the National Library of Medicine. His principal project involved the development of the Biomedical Translational Research Information System (BTRIS), an NIH-wide clinical research data resource. In 2015, he left the NIH to be the inaugural Director of the Informatics Institute at the University of Alabama at Birmingham. The Institute is charged with improving informatics research, education, and service across the University, supporting the Personalized Medicine Institute, the Center for Genomic Medicine, and the University Health System Foundation, including improvement of and access to electronic health records. He holds the rank of Tenured Professor in Medicine and is the Chief for the Informatics Section in the Division of General Internal Medicine. He continues to conduct research in clinical informatics and clinical research informatics, he was Director of the NLM’s weeklong Biomedical Informatics course for 16 years, and teaches at Columbia University and Georgetown University as an Adjunct Professor. He is an Associate Editor of the *Journal of Biomedical Informatics*. His honors include Fellowships of the American College of Physicians, the New York Academy of Medicine and the American College of Medical Informatics (Past President), the Priscilla Mayden Award from the University of Utah, the Donald A.B. Lindberg Award for Innovation in Informatics and the President’s Award, both from the American Medical

Informatics Association, the Morris F. Collen Award of the American College of Medical Informatics, the Medal of Honor from New York Medical College, the NIH Clinical Center Director's Award (twice), and induction into the National Academy of Medicine (formerly the Institute of Medicine).

### **Michael F. Chiang**

is Director of the National Eye Institute, at the National Institutes of Health in Bethesda, Maryland. His clinical practice focuses on pediatric ophthalmology, and he is board-certified in clinical informatics. His research develops and applies biomedical informatics methods to clinical ophthalmology in areas such as retinopathy of prematurity (ROP), telehealth, artificial intelligence, clinical information systems, genotype-phenotype correlation, and data analytics. His group has published over 200 peer-reviewed papers, and has developed an assistive artificial intelligence system for ROP that received breakthrough status from the US Food and Drug Administration. He received a BS in Electrical Engineering and Biology from Stanford University, an MD from the Harvard-MIT Division of Health Sciences and Technology, and an MA in Biomedical Informatics from Columbia University. He completed clinical training at the Johns Hopkins Wilmer Eye Institute. Between 2001 and 2010, he worked at Columbia University, where he was Anne S. Cohen Associate Professor of Ophthalmology & Biomedical Informatics, director of medical student education in ophthalmology, and director of the introductory graduate student course in biomedical informatics. From 2010 to 2020, he was Knowles Professor of Ophthalmology & Medical Informatics and Clinical Epidemiology, and Associate Director of the Casey Eye Institute, at the Oregon Health & Science University (OHSU) Casey Eye Institute. He has served as a member of the American Academy of Ophthalmology (AAO) Board of Trustees, Chair of the AAO IRIS Registry Data Analytics Committee, Chair of the AAO Task Force on Artificial Intelligence, Chair of the AAO Medical Information Technology Committee, and on numerous other national and local committees. He currently serves as an Associate Editor for *JAMIA*, and is on the Editorial Board for *Ophthalmology* and the *Asia-Pacific Journal of Ophthalmology*.

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- Why is information and knowledge management a central issue in biomedical research, clinical practice, and public health?
- What are integrated information management environments, and how are they affecting the practice of medicine, the promotion of health, and biomedical research?
- What do we mean by the terms *biomedical informatics*, *medical computer science*, *medical computing*, *clinical informatics*, *nursing informatics*, *bioinformatics*, *public health informatics*, and *health informatics*?
- What is *translational research*, why is it being heavily promoted and supported, how does it depend on *translational bioinformatics* and *clinical research informatics*, and how do these all relate to *precision medicine*?
- Why should health professionals, life scientists, and students of the health professions learn about biomedical informatics concepts and informatics applications?
- How has the development of modern computing technologies and the Internet changed the nature of biomedical computing?
- How is biomedical informatics related to clinical practice, public health, biomedical engineering, molecular biology, decision science, information science, and computer science?
- How does information in clinical medicine and health differ from information in the basic sciences?
- How can changes in computer technology and the financing of health care influence the integration of biomedical computing into clinical practice?

## 1.1 The Information Revolution Comes to Medicine

---

After scientists had developed the first digital computers in the 1940s, society was told that these new machines would soon be serving routinely as memory devices, assisting with calculations and with information retrieval. Within the next decade, physicians and other health professionals had begun to hear about the dramatic effects that such technology would have on clinical practice.

More than seven decades of remarkable progress in computing have followed those early predictions, and many of the original prophecies have come to pass. Stories regarding the “information revolution”, “artificial intelligence”, and “big data” fill our newspapers and popular magazines, and today’s children show an uncanny ability to make use of computers (including their handheld mobile versions) as routine tools for study, communication, and entertainment. Similarly, clinical workstations have been available on hospital wards and in outpatient offices for decades, and in some settings have been supplanted by mobile tablets with wireless connectivity.

Not long ago, the health care system was perceived as being slow to understand information technology and slow to exploit it for its unique practical and strategic functionalities. This is no longer the case. The enormous technological advances of the last four decades—personal computers and graphical interfaces, laptop machines, new methods for human-computer interaction, innovations in mass storage of data (both locally and in the “cloud”), mobile devices, personal health-monitoring devices, the Internet, wireless communications, social media, and more—have all combined to make use of computers by health workers and biomedical scientists part of today’s routine. This new world is already upon us, but its greatest influence is yet to come as today’s prominent innovations such as

electronic health records and decision-support software are further refined. This book will teach you about our present resources and accomplishments, and about gaps that need to be addressed in the years ahead.

When one considers today's penetration of computers and communication into our daily lives, it is remarkable that the first personal computers were introduced as recently as the late 1970s; local area networking has been available only since the 1980s; the World Wide Web dates only to the early 1990s; and smart phones, social networking, tablet computers, wearable devices, and wireless communication are even more recent. This dizzying rate of change, combined with equally pervasive and revolutionary changes in almost all international health care systems, makes it difficult for public-health planners and health-institutional managers to try to deal with both issues at once.

As new technologies have been introduced and adopted in health settings, unintended consequences have emerged, such as **ransomware** and other security challenges that can compromise the protection and privacy of patient data. Yet many observers now believe that rapid changes in both technology and health systems are inextricably related. We can see that planning for the new health care environments of the coming decades requires a deep understanding of the role that information technology is likely to play in those environments.

What might that future hold for the typical practicing clinician? As we discuss in detail in ► Chap. 14, no applied clinical computing topic is gaining more attention currently than is the issue of **electronic health records** (EHRs). Health care organizations have largely replaced their paper-based recording systems, recognizing that they need to have digital systems in place that create opportunities to facilitate patient care that is safe and effective, to answer questions that are crucially important for strategic planning, to sup-

port a better understanding of how they and their providers compare with other organizations in their local or regional competitive environment, and to support reporting to regulatory agencies.

In the past, administrative and financial data were the major elements required for planning, but in recent years comprehensive clinical data have also become important for institutional self-analysis and strategic planning. Furthermore, the inefficiencies and frustrations associated with the use of paper-based medical records are well accepted (Dick and Steen 1991 (Revised 1997)), especially when inadequate access to clinical information is one of the principal barriers that clinicians encounter when trying to increase their efficiency in order to meet productivity goals for their practices.

### 1.1.1 Integrated Access to Clinical Information

---

Encouraged by **health information technology** (HIT) vendors (and by the US government, as is discussed later), most health care institutions have or are developing integrated computer-based information-management environments. These underlie a clinical world in which computational tools assist not only with patient-care matters (e.g., reporting results of tests, allowing direct entry of orders or patient information by clinicians, facilitating access to transcribed reports, and in some cases supporting **telemedicine** applications or decision-support functions) but also with administrative and financial topics (e.g., tracking of patients within the hospital, managing materials and inventory, supporting personnel functions, and managing the payroll), with research (e.g., analyzing the outcomes associated with treatments and procedures, performing quality assurance, supporting clinical trials, and implementing various treatment protocols), with access to

scholarly information (e.g., accessing digital libraries, supporting bibliographic search, and providing access to drug information databases), and even with office automation (e.g., providing access to spreadsheets and document-management software). The key idea, however, is that at the heart of the evolving integrated environments lies an electronic health record that is intended to be accessible, confidential, secure, acceptable to clinicians and patients, and integrated with other types of useful information to assist in planning and problem solving.

### 1.1.2 Today's Electronic Health Record (EHR) Environment

The traditional paper-based medical record is now recognized as being woefully inadequate for meeting the needs of modern medicine. It arose in the nineteenth century as a highly personalized “lab notebook” that clinicians could use to record their observations and plans so that they could be reminded of pertinent details when they next saw the same patient. There were no regulatory requirements, no assumptions that the record would be used to support communication among varied providers of care, and few data or test results to fill up the record's pages. The record that met the needs of clinicians a century or so ago struggled mightily to adjust over the decades and to accommodate to new requirements as health care and medicine changed. Today the inability of paper charts to serve the best interests of the patient, the clinician, and the health system is no longer questioned (see ► Chaps. 14 and 16).

Most organizations have found it challenging (and expensive) to move to a paperless, electronic clinical record. This observation forces us to ask the following questions: “What is a health record in the modern world? Are the available products and systems well matched with the modern notions of a comprehensive health record? Do they meet the needs of individual users as well as the health systems themselves? Are they efficient, easy to use, and smoothly integrated into clinical workflow? How should our concept of the

comprehensive health record evolve in the future, as technology creates unprecedented opportunities for innovation?”

The complexity associated with automating clinical-care records is best appreciated if one analyzes the processes associated with the creation and use of such records rather than thinking of the record as a physical object (such as the traditional paper chart) that can be moved around as needed within the institution. For example, on the input side (■ Fig. 1.1), an electronic version of the paper chart requires the integration of processes for data capture and for merging information from diverse sources.

The contents of the paper record were traditionally organized chronologically—often a severe limitation when a clinician sought to find a specific piece of information that could occur almost anywhere within the chart. To be useful, the electronic record system has to make it easy to access and display needed data, to analyze them, and to share them among colleagues and with secondary users of the record who are not involved in direct patient care (■ Fig. 1.2). Thus, the EHR, as an adaptation of the paper record, is best viewed not as an object, or a product, but rather as a set of processes that an organization puts into place, supported by technology (■ Fig. 1.3).

Implementing electronic records is inherently a systems-integration task. It accordingly requires a custom-tailored implementation at each institution, given the differences in existing systems and practices that must be suitably integrated. Joint development and local adaptation are crucial, which implies that the institutions that purchase such systems must have local expertise that can oversee and facilitate an effective implementation process, including elements of process re-engineering and cultural change that are inevitably involved.

Experience has shown that clinicians are “horizontal” users of information technology (Greenes and Shortliffe 1990). Rather than becoming “power users” of a narrowly defined software package, they tend to seek broad functionality across a wide variety of systems and resources. Thus, routine use of comput-

■ **Fig. 1.1** Inputs to the clinical-care record. The traditional paper record was created by a variety of organizational processes that captured varying types of information (notes regarding direct encounters between health professionals and patients, laboratory or radio-

logic results, reports of telephone calls or prescriptions, and data obtained directly from patients). The paper record thus was a merged collection of such data, generally organized in chronological order

ers, and of EHRs, is most easily achieved when the computing environment offers a critical mass of functionality that makes the system both smoothly integrated with workflow and useful for essentially every patient encounter.

The arguments for automating clinical-care records are summarized in ► Chaps. 2 and 14 and in the now classic Institute of Medicine's report on **computer-based patient records (CPRs)** (Dick and Steen 1991 (Revised 1997)).<sup>1</sup> One argument that warrants emphasis is the importance of the EHR in supporting **clinical trials**—experiments in which data from specific patient interactions are pooled

and analyzed in order to learn about the safety and efficacy of new treatments or tests and to gain insight into disease processes that are not otherwise well understood. Medical researchers were constrained in the past by clumsy methods for identifying patients who met inclusion criteria for clinical trials as well as acquiring the data needed for the trials, generally relying on manual capture of information onto datasheets that were later transcribed into computer databases for statistical analysis (► Fig. 1.4). The approach was labor-intensive, fraught with opportunities for error, and added to the high costs associated with randomized prospective research protocols.

The use of EHRs has offered many advantages to those carrying out clinical research (see ► Chap. 27). Most obviously, it helps to eliminate the manual task of extracting data from charts or filling out specialized data-

<sup>1</sup> The Institute of Medicine, part of the National Academy of Sciences, is now known as the National Academy of Medicine.

■ **Fig. 1.2** Outputs from the clinical-care record. Once information was collected in the traditional paper chart, it needed to be provided to a wide variety of potential users of the information that it contained. These users included health professionals and the patients themselves, as well as “secondary users” (represented here by the individuals in business suits) who had valid reasons for accessing the record but who were not involved with

direct patient care. Numerous providers are typically involved in a patient’s care, so the chart also served as a means for communicating among them. The traditional mechanisms for displaying, analyzing, and sharing information from such records resulted from a set of processes that often varied substantially across several patient-care settings and institutions

sheets. The data needed for a study can often be derived directly from the EHR, thus making much of what is required for research data collection simply a by-product of routine clinical record keeping (■ Fig. 1.5). Other advantages accrue as well. For example, the record environment can help to ensure compliance with a research protocol, pointing out to a clinician when a patient is eligible for a study or when the protocol for a study calls for a specific management plan given the currently available data about that patient. We are also seeing the development of novel authoring environments for clinical trial protocols that can help to ensure that the data elements needed for the trial are compatible with the local EHR’s conventions for representing patient descriptors.

Note that ■ Fig. 1.5 represents a study at a single institution and often for a limited subset of the patients who receive care there. Yet much research is carried out with very large numbers of patients, such as within a regional health care system, statewide, or nationally. Accordingly, the size of research datasets can get very large, but analyzing across them introduces challenges related to data exchange and the standardization of the ways in which individual data elements are defined, identified, or stored (see ► Chap 8). Retrospective studies on data collected in the past typically cannot assume a prior standardization of the elements that will be needed, thereby requiring analyses that infer relationships among specific descriptors in different institutions represented in different ways. When the number of data elements

**Fig. 1.3** Complex processes demanded of the record. As shown in **Figs. 1.1** and **1.2**, the paper chart evolved to become the incarnation of a complex set of organizational processes, which both gathered information to be shared and then distributed that information to those who had

valid reasons for accessing it. Yet paper-based documents were severely limited in meeting the diverse requirements for data collection and information access that are implied by this diagram. These deficiencies accounted in large part for the effort to create today's electronic health records

is large, and the population being studied is also vast, the challenges are often described as “big data” analytics (James et al. 2013).

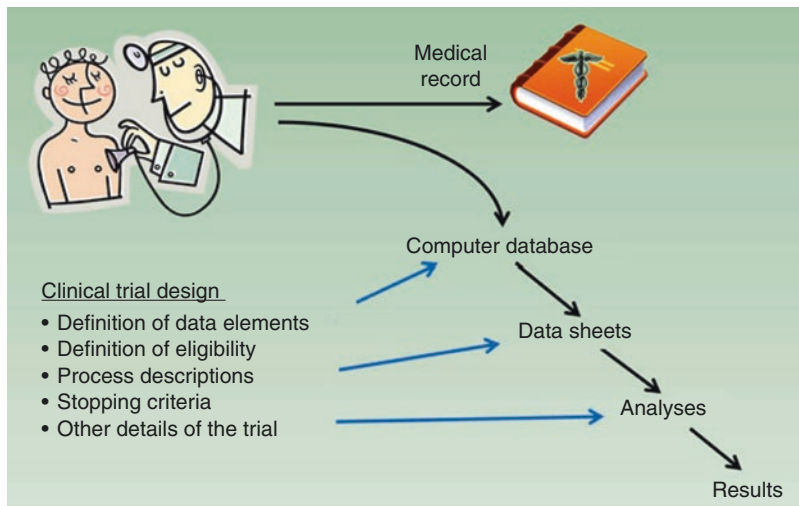

Another theme in the changing world of health care is the increasing investment in the creation of **standard order sets**, **clinical guidelines**, and **clinical pathways** (see ► Chap. 24), generally in an effort to reduce practice variability and to develop consensus approaches to recurring management problems. Several government and professional organizations, as well as individual provider groups, have invested heavily in guideline development, often putting an emphasis on using clear evidence from the literature, rather than expert opinion alone, as the basis for the advice. Despite the success in creating such **evidence-based guidelines**, there is a growing recognition that we need better methods for delivering the decision logic to the point of care. Guidelines

that appear in monographs or journal articles tend to sit on shelves, unavailable when the knowledge they contain would be most valuable to practitioners. Computer-based tools for implementing such guidelines, and integrating them with the EHR, present a means for making high-quality advice available in the routine clinical setting. Many organizations are accordingly integrating decision-support tools with their EHR systems (see ► Chaps. 14 and 24), and there are highly visible commercial efforts underway to provide computer-based diagnostic decision support to practitioners.<sup>2</sup>

There are at least five major issues that have consistently constrained our efforts to build effective EHRs: (1) the need for stan-

<sup>2</sup> ► <https://ehrintelligence.com/news/top-clinical-decision-support-system-cdss-companies-by-ambulatory-inpatient/>; ► <https://www.ibm.com/watson/health/>. (Accessed 5/29/19/).

**Fig. 1.4** Traditional data collection for clinical trials. Until the introduction of EHRs and similar systems, the gathering of research data for clinical studies was typically a manual task. Physicians who cared for patients enrolled in trials, or their research assistants, would be asked to fill out special datasheets for later transcription into computer databases. Alternatively,

data managers were often hired to abstract the relevant data from the paper chart. The trials were generally designed to define data elements that were required and the methods for analysis, but it was common for the process of collecting those data in a structured format to be left to manual processes at the point of patient care

**Fig. 1.5** Role of electronic health records (EHRs) in supporting clinical trials. With the introduction of EHR systems, the collection of much of the research data for clinical trials can become a by-product of the routine care of the patients. Research data may be analyzed directly from the clinical data repository, or a secondary research database may be created by downloading information from the online patient records. The manual processes in

Fig. 1.4 are thereby largely eliminated. In addition, the interaction of the physician with the EHR permits two-way communication, which can greatly improve the quality and efficiency of the clinical trial. Physicians can be reminded when their patients are eligible for an experimental protocol, and the computer system can also remind the clinicians of the rules that are defined by the research protocol, thereby increasing compliance with the experimental plan

dards in the area of clinical terminology; (2) concerns regarding data privacy, confidentiality, and security; (3) challenges in data entry by physicians; (4) difficulties associated with the integration of record systems with other information resources in the health care setting, and (5) designing and delivering systems that are efficient, acceptable to clinicians, and intuitive to use. The first of these issues is discussed in detail in ► Chap. 7, and privacy is one of the central topics in ► Chap. 12. Issues of direct data entry by clinicians are discussed in ► Chaps. 2 and 14 and throughout many other chapters as well. ► Chapter 15 examines the fourth topic, focusing on recent trends in networked data integration, and offers solutions for the ways in which the EHR can be better joined with other relevant information resources and clinical processes, especially within communities where patients may have records with multiple providers and health care systems (Yasnoff et al. 2013). Finally, issues of the interface between computers and clinicians (or other users), with a cognitive emphasis, are the subject of ► Chap. 5.

### 1.1.3 Anticipating the Future of Electronic Health Records

---

One of the first instincts of software developers is to create an electronic version of an object or process from the physical world. Some familiar notion provides the inspiration for a new software product. Once the software version has been developed, however, human ingenuity and creativity often lead to an evolution that extends the software version far beyond what was initially contemplated. The computer can thus facilitate paradigm shifts in how we think about such familiar concepts.

Consider, for example, the remarkable difference between today's office automation software and the typewriter, which was the original inspiration for the development of "word processors". Although the early word processors were designed largely to allow users to avoid retyping papers each time a minor change was made to a document, the

document-management software of today bears little resemblance to a typewriter. Consider all the powerful desktop-publishing facilities, integration of figures, spelling correction, grammar aids, "publishing" online, collaboration on individual documents by multiple users, etc. Similarly, today's spreadsheet programs bear little resemblance to the tables of numbers that we once created on graph paper. To take an example from the financial world, consider automatic teller machines (ATMs) and their facilitation of today's worldwide banking in ways that were never contemplated when the industry depended on human bank tellers.

It is accordingly logical to ask what the health record will become after it has been effectively implemented on computer systems and new opportunities for its enhancement become increasingly clear to us. It is clear that EHRs a decade from now will be remarkably different from the antiquated paper folders that used to dominate our health care environments. We might similarly predict that the state of today's EHR is roughly comparable to the status of commercial aviation in the 1930s. By that time air travel had progressed substantially from the days of the Wright Brothers, and air travel was becoming common. But 1930s air travel seems archaic by modern standards, and it is logical to assume that today's EHRs, albeit much better than both paper records and the early computer-based systems of the 1960s and 1970s, will be greatly improved and further modernized in the decades ahead.

If people had failed to use the early airplanes for travel, the quality and efficiency of airplanes and air travel would not have improved as they have. A similar point can be made about the importance of committing to the use of EHRs today, even though we know that they need to be much better in the future. We must also commit to assuring that those improvements are made, which suggests a dynamic interaction and interdependency among the researchers who address limitations in EHRs and their underlying methods and philosophy, the EHR compa-

nies that currently exist or will arise in the future, and the users who identify requirements and areas for improvement. These companies must look to creative researchers, both within their own companies and in academia, who will forge the changes that will encourage EHR users to embrace and appreciate the technology much more than they often do today.

## 1.2 Communications Technology and Health Data Integration

An obvious opportunity for changing the role and functionality of clinical-care records in the digital age is the power and ubiquity of the Internet. The Internet began in 1968 as a U.S. research activity funded by the Advanced Research Projects Agency (ARPA) of the Department of Defense. Initially known as the **ARPANET**, the network began as a novel mechanism for allowing a handful of defense-related mainframe computers, located mostly at academic institutions or in the research facilities of military contractors, to share data files with each other and to provide remote access to computing power at other locations. The notion of electronic mail arose soon thereafter, and machine-to-machine electronic mail exchanges quickly became a major component of the network's traffic. As the technology matured, its value for nonmilitary research activities was recognized, and by 1973 the first medically related research computer had been added to the network (Shortliffe 1998a, 2000).

During the 1980s, the technology began to be developed in other parts of the world, and the National Science Foundation took over the task of running the principal high-speed **backbone network** in the United States. Hospitals, mostly academic centers, began to be connected to what had by then become known as the Internet, and in a major policy move it was decided to allow commercial organizations to join the network as well. By April 1995, the Internet in the United States had become a fully com-

mercialized operation, no longer depending on the U.S. government to support even the major backbone connections. Today, the Internet is ubiquitous, worldwide, accessible through mobile wireless devices, and has provided the invisible but mandatory infrastructure for social, political, financial, scientific, corporate, and entertainment ventures. Many people point to the Internet as a superb example of the facilitating role of federal investment in promoting innovative technologies. The Internet is a major societal force that arguably would never have been created if the research and development, plus the coordinating activities, had been left to the private sector.

The explosive growth of the Internet did not occur until the late 1990s, when the **World Wide Web** (which had been conceived initially by the physics community as a way of using the Internet to share preprints with photographs and diagrams among researchers) was introduced and popularized. Navigating the Web is highly intuitive, requires no special training, and provides a mechanism for access to multimedia information that accounts for its remarkable growth as a worldwide phenomenon. It is also accessible by essentially all digital devices—computers, tablets, smart phones, and a plethora of personal monitors and “smart home” tools—which is a tribute to its design and its compatibility with newer networking technologies, such as **Bluetooth** and **Wi-Fi**.

The societal impact of this communications phenomenon cannot be overstated, especially given the international connectivity that has grown phenomenally in the past two decades. Countries that once were isolated from information that was important to citizens, ranging from consumers to scientists to those interested in political issues, are now finding new options for bringing timely information to the desktop machines and mobile devices of individuals with an Internet connection.

There has in turn been a major upheaval in the telecommunications industry, with companies that used to be in different busi-

nesses (e.g., cable television, Internet services, and telephone) now finding that their activities and technologies have merged. In the United States, legislation was passed in 1996 to allow new competition to develop and new industries to emerge. We have subsequently seen the merging of technologies such as cable television, telephone, networking, and satellite communications. High-speed lines into homes and offices are widely available, wireless networking is ubiquitous, and inexpensive mechanisms for connecting to the Internet without using conventional computers (e.g., using cell phones or **set-top boxes**) have also emerged. The impact on everyone has been great and hence it is affecting the way that individuals seek health-related information while also enhancing how patients can gain access to their health care providers and to their clinical data.

The Internet also has exhibited unintended consequences, especially in the world of social media, which has created opportunities for promoting political unrest, social shaming, and dissemination of falsehoods. In the world of health care, the Internet has created opportunities for attacks on personal privacy, even while facilitating socially valuable exchanges of data among institutions and individuals. Many of these practical, legal, and ethical challenges are the subject of ► Chap. 12.

Just as individual hospitals and health care systems have come to appreciate the importance of integrating information from multiple clinical and administrative systems within their organizations (see ► Chap. 16), health planners and governments now appreciate the need to develop integrated information resources that combine clinical and health data from multiple institutions within regions, and ultimately nationally (see ► Chaps. 15 and 18). As you will see, the Internet and the role of digital communications has therefore become a major part of modern medicine and health. Although this topic recurs in essentially every chapter in this book, we introduce it in the following sections because of its importance to modern technical issues and policy directions.

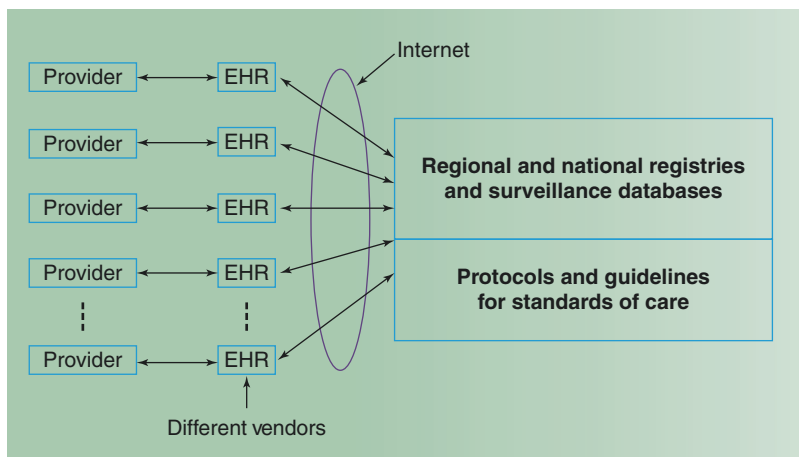

### 1.2.1 A Model of Integrated Disease Surveillance<sup>3</sup>

To emphasize the role that the nation's networking infrastructure is playing in integrating clinical data and enhancing care delivery, consider one example of how disease surveillance, prevention, and care are increasingly being influenced by information and communications technology. The goal is to create an information-management infrastructure that will allow all clinicians, regardless of practice setting (hospitals, emergency rooms, small offices, community clinics, military bases, multispecialty groups, etc.) to use EHRs in their practices both to assist in patient care and to provide patients with counsel on illness prevention. The full impact of this use of electronic resources will occur when data from all such records are pooled in regional and national **registries** or surveillance databases (► Fig. 1.6), mediated through secure connectivity with the Internet. The challenge, of course, is to find a way to integrate data from such diverse practice settings, especially since there are multiple vendors and system developers active in the marketplace, competing to provide value-added capabilities that will excite and attract the practitioners for whom their EHR product is intended.

The practical need to pool and integrate clinical data from such diverse resources and systems emphasizes the practical issues that need to be addressed in achieving such functionality and resources. Interestingly, most of the barriers are logistical, political, and financial rather than technical in nature:

- *Encryption of data:* Concerns regarding privacy and data protection require that Internet transmission of clinical information occur only if those data are encrypted, with an established mechanism for identifying and authenticating individuals before they are allowed to decrypt the information for surveillance or research use.

3 This section is adapted from a discussion that originally appeared in (Shortliffe and Sondik 2004).

**Fig. 1.6** A future vision of surveillance databases, in which clinical data are pooled in regional and national registries or repositories through a process of data submission that occurs over the Internet (with attention to privacy and security concerns as discussed in the text).

When information is effectively gathered, pooled, and analyzed, there are significant opportunities for feeding back the results of derived insights to practitioners at the point of care. Thus the arrows indicate a bi-directional process. See also ► Chap. 15

- *Protection of stored clinical data:* Even when data are stored within an institution, there are opportunities for attack over the Internet, which can be an affront to patient privacy or, equally seriously, an opportunity for installing **malware** within an institution, resulting in rogue uses of data or even a lockout of valid users from crucially important functions or data. **Cybersecurity** has accordingly become a major topic of concern for health care institutions and other practice settings.<sup>4</sup>
- *HIPAA-compliant policies:* The privacy and security rules that resulted from the 1996 **Health Insurance Portability and Accountability Act (HIPAA)** do not prohibit the pooling and use of such data, but they do lay down policy rules and technical security practices that must be part of the solution in achieving the vision we are discussing here.
- *Standards for data transmission and sharing:* Sharing data over networks requires that all developers of EHRs and clinical databases adopt a single set of

standards for communicating and exchanging information. The major enabling standard for such sharing, Health Level 7 (HL7), was introduced decades ago and, after years of work, has been uniformly adopted, implemented, and utilized. However, a uniform “envelope” for digital communication, such as HL7, does not assure that the contents of such messages will be understood or standardized. The pooling and integration of data requires the adoption of standards for clinical terminology and potentially for the schemas used to store clinical information in databases. Thus true interoperability of such systems requires additional standards to be adopted, many of which are discussed in ► Chap. 7.

- *Quality control and error checking:* Any system for accumulating, analyzing, and utilizing clinical data from diverse sources must be complemented by a rigorous approach to quality control and error checking. It is crucial that users have faith in the accuracy and comprehensiveness of the data that are collected in such repositories, because policies, guidelines, and a variety of metrics can be derived over time from such information.

<sup>4</sup> ► <https://www.theverge.com/2019/4/4/18293817/cybersecurity-hospitals-health-care-scan-simulation> (Accessed 5/29/19).

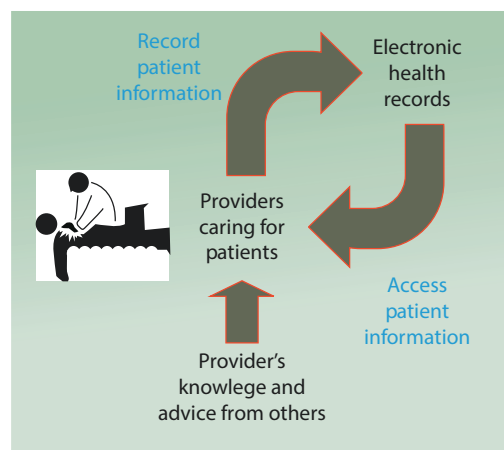

- *Regional and national registries and surveillance databases:* Any adoption of the model in [Fig. 1.6](#) will require mechanisms for creating, funding, and maintaining the regional and national databases or registries that are involved (see [Chap. 15](#)). The growing amount of data that can be gathered in this way are naturally viewed as part of the “big data” problem that has characterized modern data science. The role of state and federal governments in gathering and curating such databases will need to be clarified, and the political issues addressed (including the concerns of some members of the populace that any government role in managing or analyzing their health data may have societal repercussions that threaten individual liberties, employability, and the like).
- Clinical guidelines, adapted for execution and integration into patient-specific decision support rather than simply provided as text documents
- Opportunities for distributed (community-based) clinical research, whereby patients are enrolled in clinical trials and protocol guidelines are in turn integrated with the clinicians’ EHR to support protocol-compliant management of enrolled patients

With the establishment of registries and surveillance databases, and a robust system of Internet integration with EHRs, summary information can flow back to providers to enhance their decision making at the point of care ([Fig. 1.6](#)). This assumes standards that allow such information to be integrated into the vendor-supplied products that the clinicians use in their practice settings. These may be EHRs or their order-entry components that clinicians use to specify the actions that they want to have taken for the treatment or management of their patients (see [Chaps. 14 and 16](#)). Furthermore, as is shown in [Fig. 1.6](#), the databases can help to support the creation of evidence-based guidelines, or clinical research protocols, which can be delivered to practitioners through the feedback process. Thus one should envision a day when clinicians, at the point of care, will receive integrated, non-dogmatic, supportive information regarding:

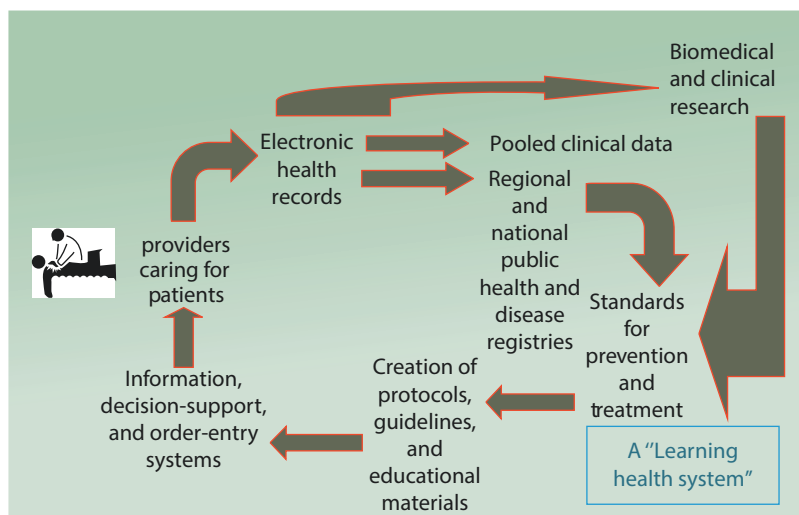

- Recommended steps for health promotion and disease prevention
- Detection of syndromes or problems, either in their community or more widely
- Trends and patterns of public health importance, a capability emphasized by the need for rapidly changing data on cases and deaths during the **COVID-19** pandemic in 2020.

## 1.2.2 The Goal: A Learning Health System

We have been stressing the cyclical role of information—its capture, organization, interpretation, and ultimate use. You can easily understand the small cycle that is implied: patient-specific data and plans entered into an EHR and subsequently made available to the same practitioner or others who are involved in that patient’s care ([Fig. 1.7](#)). Although this view is a powerful contributor to improved data management in the care of patients, it fails to include a larger view of the societal value of the information that is contained in clinical-care records. In fact, such straightforward use of EHRs for direct patient care would not have met some of the

**Fig. 1.7** There is a limited view of the role of EHRs that sees them as intended largely to support the ongoing care of the patient whose clinical data are stored in the record

**Fig. 1.8** The ultimate goal is to create a cycle of information flow, whereby data from local distributed electronic health records (EHRs) and their associated clinical datasets are routinely and effortlessly submitted to registries and research databases. The resulting new

knowledge then can feed back to practitioners at the point of care, using a variety of computer-supported decision-support delivery mechanisms. This cycle of new knowledge, driven by experience, and fed back to clinicians, has been dubbed a “learning health system”

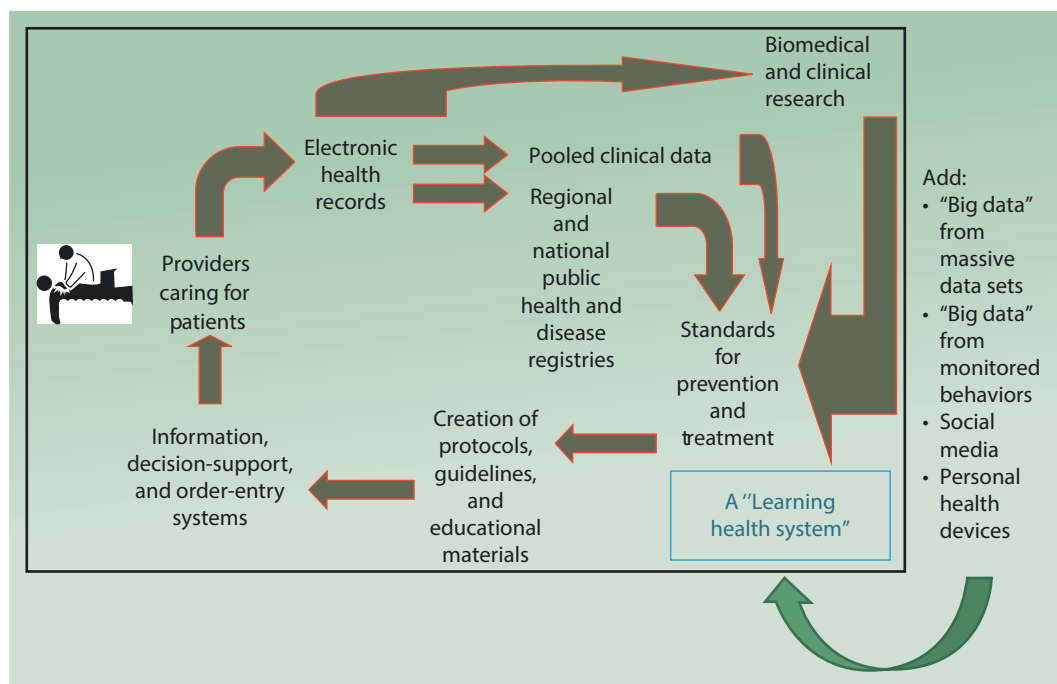

requirements that the US government specified after 2009 when determining eligibility for payment of incentives to clinicians or hospitals who implemented EHRs (see the discussion of the government HITECH program in ► Sect. 1.3).

Consider, instead, an expanded view of the health surveillance model introduced in ► Sect. 1.2.1 (► Fig. 1.8). Beginning at the left of the diagram, clinicians caring for patients use electronic health records, both to record their observations and to gain access to information about the patient. Information from these records is then stored in local patient-care clinical databases and forwarded automatically to regional and national registries as well as to research databases that can support retrospective studies (see ► Chap. 15) or formal institutional or community-based clinical trials (see ► Chap. 27). The analyzed information from institutional datasets, registries and research studies can in turn be used to develop standards for prevention and treatment, with major guidance from biomedical research. Researchers can draw information either directly from the health records or from the pooled data in registries. The standards

for treatment in turn can be translated into protocols, guidelines, and educational materials. This new knowledge and decision-support functionality can then be delivered over the network back to the clinicians so that the information informs patient care, where it is integrated seamlessly with EHRs and order-entry systems.

This notion of a system that allows us to learn from what we do, unlocking the experience that has traditionally been stored in unusable form in paper charts, is gaining wide attention now that we can envision an interconnected community of clinicians and institutions, building digital data resources using EHRs. The concept has been dubbed a **learning health system** and is an ongoing subject of study by the National Academy of Medicine (Daley 2013), which has published a series of reports on the topic.<sup>5</sup> It is also the organizing conceptual framework for a

■ **Fig. 1.9** Today the *learning health system* is increasingly embracing new forms of massive health-related data, often from outside the clinical care setting and

derived from population activities that reflect individuals' health, activities, and attitudes

recently created department at the University of Michigan Medical School<sup>6</sup> and for a new scientific journal.<sup>7</sup>

Although the learning health system concept of ■ Fig. 1.8 may at first seem expansive and all-inclusive, in recent years we have learned that there are other important inputs to the health care environment and these can have important implications for what we learn by analyzing what both patients and healthy individuals do. Some of these data sources are immense and are in line with the recent interest in "big data" analytics (■ Fig. 1.9). Consider, for example, the analysis of huge datasets associated with full human genome specifications for individuals and populations. Another approach for gathering massive amounts of relevant health-related data is to

monitor the behavior of individuals as they use online information resources, searching for health-related information. Social media exchanges (e.g., Twitter, Facebook) have also been used to extract health-related information, such as complaints that suggest early stages of communicable diseases or expressed attitudes towards diseases and treatment. The explosive adoption of health monitoring devices (e.g., step counters, exercise analyzers, cardiac or sleep monitors) has also offered a useful source of large-scale information that is only beginning to be merged with other data in our learning health system.

### 1.2.3 Implications of the Internet for Patients

With the penetration of the Internet, patients, as well as healthy individuals, have turned to the Internet for health information. It is a rare North American physician who has not

6 ▶ <https://medicine.umich.edu/dept/learning-health-sciences> (Accessed 05/03/2020)

7 ▶ <https://onlinelibrary.wiley.com/journal/23796146> (Accessed 05/03/2020)

encountered a patient who comes to an appointment armed with a question, or a stack of printouts, that arose due to medically related searches on the net. The companies that provide search engines for the Internet report that health-related sites are among the most popular ones being explored by consumers. As a result, physicians and other care providers have learned that they must be prepared to deal with information that patients discover on the net and bring with them when they seek care from clinicians. Some of the information is timely and excellent; in this sense, physicians can often learn about innovations from their patients and need to be open to the kinds of questions that this enhanced access to information will generate from patients in their practices.

On the other hand, much of the health information on the Web lacks peer review or is purely anecdotal. People who lack medical training can be misled by such information, just as they have been poorly served in the past by printed information in books and magazines dealing with fad treatments from anecdotal sources. This also creates challenges for health care providers, who often feel pressured to handle more issues in less time due to economic pressures. In addition, some sites provide personalized advice, sometimes for a fee, with all the attendant concerns about the quality of the suggestions and the ability to give valid advice based on an electronic-mail or Web-based interaction.

In a positive light, communications technologies offer clinicians creative ways to interact with their patients and to provide higher quality care. Years ago, medicine adopted the telephone as a standard vehicle for facilitating patient care, and we now take this kind of interaction with patients for granted. If we extend the audio channel to include our visual sense as well, typically relying on the Internet as our communication mechanism, the notion of **telemedicine** emerges (see ► Chap. 20). This notion of “medicine at a distance” arose early in the twentieth century (see ■ Fig. 1.10), but the technology was too limited for much penetration of the idea beyond telephone conversations until the last 30–40 years. The use of telemedicine has subsequently grown rap-

idly, and there are settings in which it is already proving to be successful and cost-effective (e.g., rural care, international medicine, **tele-radiology**, and video-based care of patients in prisons). Similarly, there are now a large number of **apps** (designed for smart phones, tablets, or desktop machines) that offer specialized medical care or advice or assist with health data management and communication with providers and support groups (see ► Chaps. 11 and 20).

## 1.2.4 Requirements for Achieving the Vision

---

Efforts that continue to push the state of the art in Internet technology all have significant implications for the future of health care delivery in general and of EHRs and their integration in particular (Shortliffe 1998b, 2000). But in addition to increasing speed, reliability, security, and availability of the Internet, there are many other areas that need attention if the vision of a learning health system is to be achieved.

### 1.2.4.1 Education and Training

There is a difference between computer literacy (familiarity with computers and their routine uses in our society) and knowledge of the role that computing and communications technology can and should play in our health system. We need to do a better job of training future clinicians in the latter area. Otherwise we will leave them poorly equipped for the challenges and opportunities they will face in the rapidly changing practice environments that surround them (Shortliffe 2010). Not only do they need to feel comfortable with the technology itself, but they need to understand the profound effect that it has had on the practice of medicine—with many more changes to come. Medicine, and other health professions, are being asked to adapt in ways that were not envisioned even a decade or two ago. Not all individuals embrace such change, but younger clinicians, who have grown up with technology in almost all aspects of their lives, have high

■ **Fig. 1.10** “The Radio Doctor”: long before television was invented, creative observers were suggesting how doctors and patients could communicate using

advanced technologies. This 1924 example is from the cover of a popular magazine and envisions video enhancements to radio. (Source: “Radio News” 1924)

expectations for how digital systems and tools should enhance their professional experience. What is even more challenging, perhaps, is that assumptions that they have made about the field they have entered may no longer be valid in the coming years, as some skills are no longer required and new requirements are viewed as dramatically different from what health professionals have had to know in the past.

Furthermore, in addition to the implications for education of health professionals about computer-related topics, much of the future vision we have proposed here can be achieved only if educational institutions produce a cadre of talented individuals who are highly skilled in computing and communications technology but also have a deep understanding of the biomedical milieu and of the needs of practitioners and other health work-

ers. Computer science training alone is not adequate. Fortunately, there are increasing numbers of formal training programs in what has become known as **biomedical informatics** (see ► Sect. 1.4) that provide custom-tailored educational opportunities. Many of the trainees are life science researchers, physicians, nurses, pharmacists, and other health professionals who see the career opportunities and challenges at the intersections of biomedicine, information science, computer science, decision science, data science, cognitive science, and communications technologies. As has been clear for three decades (Greenes and Shortliffe 1990), however, the demand for such individuals far outstrips the supply, both for academic and industrial career pathways.<sup>8,9</sup> We need more training programs,<sup>10</sup> expansion of those that already exist, plus support for junior faculty in health science schools who may wish to pursue additional training in this area.

#### 1.2.4.2 Organizational and Management Change

Second, as implied above, there needs to be a greater understanding among health care leaders regarding the role of specialized multidisciplinary expertise in successful clinical systems implementation. The health care system provides some of the most complex organizational structures in society (Begun et al. 2003), and it is simplistic to assume that off-the-shelf products will be smoothly introduced into a new institution without major analysis, redesign, and cooperative joint-development efforts. Underinvestment and a

failure to understand the requirements for process reengineering as part of software implementation, as well as problems with technical leadership and planning, account for many of the frustrating experiences that health care organizations report in their efforts to use computers more effectively in support of patient care and provider productivity.

The notion of a learning health system described previously is meant to motivate your enthusiasm for what lies ahead and to suggest the topics that need to be addressed in a book such as this one. Essentially all of the following chapters touch on some aspect of the vision of integrated systems that extend beyond single institutions. Before embarking on these topics, however, we must emphasize two points. First, the cyclical creation of new knowledge in a learning health care system will become reality only if individual hospitals, academic medical centers, and national coordinating bodies work together to provide the standards, infrastructure, and resources that are necessary. No individual system developer, vendor, or administrator can mandate the standards for connectivity, data pooling, and data sharing implied by a learning health care system. A national initiative of cooperative planning and implementation for computing and communications resources within and among institutions and clinics is required before practitioners will have routine access to the information that they need (see ► Chap. 15). A major federal incentive program for EHR implementation was a first step in this direction (see ► Sect. 1.3). The criteria that are required for successful EHR implementation are sensitive to the need for data integration, public-health support, and a learning health system.

Second, although our presentation of the learning health system notion has focused on the clinician's view of integrated information access, other workers in the field have similar needs that can be addressed in similar ways. The academic research community has already developed and made use of much of the technology that needs to be coalesced if the clinical user is to have similar access to data and information. There is also the

10 A directory of some existing training programs is available at ► <http://www.amia.org/education/programs-and-courses> (Accessed 5/30/19).

patient's view, which must be considered in the notion of patient-centered health care that is now broadly accepted and encouraged (Ozkaynak et al. 2013).

### 1.3 The US Government Steps In

During the early decades of the evolution of clinical information systems for use in hospitals, patient care, and public health, the major role of government was in supporting the research enterprise as new methods were developed, tested, and formally evaluated. The topic was seldom mentioned by the nation's leaders, however, even during the 1990s when the White House was viewed as being especially tech savvy. It was accordingly remarkable when, in the President's State of the Union address in 2004 (and in each of the following years of his administration), President Bush called for universal implementation of electronic health records within 10 years. The Secretary of Health and Human Services, Tommy Thompson, was similarly supportive and, in May 2004, created an entity intended to support the expansion of the use of EHRs—the **Office of the National Coordinator for Health Information Technology** (initially referred to by the full acronym ONCHIT, but later shortened simply to ONC).

There was initially limited budget for ONC, although the organization served as a convening body for EHR-related planning efforts and the National Health Information Infrastructure (see ► Chaps. 14, 15 and 29). The topic of EHRs subsequently became a talking point for both major candidates during the Presidential election in 2008, with strong bipartisan support. Then, in early 2009, Congress enacted the American Recovery and Reinvestment Act (ARRA), also known as the economic “Stimulus Bill”. One portion of that legislation was known as the **Health Information Technology for Economic and Clinical Health (HITECH) Act**. It was this portion of the bill that provided significant fiscal incentives for health systems, hospitals, and providers to implement EHRs in their practices and eventual financial penalties for lack of implementation. Such

payments were made available, however, only when eligible organizations or individual practitioners implemented EHRs that were “certified” as meeting minimal standards and when they could document that they were making “meaningful use” of those systems. You will see references to such certification and **meaningful use** criteria in other chapters in this volume.

This volume also offers a discussion of HIT policy and the federal government in ► Chap. 29. Although the process of EHR implementation is approaching completion in the US, both in health systems and practices, the current status is largely due to this legislative program: because of the federal stimulus package, large numbers of hospitals, systems, and practitioners invested in EHRs and incorporated them into their practices. Furthermore, the demand for workers skilled in health information technology grew much more rapidly than did the general job market, even within health care (► Fig. 1.11). It is a remarkable example of how government policy and investment can stimulate major transitions in systems such as health care, where many observers had previously felt that progress had been unacceptably slow (Shortliffe 2005).

### 1.4 Defining Biomedical Informatics and Related Disciplines

With the previous sections of this chapter as background, let us now consider the scientific discipline that is the subject of this volume and has led to the development of many of the functionalities that need to be brought together in the integrated biomedical-computing environment of the future. The remainder of this chapter deals with biomedical informatics as a field and with biomedical and health information as a subject of study. It provides additional background needed to understand many of the subsequent chapters in this book.

Reference to the use of computers in biomedicine evokes different images depending on the nature of one's involvement in the field. To a hospital administrator, it might suggest

**Fig. 1.11** Impact of the HITECH Act on health information technology (IT) employment. Percent change in online health IT job postings per month for first 3 years, relative to health care jobs and all jobs: normalized to February 2009 when ARRA passed. (Source:

ONC analysis of data from O'Reilly Job Data Mart, ONC Data Brief, No. 2, May 2012 (► [https://www.healthit.gov/sites/default/files/pdf/0512\\_ONCData-Brief2\\_JobPostings.pdf](https://www.healthit.gov/sites/default/files/pdf/0512_ONCData-Brief2_JobPostings.pdf) (Accessed 5/6/2019)))

the maintenance of clinical-care records using computers; to a decision scientist, it might mean the assistance by computers in disease diagnosis; to a basic scientist, it might mean the use of computers for maintaining, retrieving, and analyzing gene-sequencing information. Many physicians immediately think of office-practice tools for tasks such as patient billing or appointment scheduling, and of electronic health record systems for clinical documentation. Nurses often think of computer-based tools for charting the care that they deliver, or decision-support tools that assist in applying the most current patient-care guidelines. The field includes study of all these activities and a great many others too. More importantly, it includes the consideration of various external factors that affect the biomedical setting. Unless you keep in mind these surrounding factors, it may be

difficult to understand how biomedical computing can help us to tie together the diverse aspects of health care and its delivery.

To achieve a unified perspective, we might consider four related topics: (1) the concept of biomedical information (why it is important in biological research and clinical practice and why we might want to use computers to process it); (2) the structural features of medicine, including all those subtopics to which computers might be applied; (3) the importance of evidence-based knowledge of biomedical and health topics, including its derivation and proper management and use; and (4) the applications of computers and communication methods in biomedicine and the scientific issues that underlie such efforts. We mention the first two topics briefly in this and the next chapter, and we provide references in the Suggested Readings section for readers who

wish to learn more. The third topic, knowledge to support effective decision making in support of human health, is intrinsic to this book and occurs in various forms in essentially every chapter. The fourth topic, however, is the principal subject of this book.

Computers have captured the imagination (and attention) of our society. Today's younger individuals have grown up in a world in which computers are ubiquitous and useful. Because the computer as a machine is exciting, people may pay a disproportionate amount of attention to it as such—at the expense of considering what the computer can do given the numbers, concepts, ideas, and cognitive underpinnings of fields such as medicine, health, and biomedical research. Computer scientists, philosophers, psychologists, and other scholars increasingly consider such matters as the nature of information and knowledge and how human beings process such concepts. These investigations have been given a sense of timeliness (if not urgency) by the simple existence of the computer. The cognitive activities of clinicians in practice probably have received more attention over the past three or four decades than in all previous history (see ► Chap. 4). Again, the existence of the computer and the possibilities of its extending a clinician's cognitive powers have motivated many of these studies. To develop computer-based tools to assist with decisions, we must understand more clearly such human processes as diagnosis, therapy planning, decision making, and problem solving in medicine. We must also understand how personal and cultural beliefs affect the way in which information is interpreted and decisions are ultimately made.

### 1.4.1 Terminology

---

Although, starting in the 1960s, a growing number of individuals conducting serious biomedical research or undertaking clinical practice had access to a computer system, there was initial uncertainty about what name should be used for the biomedical application of computer science concepts. The name computer science was itself new in 1960 and was

only vaguely defined. Even today, the term computer science is used more as a matter of convention than as an explanation of the field's scientific content.

In the 1970s we began to use the phrase **medical computer science** to refer to the subdivision of computer science that applies the methods of the larger field to medical topics. As you will see, however, medicine has provided a rich area for computer science research, and several basic computing insights and methodologies have been derived from applied medical-computing research.

The term **information science**, which is occasionally used in conjunction with computer science, originated in the field of library science and is used to refer, somewhat generally, to the broad range of issues related to the management of both paper-based and electronically stored information. Much of what information science originally set out to be is now drawing evolving interest under the name **cognitive science**.

**Information theory**, in contrast, was first developed by scientists concerned about the physics of communication; it has evolved into what may be viewed as a branch of mathematics. The results scientists have obtained with information theory have illuminated many processes in communications technology, but they have had little effect on our understanding of human information processing.

The terms **biomedical computing** or **bio-computation** have been used for a number of years. They are non-descriptive and neutral, implying only that computers are employed for some purpose in biology or medicine. They are often associated with bioengineering applications of computers, however, in which the devices are viewed more as tools for a bioengineering application than as a primary focus of research.

In the 1970s, inspired by the French term for computer science (*informatique*), the English-speaking community began to use the term **medical informatics**. Those in the field were attracted by the word's emphasis on *information*, which they saw as more central to the field than the computer itself, and it gained momentum as a term for the discipline, espe-

cially in Europe, during the 1980s. The term is broader than **medical computing** (it includes such topics as medical statistics, record keeping, and the study of the nature of medical information itself) and deemphasizes the computer while focusing instead on the nature of the field to which computations are applied. Because the term *informatics* became widely accepted in the United States only in the late 1980s, **medical information science** was also used earlier in North America; this term, however, may be confused with library science, and it does not capture the broader implications of the European term. As a result, the name *medical informatics* appeared by the late 1980s to have become the preferred term, even in the United States. Indeed, this is the name of the field that we used in the first two editions of this textbook (published in 1990 and 2000), and it is still sometimes used in professional, industrial, and academic settings. However, many observers expressed concern that the adjective “medical” is too focused on physicians and disease, failing to appreciate the relevance of this discipline to other health and life-science professionals and to health promotion and disease prevention. Thus, the term **health informatics**, or health care informatics, gained some popularity, even though it has the disadvantage of tending to exclude applications to biomedical research (► Chaps. 9 and 26) and, as we shall argue shortly, it tends to focus the field’s name on application domains (clinical care, public health, and prevention) rather than the basic discipline and its broad range of applicability.

Applications of informatics methods in biology and genetics exploded during the 1990s due to the human genome project<sup>11</sup> and the growing recognition that modern life-science research was no longer possible without computational support and analysis (see ► Chaps. 9 and 26). By the late 1990s, the use of informatics methods in such work had become widely known as **bioinformatics** and the director of the National Institutes of Health (NIH) appointed an advisory group

called the Working Group on Biomedical Computing. In June 1999, the group provided a report<sup>12</sup> recommending that the NIH undertake an initiative called the **Biomedical Information Science and Technology Initiative (BISTI)**. With the subsequent creation of another NIH organization called the Bioinformatics Working Group, the visibility of informatics applications in biology was greatly enhanced. Today bioinformatics is a major area of activity at the NIH<sup>13</sup> and in many universities and biotechnology companies around the world. The explosive growth of this field, however, has added to the confusion regarding the naming conventions we have been discussing. In addition, the relationship between *medical informatics* and *bioinformatics* became unclear. As a result, in an effort to be more inclusive and to embrace the biological applications with which many medical informatics groups had already been involved, the name *medical informatics* gradually gave way to biomedical informatics (BMI). Several academic groups have changed their names, and a major medical informatics journal (*Computers and Biomedical Research*, first published in 1967) was reborn in 2001 as *The Journal of Biomedical Informatics*.<sup>14</sup>

Despite this convoluted naming history, we believe that the broad range of issues in biomedical information management does require an appropriate name and, beginning with the third edition of this book (2006), we used the term **biomedical informatics** for this purpose. It has become the most widely accepted term for the core discipline and should be viewed as encompassing broadly all areas of application in health, clinical practice, and biomedical research. When we speak specifically about computers and their use within biomedical informatics activities, we use the terms biomedical computer science (for the methodologic issues) or biomedical computing (to describe the activity itself).

14 ► <http://www.journals.elsevier.com/journal-of-bio-medical-informatics> (Accessed 5/30/19).

Note, however, that biomedical informatics has many other component sciences in addition to computer science. These include the decision sciences, statistics, cognitive science, data science, information science, and even management sciences. We return to this point shortly when we discuss the basic versus applied nature of the field when it is viewed as a basic research discipline.

Although labels such as these are arbitrary, they are by no means insignificant. In the case of new fields of endeavor or branches of science, they are important both in designating the field and in defining or restricting its contents. The most distinctive feature of the modern computer is the generality of its application. The nearly unlimited range of computer uses complicates the business of naming the field. As a result, the nature of computer science is perhaps better illustrated by examples than by attempts at formal definition. Much of this book presents examples that do just this for biomedical informatics as well.

The American Medical Informatics Association (AMIA), which was founded in the late 1980s under the former name for the

discipline, has recognized the confusion regarding the field and its definition.<sup>15</sup> They accordingly appointed a working group to develop a formal definition of the field and to specify the core competencies that need to be acquired by students seeking graduate training in the discipline. The resulting definition, published in AMIA's journal and approved by the full board of the organization, identifies the focus of the field in a simple sentence and then adds four clarifying corollaries that refine the definition and the field's scope and content (► Box 1.1). We adopt this definition, which is very similar to the one we offered in previous editions of this text. It acknowledges that the emergence of biomedical informatics as a new discipline is due in large part to rapid advances in computing and communications technology, to an increasing awareness that the knowledge base of biomedicine is essentially unmanageable by traditional paper-based methods, and to a growing conviction that the process of informed decision making is as important to modern biomedicine as is the collection of facts on which clinical decisions or research plans are made.

### Box 1.1: Definition of Biomedical Informatics

*Biomedical informatics (BMI) is the interdisciplinary field that studies and pursues the effective uses of biomedical data, information, and knowledge for scientific inquiry, problem solving, and decision making, driven by efforts to improve human health.*

**Scope and breadth of discipline:** BMI investigates and supports reasoning, modeling, simulation, experimentation, and translation across the spectrum from molecules to individuals and to populations, from biological to social systems, bridging basic and clinical research and practice and the health care enterprise.

**Theory and methodology:** BMI develops, studies, and applies theories, methods, and processes for the generation, storage, retrieval, use, management, and sharing of biomedical data, information, and knowledge.

**Technological approach:** BMI builds on and contributes to computer, telecommunication, and information sciences and technologies, emphasizing their application in biomedicine.

**Human and social context:** BMI, recognizing that people are the ultimate users of biomedical information, draws upon the social and behavioral sciences to inform the design and evaluation of technical solutions, policies, and the evolution of economic, ethical, social, educational, and organizational systems.

### 1.4.2 Historical Perspective

The modern digital computer grew out of developments in the United States and abroad during World War II, and general-purpose computers began to appear in the marketplace by the mid-1950s (■ Fig. 1.12). Speculation about what might be done with such machines (if they should ever become reliable) had, however, begun much earlier. Scholars, at least as far back as the Middle Ages, often had raised the question of whether human reasoning might be explained in terms of formal or **algorithmic processes**. Gottfried Wilhelm von Leibnitz, a seventeenth-century German philosopher and mathematician, tried to develop a calculus that could be used to simulate human reasoning. The notion of a “logic engine” was subsequently worked out by Charles Babbage in the mid nineteenth century.

The first practical application of automatic computing relevant to medicine was Herman Hollerith’s development of a punched-card data-processing system for the 1890 U.S. census (■ Fig. 1.13). His methods were soon adapted to **epidemiologic** and public health surveys, initiating the era of electro-mechanical punched-card data-processing technology, which matured and was widely adopted during the 1920s and 1930s. These techniques were the precursors of the stored

program and wholly electronic digital computers, which began to appear in the late 1940s (Collen 1995).

One early activity in biomedical computing was the attempt to construct systems that would assist a physician in decision making (see ► Chap. 24). Not all biomedical-computing programs pursued this course, however. Many of the early ones instead investigated the notion of a total **hospital information system** (HIS; see ► Chap. 16). These projects were perhaps less ambitious in that they were more concerned with practical applications in the short term; the difficulties they encountered, however, were still formidable. The earliest work on HISs in the United States was probably that associated with the MEDINET project at General Electric, followed by work at Bolt, Beranek, Newman in Cambridge, Massachusetts, and then at the Massachusetts General Hospital (MGH) in Boston. A number of hospital application programs were developed at MGH by Barnett and his associates over three decades beginning in the early 1960s. Work on similar systems was undertaken by Warner at Latter Day Saints (LDS) Hospital in Salt Lake City, Utah, by Collen at Kaiser Permanente in Oakland, California, by Wiederhold at

Stanford University in Stanford, California, and by scientists at Lockheed in Sunnyvale, California.<sup>16</sup>

The course of HIS applications bifurcated in the 1970s. One approach was based on the concept of an integrated or monolithic design in which a single, large, *time-shared computer* would be used to support an entire collection of applications. An alternative was a distributed design that favored the separate implementation of specific applications on smaller individual computers—minicomputers—thereby permitting the independent evolution of systems in the respective application areas. A common assumption was the existence of a single shared database of patient information. The multi-machine model was not practical, however, until network technologies permitted rapid and reliable communication among distributed and (sometimes) heterogeneous types of machines. Such distributed HISs began to appear in the 1980s (Simborg et al. 1983).

Biomedical-computing activity broadened in scope and accelerated with the appearance of the minicomputer in the early 1970s. These machines made it possible for individual departments or small organizational units to acquire their own dedicated computers and to develop their own application systems (■ Fig. 1.14). In tandem with the introduction of general-purpose software tools that provided standardized facilities to individuals with limited computer training (such as the UNIX operating system and programming environment), the minicomputer put more computing power in the hands of more biomedical investigators than did any other single development until the introduction of the microprocessor, a central processing unit (CPU) contained on one or a few chips (■ Fig. 1.15).

Everything changed radically in the late 1970s and early 1980s, when the microproces-

sor and the personal computer (PC) or microcomputer became available. Not only could hospital departments afford minicomputers but now individuals also could afford micro-

■ Fig. 1.14 Departmental system. Hospital departments, such as the clinical laboratory, were able to implement their own custom-tailored systems when affordable minicomputers became available. These departments subsequently used microcomputers to support administrative and clinical functions. (Copyright 2013 Hewlett-Packard Development Company, LP. Reproduced from ~1985 original with permission)

■ Fig. 1.15 Miniature computer. The microprocessor, or “computer on a chip,” revolutionized the computer industry in the 1970s. By installing chips in small boxes and connecting them to a computer terminal, engineers produced the personal computer (PC)—an innovation that made it possible for individual users to purchase their own systems

<sup>16</sup> The latter system was later taken over and further developed by the Technicon Corporation (subsequently TDS Healthcare Systems Corporation). Later the system was part of the suite of products available from Eclipsys, Inc. (which in turn was acquired by Allscripts, Inc in 2010).

computers. This change enormously broadened the base of computing in our society and gave rise to a new software industry. The first articles on computers in medicine had appeared in clinical journals in the late 1950s, but it was not until the late 1970s that the first use of computers in advertisements dealing with computers and aimed at physicians began to appear (■ Fig. 1.16). Within a few years, a wide range of computer-based information-management tools were available as commercial products; their descriptions began to appear in journals alongside the traditional advertisements for drugs and other medical products. Today individual physicians find it practical to employ PCs in a variety of settings, including for applications in patient care or clinical investigation.

Today we enjoy a wide range of hardware of various sizes, types, prices, and capabilities, all of which will continue to evolve in the decades ahead. The trend—reductions in size and cost of computers with simultaneous increases in power (■ Fig. 1.17)—shows no sign of slowing, although scientists foresee the

■ Fig. 1.16 Medical advertising. An early advertisement for a portable computer terminal that appeared in general medical journals in the late 1970s. The development of compact, inexpensive peripheral devices and personal computers (PCs) inspired future experiments in marketing directly to clinicians (Reprinted by permission of copyright holder Texas Instruments Incorporated © 1985)

■ Fig. 1.17 Moore's Law. Former Intel chairman Gordon Moore is credited with popularizing the "law" that the size and cost of microprocessor chips will half every 18 months while they double in computing power. This

graph shows the exponential growth in the number of transistors that can be integrated on a single microprocessor chip. The trend continues to this day. (Source: Wikipedia: ► [https://en.wikipedia.org/wiki/Transistor\\_count](https://en.wikipedia.org/wiki/Transistor_count))

■ **Fig. 1.18** The National Library of Medicine (NLM). The NLM, on the campus of the National Institutes of Health (NIH) in Bethesda, Maryland, is the principal biomedical library for the nation (see ► Chap. 23). It is also a major source of support for research and training in biomedical informatics, both at NIH and in universities throughout the US. (Photograph courtesy of the National Library of Medicine)

ultimate physical limitations to the miniaturization of computer circuits.<sup>17</sup>

Progress in biomedical-computing research will continue to be tied to the availability of funding from either government or commercial sources. Because most biomedical-computing research is exploratory and is far from ready for commercial application, the federal government has played a key role in funding the work of the last four decades, mainly through the NIH and the Agency for Health Care Research and Quality (AHRQ). The National Library of Medicine (NLM) has assumed a primary role for biomedical informatics, especially with support for basic research in the field (■ Fig. 1.18). As increasing numbers of applications prove successful in the commercial marketplace, it is likely that more development work will shift to industrial settings and that university programs will focus increasingly on fundamental research problems viewed as too speculative for short-term commercialization – as has occurred in the field of computer science over the past several decades.

### 1.4.3 Relationship to Biomedical Science and Clinical Practice

The exciting accomplishments of biomedical informatics, and the implied potential for future benefits to medicine, must be viewed in the context of our society and of the existing health care system. As early as 1970, an eminent clinician suggested that computers might in time have a revolutionary influence on medical care, on medical education, and even on the selection criteria for health-science trainees (Schwartz 1970). The subsequent enormous growth in computing activity has been met with some trepidation by health professionals. They ask where it will all end. Will health workers gradually be replaced by computers? Will nurses and physicians need to be highly trained in computer science or informatics before they can practice their professions effectively? Will both patients and health workers eventually revolt rather than accept a trend toward automation that they believe may threaten the traditional humanistic values in health care delivery (see ► Chap. 12) (Shortliffe 1993a)? Will clinicians be viewed as outmoded and backward if they do not turn to computational tools for assistance with information management and decision making (■ Fig. 1.19)?

Biomedical informatics is intrinsically entwined with the substance of biomedical science. It determines and analyzes the structure of biomedical information and knowledge, whereas biomedical science is constrained by that structure. Biomedical informatics melds the study data, information, knowledge, decision making, and supporting technologies with analyses of biomedical information and knowledge, thereby

addressing specifically the interface between the science of information and knowledge management and biomedical science. To illustrate what we mean by the “structural” features of biomedical information and knowledge, we can contrast the properties of the information and knowledge typical of such fields as physics or engineering with the properties of those typical of biomedicine (see ► Box 1.2).

### Box 1.2: The Nature of Medical Information

*This material is adapted from a small portion of a classic book on this topic. It was written by Dr. Scott Blois, who coauthored the introductory chapter to this textbook in its 1st edition, which was published shortly after his death. Dr. Blois was a scholar who directed the informatics program at the University of California San Francisco and served as the first president of the American College of Medical Informatics (ACMI). [Blois, M. S. (1984). *Information and medicine: The nature of medical descriptions*. Berkeley: University of California Press].*

From the material in this chapter, you might conclude that biomedical applications do not raise any unique problems or concerns. On the contrary, the biomedical environment raises several issues that, in interesting ways, are quite distinct from those encountered in most other domains of applied computing. Clinical information seems to be systematically different from the information used in physics, engineering, or even clinical chemistry (which more closely resembles chemical applications generally than it does medical ones). Aspects of biomedical information include an essence of uncertainty—we can never know all about a physiological process—and this results in inevitable variability among individuals. These differences raise special problems and some investigators suggest that biomedical computer science differs from conventional computer science in fundamental ways. We shall explore these differences only briefly here; for details, you can

consult Blois’ book on this subject (see Suggested Readings).

Let us examine an instance of what we will call a low-level (or readily formalized) science. Physics is a natural starting point; in any discussion of the hierarchical relationships among the sciences (from the fourth-century BC Greek philosopher Aristotle to the twentieth-century U.S. librarian Melvil Dewey), physics will be placed near the bottom. Physics characteristically has a certain kind of simplicity, or generality. The concepts and descriptions of the objects and processes of physics, however, are necessarily used in all applied fields, including medicine. The laws of physics and the descriptions of certain kinds of physical processes are essential in representing or explaining functions that we regard as medical in nature. We need to know something about molecular physics, for example, to understand why water is such a good solvent; to explain how nutrient molecules are metabolized, we talk about the role of electron-transfer reactions.

Applying a computer (or any formal computation) to a physical problem in a medical context is no different from doing so in a physics laboratory or for an engineering application. The use of computers in various **low-level processes** (such as those of physics or chemistry) is similar and is independent of the application. If we are talking about the solvent properties of water, it makes no difference whether we happen to be working in geology, engineering, or medicine. Such low-level processes of physics are particularly receptive to

mathematical treatment, so using computers for these applications requires only conventional numerical programming.

In biomedicine, however, there are other **higher-level processes** carried out in more complex objects such as organisms (one type of which is patients). Many of the important informational processes are of this kind. When we discuss, describe, or record the properties or behavior of human beings, we are using the descriptions of very high-level objects, the behavior of whom has no counterpart in physics or in engineering. The person using computers to analyze the descriptions of these high-level objects and processes encounters serious difficulties (Blois 1984).

One might object to this line of argument by remarking that, after all, computers are used routinely in commercial applications in which human beings and situations concerning them are involved and that relevant computations are carried out successfully. The explanation is that, in these commercial applications, the descriptions of human beings and their activities have been so highly abstracted that the events or processes have been reduced to low-level objects. In biomedicine, abstractions carried to this degree would be worthless from either a clinical or research perspective.

For example, one instance of a human being in the banking business is the customer, who may deposit, borrow, withdraw, or invest money. To describe commercial activities such as these, we need only a few properties; the customer can remain an abstract entity. In clinical medicine, however, we could not begin to deal with a patient represented with such skimpy abstractions. We must be prepared to analyze most of the complex behaviors that human beings display and to describe patients as completely as possible. We must deal with the rich descriptions occurring at high levels in the hierarchy, and we may be hard pressed

to encode and process this information using the tools of mathematics and computer science that work so well at low levels. In light of these remarks, the general enterprise known as **artificial intelligence (AI)** can be aptly described as the application of computer science to high-level, real-world problems.

Biomedical informatics thus includes computer applications that range from processing of very low-level descriptions, which are little different from their counterparts in physics, chemistry, or engineering, to processing of extremely high-level ones, which are completely and systematically different. When we study human beings in their entirety (including such aspects as human cognition, self-consciousness, intentionality, and behavior), we must use these high-level descriptions. We will find that they raise complex issues to which conventional logic and mathematics are less readily applicable. In general, the attributes of low-level objects appear sharp, crisp, and unambiguous (e.g., “length,” “mass”), whereas those of high-level ones tend to be soft, fuzzy, and inexact (e.g., “unpleasant scent,” “good”).

Just as we need to develop different methods to describe high-level objects, the inference methods we use with such objects may differ from those we use with low-level ones. In formal logic, we begin with the assumption that a given proposition must be either true or false. This feature is essential because logic is concerned with the preservation of truth value under various formal transformations. It is difficult or impossible, however, to assume that all propositions have truth values when we deal with the many high-level descriptions in medicine or, indeed, in everyday situations. Such questions as “Was Woodrow Wilson a good president?” cannot be answered with a “yes” or “no” (unless we limit the question to specific criteria for determining the goodness of presidents). Many common questions in biomedicine have the same property.

■ **Fig. 1.20** Biomedical informatics as basic science. We view the term biomedical informatics as referring to the basic science discipline in which the development and evaluation of new methods and theories are a primary focus of activity. These core concepts and methods in turn have broad applicability in the health and biomedical sciences. The informatics subfields indicated by the terms across the bottom of this figure are accordingly best viewed as application domains for a common

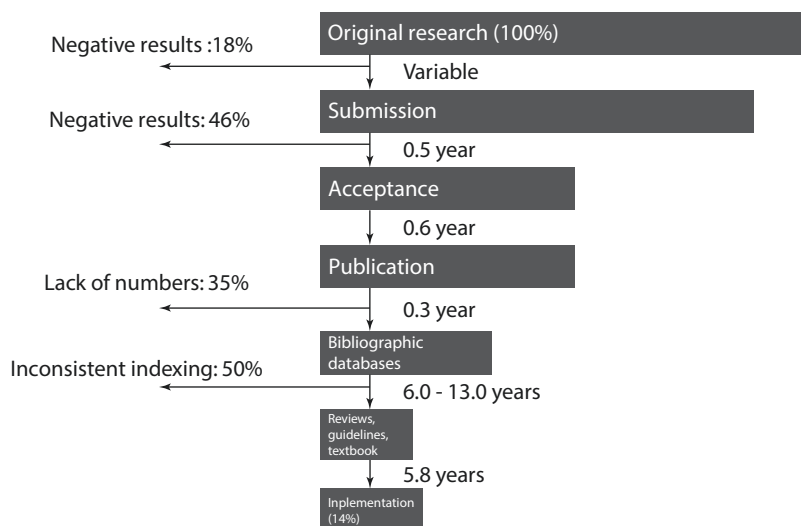

set of concepts and techniques from the field of biomedical informatics. Note that work in biomedical informatics is motivated totally by the application domains that the field is intended to serve (thus the two-headed arrows in the diagram). Therefore the basic research activities in the field generally result from the identification of a problem in the real world of health or biomedicine for which an informatics solution is sought (see text)

Biomedical informatics is perhaps best viewed as a basic biomedical science, with a wide variety of potential areas of application (■ Fig. 1.20). The analogy with other **basic sciences** is that biomedical informatics uses the results of past experience to understand, structure, and encode objective and subjective biomedical findings and thus to make them suitable for processing. This approach supports the integration of the findings and their analyses. In turn, the selective distribution of newly created knowledge can aid patient care, health planning, and basic biomedical research.

Biomedical informatics is, by its nature, an **experimental science**, characterized by posing questions, designing experiments, performing analyses, and using the information gained to design new experiments. One goal is simply to search for new knowledge, called **basic research**. A second goal is to use this knowledge for practical ends, called **applications (applied) research**. There is a continuity between these two endeavors (see ■ Fig. 1.20). In biomedical informatics, there is an espe-

cially tight coupling between the application areas, broad categories of which are indicated at the bottom of ■ Fig. 1.20, and the identification of basic research tasks that characterize the scientific underpinnings of the field. Research, however, has shown that there can be a very long period of time between the development of new concepts and methods in basic research and their eventual application in the biomedical world (Balas and Boren 2000). Furthermore (see ■ Fig. 1.21), many discoveries are discarded along the way, leaving only a small percentage of basic research discoveries that have a practical influence on the health and care of patients.

Work in biomedical informatics (BMI) is inherently motivated by problems encountered in a set of applied domains in biomedicine. The first of these historically has been clinical care (including medicine, nursing, dentistry, and veterinary care), an area of activity that demands patient-oriented informatics applications. We refer to this area as **clinical informatics**.<sup>18</sup> It includes several sub-

■ **Fig. 1.21** Phases in the transfer of research into clinical practice. A synthesis of studies focusing on various phases of this transfer has indicated that it takes an average of 17 years to make innovation part of routine care (Balas and Boren 2000). Pioneering institutions often apply innovations much sooner, sometimes within a few weeks, but nationwide introduction is usually slow.

National utilization rates of specific, well-substantiated procedures also suggest a delay of two decades in reaching the majority of eligible patients. For a well-documented study of such delays and their impact in an important area of clinical medicine, see (Krumholz et al. 1998). (Figure courtesy of Dr. Andrew Balas, used with permission)

topics and areas of specialized expertise, including patient-care foci such as **nursing informatics**, **dental informatics**, and even **veterinary informatics**. Furthermore, the former name of the discipline, **medical informatics**, is now reserved for those applied research and practice topics that focus on disease and the role of physicians. As was previously discussed, the term “medical informatics” is no longer used to refer to the discipline as a whole.

Closely tied to clinical informatics is **public health informatics** (■ Fig. 1.20), where simi-

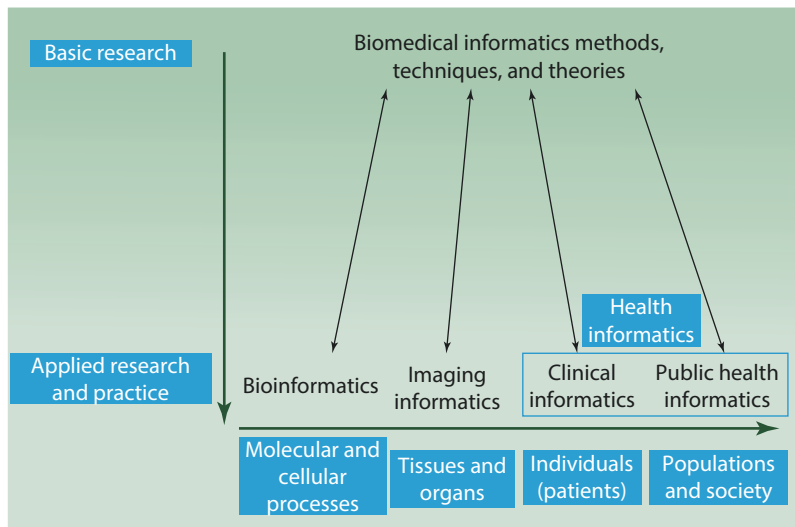

lar methods are generalized for application to populations of patients rather than to single individuals (see ► Chap. 18). Thus clinical informatics and public health informatics share many of the same methods and techniques. The closeness of their relationship was amply demonstrated by the explosion in informatics research and applications that occurred in response to the COVID-19 pandemic.<sup>19</sup> By mid-2020, several articles had appeared to demonstrate the tight relationship between EHRs and public health informatics for management of the outbreak (Reeves et al. 2020).

Two other large areas of application overlap in some ways with clinical informatics and public health informatics. These include **imaging informatics** (and the set of issues developed around both radiology and other image management and image analysis domains such as pathology, dermatology, and molecular visualization—see ► Chaps. 10 and 22). Finally, there

18 Clinical informatics was approved in 2013 by the American Board of Medical Specialties as a formal subspecialty of medicine (Finnell and Dixon, 2015), with board certification examinations offered for eligible candidates by the American Board of Preventive Medicine (► <https://www.theabpm.org/become-certified/subspecialties/clinical-informatics/> (Accessed 6/1/19)). AMIA is formulating a similar certification program, AMIA Health Informatics Certification (AHIC) for non-physicians who are working in the clinical informatics area (► <https://www.amia.org/ahic>, Accessed 1/5/2020).

19 ► <https://www.amia.org/COVID19> (Accessed 05/03/2020)

■ **Fig. 1.22** Building on the concepts of ■ Fig. 1.20, this diagram demonstrates the breadth of the biomedical informatics field. The relationship between biomedical informatics as a core scientific discipline and its diverse array of application domains that span biological science, imaging, clinical practice, public health, and

others not illustrated (see text). Note that “health informatics” is the term used to refer to applied research and practice in clinical and public health informatics. It is not a synonym for the underlying discipline, which is “biomedical informatics”

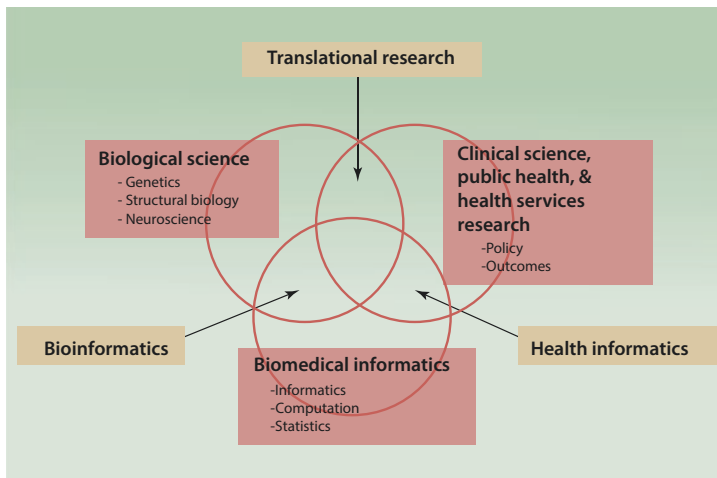

is the burgeoning area of **bioinformatics**, which at the molecular and cellular levels is offering challenges that draw on many of the same informatics methods as well (see ► Chaps. 9 and 26).

As is shown in ■ Fig. 1.22, there is a spectrum as one moves from left to right across these BMI application domains. In bioinformatics, workers deal with molecular and cellular processes in the application of informatics methods. At the next level, workers focus on tissues and organs, which tend to be the emphasis of imaging informatics work (also called **structural informatics** by some investigators). Progressing to clinical informatics, the focus is on individual patients, and finally to public health, where researchers address problems of populations and of society, including prevention. The core science of biomedical informatics has important contributions to make across that entire spectrum, and many informatics methods are broadly applicable across the full range of domains.

Note from ■ Fig. 1.20 that biomedical informatics and bioinformatics are not synonyms and it is incorrect to refer to the scientific discipline as bioinformatics, which is, rather, an important area of application of BMI methods

and concepts. Similarly, the term health informatics, which refers to applied research and practice in clinical and public-health informatics, is also not an appropriate name for the core discipline, since BMI is applicable to basic human biology as well as to health.

We acknowledge that the four major areas of application shown in ■ Fig. 1.19 have “fuzzy” boundaries, and many areas of applied informatics research involve more than one of the categories. For example, **biomolecular imaging** involves both bioinformatics and imaging informatics concepts. Similarly, **personal** or **consumer health informatics** (see ► Chap. 11) includes elements of both clinical informatics and public-health informatics. Another important area of BMI research activities is **pharmacogenomics** (see ► Chap. 27), which is the effort to infer genetic determinants of human drug response. Such work requires the analysis of linked **genotypic** and **phenotypic** databases, and therefore lies at the intersection of bioinformatics and clinical informatics. Similarly, ► Chap. 28 presents the role of informatics in **precision medicine**, which relies heavily on both bioinformatics and clinical informatics concepts and systems.

**Fig. 1.23** A Venn diagram that depicts the relationships among the three major disciplines: biological research, clinical medicine / public health, and biomedical informatics. *Bioinformatics*, *Health Informatics*, and *Translational Research* lie at the intersections among pairs of these fields as shown. *Precision Medicine*, which

relies on *Translational Bioinformatics* and *Clinical Research Informatics*, constitutes the area of common overlap among all three Venn circles. (Adapted with permission from a diagram developed by the Department of Biomedical Informatics at the Vanderbilt Medical Center, Nashville, TN)

Precision medicine is a product of the increasing emphasis on moving both data and concepts from basic science research into clinical science and ultimately into practice. Such efforts are typically characterized as **translational science**—a topic that has attracted major investments by the US National Institutes of Health (NIH) over the past two decades. Informatics scientists are engaged as collaborators in this translational work, which spans all four major categories of application shown in **Fig. 1.20**, pursuing work in **translational bioinformatics** (▶ Chap. 26) and **clinical research informatics** (▶ Chap. 27).<sup>20</sup> Accordingly, informatics was defined as a major component of the **Clinical and Translational Science Awards (CTSA) Program**,<sup>21</sup> support by the National Center for Advancing Translational Sciences (NCATS) at the NIH. AMIA sponsors an annual weeklong conference, known as the Informatics Summit, that presents new

research results and applications in these areas.<sup>22</sup> The interactions among bioscience, clinical science, and informatics can be nicely captured by recognizing how informatics fields and translational science relate to one another (▶ Fig. 1.23).

In general, BMI researchers derive their inspiration from one or two, rather than all, of the application areas, identifying fundamental methodologic issues that need to be addressed and testing them in system prototypes or, for more mature methods, in actual systems that are used in clinical or biomedical research settings. One important implication of this viewpoint is that the core discipline is identical, regardless of the area of application that a given individual is motivated to address, although some BMI methods have greater relevance to some domains than to others. This argues for unified BMI educational programs, ones that bring together students with a wide variety of application interests. Elective courses and internships in areas of specific

<sup>20</sup> See also the diagram in (Kulikowski et al. 2012), which shows how these two disciplines span all areas of applied biomedical informatics.

<sup>21</sup> ▶ <https://ncats.nih.gov/ctsa> (Accessed 6/2/2019).

<sup>22</sup> ▶ <https://www.amia.org/meetings-and-events> (Accessed 6/2/2019)

interest are of course important complements to the core exposures that students should receive (Kulikowski et al. 2012), but, given the need for teamwork and understanding in the field, separating trainees based on the application areas that may interest them would be counterproductive and wasteful.<sup>23</sup>

The scientific contributions of BMI also can be appreciated through their potential for benefiting the education of health professionals (Shortliffe 2010). For example, in the education of medical students, the various cognitive activities of physicians traditionally have tended to be considered separately and in isolation—they have been largely treated as though they are independent and distinct modules of performance. One activity frequently emphasized is formal education regarding medical decision making (see ► Chap. 3). The specific content of this area continues to evolve, but the discipline's dependence on formal methods regarding the use of knowledge and information reveal that it is one aspect of biomedical informatics.

A particular topic in the study of medical decision making is **diagnosis**, which is often conceived and taught as though it were a free-standing and independent activity. Medical students may thus be led to view diagnosis as a process that physicians carry out in isolation before choosing therapy for a patient or proceeding to other modular tasks. A number of studies have shown that this model is oversimplified and that such a decomposition of cognitive tasks may be quite misleading (Elstein et al. 1978a; Patel and Groen 1986). Physicians seem to deal with several tasks at the same

time. Although a diagnosis may be one of the first things physicians think about when they see a new patient, patient assessment (diagnosis, management, analysis of treatment results, monitoring of disease progression, etc.) is a process that never really terminates. A physician must be flexible and open-minded. It is generally appropriate to alter the original diagnosis if it turns out that treatment based on it is unsuccessful or if new information weakens the evidence supporting the diagnosis or suggests a second and concurrent disorder. ► Chapter 4 discusses these issues in greater detail.

When we speak of making a diagnosis, choosing a treatment, managing therapy, making decisions, monitoring a patient, or preventing disease, we are using labels for different aspects of medical care, an entity that has overall unity. The fabric of medical care is a continuum in which these elements are tightly interwoven. Regardless of whether we view computer and information science as a profession, a technology, or a science, there is no doubt about its importance to biomedicine. We can assume computers are here to stay as fundamental tools to be used in clinical practice, biomedical research, and health science education.

#### 1.4.4 Relationship to Computer Science

During its evolution as an academic entity in universities, computer science followed an unsettled course as involved faculty attempted to identify key topics in the field and to find the discipline's organizational place. Many computer science programs were located in departments of electrical engineering, because major concerns of their researchers were computer architecture and design and the development of practical hardware components. At the same time, computer scientists were interested in programming languages and software, undertakings not particularly characteristic of engineering. Furthermore, their work with algorithm design, computability

23 Many current biomedical informatics training programs were designed with this perspective in mind. Students with interests in clinical, imaging, public health, and biologic applications are often trained together and are required to learn something about each of the other application areas, even while specializing in one subarea for their own research. Several such programs were described in a series of articles in the *Journal of Biomedical Informatics* in 2007 (Tarczy-Hornoch et al. 2007) and many more have been added since that time.

theory,<sup>24</sup> and other theoretical topics seemed more related to mathematics.

Biomedical informatics draws from all of these activities—development of hardware, software, and computer science theory. Biomedical computing generally has not had a large enough market to influence the course of major hardware developments; i.e., computers serve general purposes and have not been developed specifically for biomedical applications. Not since the early 1960s (when health-computing experts occasionally talked about and, in a few instances, developed special medical terminals) have people assumed that biomedical applications would use hardware other than that designed for general use.

The question of whether biomedical applications would require specialized programming languages might have been answered affirmatively in the 1970s by anyone examining the MGH Utility Multi-Programming System, known as the MUMPS language (Greenes et al. 1970; Bowie and Barnett 1976), which was specially developed for use in medical applications. For several years, MUMPS was the most widely used language for medical record processing. Under its subsequent name, M, it is still in widespread use and has been used to develop commercial electronic health record systems. New implementations have been developed for each generation of computers. M, however, like any programming language, is not equally useful for all computing tasks. In addition, the software requirements of medicine are better understood and no longer appear to be unique; rather, they are specific to the kind of task. A program for scientific computation looks pretty much the same whether it is designed for chemical engineering or for pharmacokinetic calculations.

How, then, does BMI differ from biomedical computer science? Is the new discipline

simply the study of computer science with a “biomedical flavor”? If you return to the definition of biomedical informatics that we provided in ► Box 1.1, and then refer to ■ Fig. 1.20, you will begin to see why biomedical informatics is more than simply the biomedical application of computer science.<sup>25</sup> The issues that it addresses not only have broad relevance to health, medicine, and biology, but the underlying sciences on which BMI professionals draw are inherently interdisciplinary as well (and are not limited to computer science topics). Thus, for example, successful BMI research will often draw on, and contribute to, computer science, but it may also be closely related to the decision sciences (probability theory, decision analysis, or the psychology of human problem solving), cognitive science, information sciences, or the management sciences (■ Fig. 1.24). Furthermore, a biomedical informatics researcher will be tightly linked to some underlying problem from the real world of health or biomedicine. As ■ Fig. 1.24 illustrates, for example, a biomedical informatics basic researcher or doctoral student will typically be motivated by one of the application areas, such as those shown at the bottom of ■ Fig. 1.22, but a dissertation worthy of a PhD in the field will usually be identified by a generalizable scientific result that also contributes to one of the component disciplines (■ Fig. 1.20) and on which other scientists can build in the future.

24 Many interesting problems cannot be computed in a reasonable time and require heuristics. Computability theory is the foundation for assessing the feasibility and cost of computation to provide the complete and correct results to a formally stated problem.

25 In fact, the multidisciplinary nature of biomedical informatics has led the informatics term to be borrowed in other disciplines, including computer science organizations, even though the English name for the field was first adopted in the biomedical context. Today we even have generic full departments of informatics in the US (e.g., see ► <https://informatics.njit.edu>, Accessed 11/28/2020) and in other parts of the world as well (e.g., ► <http://www.sussex.ac.uk/informatics/>. Accessed 1/5/2020). In the US, there are full schools with informatics in their title (e.g., ► <https://luddy.indiana.edu/index.html>. Accessed 1/5/2020) and even a School of Biomedical Informatics (► <https://sbmi.uth.edu/>. Accessed 1/2/2020).

■ **Fig. 1.24** Component sciences in biomedical informatics. An informatics application area is motivated by the needs of its associated biomedical domain, to which it attempts to contribute solutions to problems. Thus any applied informatics work draws upon a biomedical domain for its inspiration, and in turn often leads to the delineation of basic research challenges in biomedical informatics that must be tackled if the applied biomed-

ical domain is ultimately to benefit. At the methodologic level, biomedical informatics draws on, and contributes to, a wide variety of component disciplines, of which computer science is only one. As ■ Figs. 1.20 and 1.22 show explicitly, biomedical informatics is inherently multidisciplinary, both in its areas of application and in the component sciences on which it draws

### 1.4.5 Relationship to Biomedical Engineering

BMI is a relatively young discipline, whereas biomedical engineering (BME) is older and well-established. Many engineering and medical schools have formal academic programs in BME, often with departmental status and full-time faculty. Only in the last two or three decades has this begun to be true of biomedical informatics academic units. How does biomedical informatics relate to biomedical engineering, especially in an era when engineering and computer science are increasingly intertwined?

**Biomedical engineering** departments emerged in the late 1960s, when technology began to play an increasingly prominent role

in medical practice.<sup>26</sup> The emphasis in such departments has tended to be research on, and development of, instrumentation (e.g., as discussed in ► Chaps. 21 and 22, advanced monitoring systems, specialized transducers for clinical or laboratory use, and imaging methods and enhancement techniques for use in radiology), with an orientation toward the

26 By the late 1960s the first BME departments were formed in the US at the University of Virginia, Case Western Reserve University, Johns Hopkins University, and Duke University (see ► <https://navigate.aimbe.org/why-bioengineering/history/>, Accessed 6/2/2019). Duke's undergraduate degree program in BMI was the first to be accredited by the Engineering Council for Professional Development (September 1972).

development of medical devices, **prostheses**, and specialized research tools. There is also a major emphasis on tissue engineering and related wet-bench research efforts. In recent years, computing techniques have been used both in the design and construction of medical devices and in the medical devices themselves. For example, the “smart” devices increasingly found in most medical specialties are all dependent on computational technology. Intensive care monitors that generate blood pressure records while calculating mean values and hourly summaries are examples of such “intelligent” devices.

The overlap between biomedical engineering and BMI suggests that it would be unwise for us to draw compulsively strict boundaries between the two fields. There are ample opportunities for interaction, and there are chapters in this book that clearly overlap with biomedical engineering topics—e.g., ► Chap. 21 on patient-monitoring systems and ► Chap. 22 on radiology systems. Even where they meet, however, the fields have differences in emphasis that can help you to understand their different evolutionary histories. In biomedical engineering, the emphasis is on medical devices and underlying methods; in BMI, the emphasis is on biomedical information and knowledge and on their management with the use of computers. In both fields, the computer is secondary, although both use computing technology. The emphasis in this book is on the informatics end of the spectrum of biomedical computer science, so we shall not spend much time examining biomedical engineering topics.

## 1.5 Integrating Biomedical Informatics and Clinical Practice

---

It should be clear from the material in this chapter that biomedical informatics is a remarkably broad and complex topic. We have argued that information management is intrinsic to both life-science research and clinical practice and that, in biomedical settings

over a half century, the use of computers to aid in information management has grown from a futuristic notion to an everyday occurrence. In fact, the EHR and other information technology tools may now be the only kind of equipment that is used by every single health care professional, regardless of specialty or professional title. In this chapter and throughout the book, we emphasize the myriad ways in which computers are used in biomedicine to ease the burdens of information management and the means by which new technology is changing the delivery of health care. The degree to which such changes are positively realized, and their rate of occurrence, are being determined in part by external forces that influence the costs of developing and implementing biomedical applications and the ability of scientists, clinicians, patients, and the health care system to accrue the potential benefits.

We can summarize several global forces that are affecting biomedical computing and that will continue to influence the extent to which computers are assimilated into clinical practice: (1) new developments in communications plus computer hardware and software; (2) a further increase in the number of individuals who have been trained in both medicine, or another health profession, and in BMI; and (3) ongoing changes in health care financing designed to control the rate of growth of health-related expenditures.

We touched on the first of these factors in ► Sect. 1.4.2, when we described the historical development of biomedical computing and the trend from mainframe computers, to microcomputers and PCs, and to the mobile devices of today. The future view outlined in ► Sect. 1.1 similarly builds on the influence that the Internet has provided throughout society during the last decade. Hardware improvements have made powerful computers inexpensive and thus available to hospitals, to departments within hospitals, and even to individual physicians. The broad selection of computers of all sizes, prices, and capabilities makes computer applications both attractive and accessible. Technological advances in

information storage devices,<sup>27</sup> including the movement of files to the “cloud”, are facilitating the inexpensive storage of large amounts of data, thus improving the feasibility of data-intensive applications, such as drawing inferences from human genome datasets (see ► Chaps. 9, 26, and 28) and the all-digital radiology department (► Chap. 22). Standardization of hardware and advances in network technology are making it easier to share data and to integrate related information-management functions within a hospital or other health care organization, although inadequacies in standards for encoding and sharing data continue to be challenging (► Chaps. 7, 14, 15, and 16).

The second factor is the frustratingly slow increase in the number of professionals who are being trained to understand the biomedical issues as well as the technical and engineering ones. Computer scientists who understand biomedicine are better able to design systems responsive to actual needs and sensitive to workflow and the clinical culture. Health professionals who receive formal training in BMI are likely to build systems using well-established techniques while avoiding the past mistakes of other developers. As more professionals are trained in the special aspects of both fields, and as the programs they develop are introduced, health care professionals are more likely to have useful and usable systems available when they turn to the computer for help with information management tasks.

The third factor affecting the integration of computing technologies into health care settings is our evolving health care system and the increasing pressure to control medical spending. The escalating tendency to apply technology to all patient-care tasks is a frequently cited phenomenon in modern medical practice. Mere physical findings no longer are

considered adequate for making diagnoses and planning treatments. In fact, medical students who are taught by more experienced physicians to find subtle diagnostic signs by examining various parts of the body nonetheless often choose to bypass or deemphasize physical examinations in favor of ordering one test after another. Sometimes, they do so without paying sufficient attention to the ensuing cost. Some new technologies replace less expensive, but technologically inferior, tests. In such cases, the use of the more expensive approach is generally justified. Occasionally, computer-related technologies have allowed us to perform tasks that previously were not possible. For example, the scans produced with computed tomography or magnetic resonance imaging (see ► Chaps. 10 and 22) have allowed physicians to visualize cross-sectional slices of the body, and medical instruments in intensive care units perform continuous monitoring of patients’ body functions that previously could be checked only episodically (see ► Chap. 21).

The development of expensive new technologies, and the belief that more technology is better, have helped to fuel rapidly escalating health care costs. In the 1970s and 1980s, such rising costs led to the introduction of managed care and **capitation**—changes in financing and delivery that were designed to curb spending. Today we are seeing a trend toward **value-based reimbursement**, which is predicated on the notion that payment for care of patients should be based on the demonstrated value received (as defined by high quality at low cost) rather than simply the existence of an encounter or procedure. Integrated computer systems can provide the means to capture data to help assess such value, while they also support detailed cost accounting, the analysis of the relationship of costs of care to the benefits of that care, evaluation of the quality of care provided, and identification of areas of inefficiency. Systems that improve the quality of care while reducing the cost of providing that care clearly will be favored. The effect of cost containment pressures on technologies that increase the cost of care while improving the quality are less clear. Medical technologies, including computers, will be

27 Technological progress in this area is occurring at a dizzying rate. Consider, for example, the announcement that scientists are advancing the notion of using DNA for data storage and can store as much as 704 terabytes of information in a gram of DNA. ► <http://www.engadget.com/2012/08/19/harvard-stores-704tb-in-a-gram-of-dna>; ► <https://homes.cs.washington.edu/~bornholt/dnastorage-asplos16/> (Accessed 5/30/19).

embraced only if they improve the delivery of clinical care while either reducing costs or providing benefits that clearly exceed their costs.

Designers of medical systems must address satisfactorily many logistical and engineering questions before innovative solutions are integrated optimally into medical practice. For example, are the machines conveniently located? Should mobile devices further replace tethered workstations? Can users complete their tasks without excessive delays? Is the system reliable enough to avoid loss of data? Can users interact easily and intuitively with the computer? Does it facilitate rather than disrupt workflow? Are patient data secure and appropriately protected from prying eyes? In addition, cost-control pressures produce a growing reluctance to embrace expensive technologies that add to the high cost of health care. The net effect of these opposing trends is in large part determining the degree to which specific systems are embraced and effectively implemented in the health care environment.

In summary, rapid advances in communications, computer hardware, and software, coupled with an increasing computer literacy of health care professionals and researchers, favor the implementation of effective computer applications in clinical practice, public health, and life sciences research. Furthermore, in the increasingly competitive health care industry, providers have a greater need for the information management capabilities supplied by computer systems. The challenge is to demonstrate in persuasive and rigorous ways the financial and clinical advantages of these systems (see ► Chap. 13).

### Suggested Readings

- Blois, M. S. (1984b). *Information and medicine: The nature of medical descriptions*. Berkeley: University of California Press. In this classic volume, the author analyzes the structure of medical knowledge in terms of a hierarchical model of information. He explores the ideas of high- and low-level sciences and suggests that the nature of medical descriptions accounts for difficulties in applying computing technology to medicine. A brief summary of key elements in this book is included as Box 1.2 in this chapter.
- Coiera, E. (2015). *Guide to health informatics* (3rd ed.). Boca Raton, FL: CRC Press. This introductory text is a readable summary of clinical and public health informatics, aimed at making the domain accessible and understandable to the non-specialist.
- Collen, M. F., & Ball, M. J. (Eds.). (2015). *A history of medical informatics in the United States* (2nd ed.). London: Springer. This comprehensive book traces the history of the field of medical informatics, and identifies the origins of the discipline's name (which first appeared in the English-language literature in 1974). The original (1995) edition was being updated by Dr. Collen when he passed away shortly after his 100th birthday. Dr. Ball organized an effort to complete the 2nd edition, enlisting participation by many leaders in the field.
- Elstein, A. S., Shulman, L. S., & Sprafka, S. A. (1978b). *Medical problem solving: An analysis of clinical reasoning*. Cambridge, MA: Harvard University Press. This classic collection of papers describes detailed studies that have illuminated several aspects of the ways in which expert and novice physicians solve medical problems. The seminal work described remains highly relevant to today's work on problem solving and clinical decision support systems.
- Friedman, C. P., Altman, R. B., Kohane, I. S., McCormick, K. A., Miller, P. L., Ozbolt, J. G., Shortliffe, E. H., Stormo, G. D., Szczepaniak, M. C., Tuck, D., & Williamson, J. (2004). Training the next generation of informaticians: The impact of BISTI and bioinformatics. *Journal of American Medical Informatics Association*, 11, 167–172. This important analysis addresses the changing nature of biomedical informatics due to the revolution in bioinformatics and computational biology. Implications for training, as well as organization of academic groups and curriculum development, are discussed.
- Hoyt, R. E., & Hersh, W. R. (2018). *Health informatics: Practical guide* (7th ed). Raleigh: Lulu.com. This introductory volume provides a broad view of informatics and is aimed especially at health professionals in management roles or IT professionals who are entering the clinical world.
- Institute of Medicine<sup>25</sup>. (1991 [revised 1997]). *The computer-based patient record: An essential*

- technology for health care*. Washington, DC: National Academy Press. National Research Council (1997). *For The Record: Protecting Electronic Health Information*. Washington, DC: National Academy Press. National Research Council (2000). *Networking Health: Prescriptions for the Internet*. Washington, DC: National Academy Press. This set of three reports from branches of the US National Academies of Science has had a major influence on health information technology education and policy over the last 25 years.
- Institute of Medicine (2000). *To err is human: Building a safer health system*. Washington, DC: National Academy Press. Institute of Medicine (2001). *Crossing the Quality Chasm: A New Health Systems for the 21st Century*. Washington, DC: National Academy Press. Institute of Medicine (2004). *Patient Safety: Achieving a New Standard for Care*. Washington, DC: National Academy Press. This series of three reports from the Institute of Medicine has outlined the crucial link between heightened use of information technology and the enhancement of quality and reduction in errors in clinical practice. Major programs in patient safety have resulted from these reports, and they have provided motivation for a heightened interest in health care information technology among policy makers, provider organizations, and even patients.
- Kalet, I. J. (2013). *Principles of biomedical informatics* (2nd ed.). New York: Academic. This volume provides a technical introduction to the core methods in BMI, dealing with storage, retrieval, display, and use of biomedical data for biological problem solving and medical decision making. Application examples are drawn from bioinformatics, clinical informatics, and public health informatics.
- National Academy of Medicine. (2018). *Procuring interoperability: Achieving high-quality, connected, and person-centered care*. Washington, DC: National Academy Press. National Academy of Medicine (2019). *Artificial Intelligence in Health Care: The Hope, the Hype, the Promise, the Peril*. Washington, DC: National Academy Press. This series of two reports from the National Academy of Medicine outlines emerging issues in biomedical informatics: interoperability (which is discussed in greater detail in Chapter 8), and artificial intelligence (which is discussed in many chapters throughout this volume).
- National Academy of Medicine. (2019). *Taking action against clinician burnout: A systems approach to professional well-being*. Washington, DC: National Academy Press. This consensus study from the National Academy of Medicine discusses the problem of clinician burnout in the United States, including areas where health care information technology may contribute or reduce these problems.
- Shortliffe, E. (1993b). Doctors, patients, and computers: Will information technology dehumanize health care delivery? *Proceedings of the American Philosophical Society*, 137(3), 390–398. In this paper, the author examines the frequently expressed concern that the introduction of computing technology into health care settings will disrupt the development of rapport between clinicians and patients and thereby dehumanize the therapeutic process. He argues, rather, that computers may eventually have precisely the opposite effect on the relationship between clinicians and their patients.

### ? Questions for Discussion

1. How do you interpret the phrase “logical behavior”? Do computers behave logically? Do people behave logically? Explain your answers.
2. What do you think it means to say that a computer program is “effective”? Make a list of a dozen computer applications with which you are familiar. List the applications in decreasing order of effectiveness, as you have explained this concept. Then, for each application, indicate your estimate of how well human beings perform the same tasks (this will require that you determine what it means for a human being to be effective). Do you discern any pattern? If so, how do you interpret it?
3. Discuss three society-wide factors that will determine the extent to which computers are assimilated into clinical practice.
4. Reread the future vision presented in ► Sect. 1.1. Describe the characteristics of an integrated environment for

- managing clinical information. Discuss two ways (either positive or negative) in which such a system could change clinical practice.
5. Do you believe that improving the technical quality of health care entails the risk of dehumanization? If so, is it worth the risk? Explain your reasoning.
  6. Consider  Fig. 1.20, which shows that bioinformatics, imaging informatics, clinical informatics, and public health informatics are all application domains of the biomedical informatics discipline because they share the same core methods and theories:
    - (a) Briefly describe two examples of core biomedical informatics methods or theories that can be applied both to bioinformatics and clinical informatics.
    - (b) Imagine that you describe  Fig. 1.20 to a mathematics faculty member, who responds that “in that case, I’d also argue that statistics, computer science, and physics are all application domains of math because they share the same core mathematical methods and theories.” In your opinion, is this a legitimate argument? In what ways is this situation similar to, and different from, the case of biomedical informatics?
    - (c) Why is biomedical informatics *not* simply computer science applied to biomedicine, or to the practice of medicine, using computers?
    - (d) How would you describe the relevance of psychology and cognitive science to the field of biomedical informatics? (Hint: See  Fig. 1.24)
  7. In 2000, a major report by the Institute of Medicine<sup>28</sup> entitled “To Err is Human: Building a Safer Health System” (see Suggested Readings) stated that up to 98,000 patient deaths were being caused by preventable medical errors in American hospitals each year.
    - (a) It has been suggested that effective electronic health record (EHR) systems should mitigate this problem. What are three specific ways in which they could be reducing the number of adverse events in hospitals?
      - (b) Are there ways in which computer-based systems could *increase* the incidence of medical errors? Explain.
      - (c) Describe a practical experiment that could be used to examine the impact of an EHR system on patient safety. In other words, propose a study design that would address whether the computer-based system increases or decreases the incidence of preventable adverse events in hospitals – and by how much.
      - (d) What are the limitations of the experimental design you proposed in (c)?
  8. It has been argued that the ability to capture “nuance” in the description of what a clinician has seen when examining or interviewing a patient may not be as crucial as some people think. The desire to be able to express one’s thoughts in an unfettered way (free text) is often used to argue against the use of structured data-entry methods using a controlled vocabulary and picking descriptors from lists when recording information in an EHR.
    - (a) What is your own view of this argument? Do you believe that it is important to the quality and/or efficiency of care for clinicians to be able to record their observations, at least part of the time, using free text/natural language?
    - (b) Many clinicians have been unwilling to use an EHR system requiring structured data entry

---

28 The Institute of Medicine (IOM), part of the former National Academy of Sciences (NAS) was reorganized in 2015 to become the National Academy of Medicine (NAM). The NAS is now known as the National Academies of Science, Engineering, and Medicine (NASEM).

because of the increased time required for documentation at the point of care and constraints on what can be expressed. What are two strategies that could be used to address this problem (other than “designing a better user interface for the system”)?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What are clinical data?
- How are clinical data used?
- What are the advantages and disadvantages of traditional paper medical records vs. electronic health records?
- What is the role of the computer in data storage, retrieval, and interpretation?
- What distinguishes a database from a knowledge base?
- How are data collection and hypothesis generation intimately linked in clinical diagnosis?
- What are the meanings of the terms *prevalence*, *predictive value*, *sensitivity*, and *specificity*?
- How are the terms related?
- What are the alternatives for entry of data into a clinical database?

## 2.1 What Are Clinical Data?

From earliest times, the ideas of ill health and its treatment have been wedded to those of the observation and interpretation of data. Whether we consider the disease descriptions and guidelines for management in early Greek literature or the modern physician's use of complex laboratory and X-ray studies, it is clear that gathering data and interpreting their meaning are central to the health care process. With the move toward the use of clinical and genomic information in assessing individual patients (their risks, prognosis, and likely responses to therapy), the sheer amounts of data that may be used in patient care have become huge. A textbook on biomedical informatics will accordingly refer time and again to issues in data collection, storage, and use. This chapter lays the foundation for this recurring set of issues that is pertinent to all aspects of the use of information, knowledge, and computers in biomedicine, both in the clinical world and in applications related to public health, biology and human genetics.

If data are central to all health care, it is because they are crucial to the process of decision making (as described in detail in ► Chaps. 3 and 4 and again in ► Chap. 26). In fact, sim-

ple reflection will reveal that all health care activities involve gathering, analyzing, or using data. Data provide the basis for categorizing the problems a patient may be having or for identifying subgroups within a population of patients. They also help a physician to decide what additional information is needed and what actions should be taken to gain a greater understanding of a patient's problem or most effectively to treat the problem that has been diagnosed.

It is overly simplistic to view data as the columns of numbers or the monitored waveforms that are a product of our technological health care environment. Although laboratory test results and other numeric data are often invaluable, a variety of more subtle types of data may be just as important to the delivery of optimal care: the awkward glance by a patient who seems to be avoiding a question during the medical interview, information about the details of a patient's symptoms or about his family or economic setting, or the subjective sense of disease severity that an experienced clinician will often have within a few moments of entering a patient's room. No clinician disputes the importance of such observations in decision making during patient assessment and management, yet the precise role of these data and the corresponding decision criteria are so poorly understood that it is difficult to record them in ways that convey their full meaning, even from one clinician to another. Despite these limitations, clinicians need to share descriptive information with others. When they cannot interact directly with one another, they often turn to the chart or electronic health record for communication purposes.

We consider a **clinical datum** to be any single observation of a patient—e.g., a temperature reading, a red blood cell count, a past history of rubella, or a blood pressure reading. As the blood pressure example shows, it is a matter of perspective whether a single observation is in fact more than one datum. A blood pressure of 120/80 might well be recorded as a single element in a setting where knowledge that a patient's blood pressure is normal is all that matters. If the difference between diastolic (while the heart cavities are beginning to fill)

and systolic (while they are contracting) blood pressures is important for decision making or for analysis, however, the blood pressure reading is best viewed as two pieces of information (systolic pressure = 120 mmHg, diastolic pressure = 80 mmHg). Human beings can glance at a written blood pressure value and easily make the transition between its unitary view as a single data point and the decomposed information about systolic and diastolic pressures. Such dual views can be much more difficult for computers, however, unless they are specifically allowed for in the design of the method for data storage and analysis. The idea of a *data model* for computer-stored medical data accordingly becomes an important issue in the design of medical data systems.

Clinical *data* may involve several different observations made concurrently, the observation of the same patient parameter made at several points in time, or both. Thus, a single datum generally can be viewed as defined by five elements:

1. The *patient* in question
2. The *parameter* being observed (e.g., liver size, urine sugar value, history of rheumatic fever, heart size on chest X-ray film)
3. The *value* of the parameter in question (e.g., weight is 70 kg, temperature is 98.6 °F, profession is steel worker)
4. The *time* of the observation (e.g., 2:30 A.M. on 14FEB2019<sup>1</sup>)
5. The *method* by which the observation was made (e.g., patient report, thermometer, urine dipstick, laboratory instrument).

Time can particularly complicate the assessment and computer-based management of data. In some settings, the date of the observation is adequate—e.g., in outpatient clinics or private offices where a patient generally is seen infrequently and the data collected need to be identified in time with no greater accuracy than a calendar date. In others, minute-

to-minute variations may be important—e.g., the frequent blood sugar readings obtained for a patient in diabetic ketoacidosis (acid production due to poorly controlled blood sugar levels) or the continuous measurements of mean arterial blood pressure for a patient in cardiogenic shock (dangerously low blood pressure due to failure of the heart muscle).

It may also be important to keep a record of the circumstances under which a data point was obtained. For example, was the blood pressure taken in the arm or leg? Was the patient lying or standing? Was the pressure obtained just after exercise? During sleep? What kind of recording device was used? Was the observer reliable? Such additional information, sometimes called contexts, methods, or modifiers, can be of crucial importance in the proper interpretation of data. Two patients with the same basic problem or symptom often have markedly different explanations for their problem, revealed by careful assessment of the modifiers of that problem.

A related issue is the uncertainty in the values of data. It is rare that an observation—even one by a skilled clinician—can be accepted with absolute certainty. Consider the following examples:

- An adult patient reports a childhood illness with fevers and a red rash in addition to joint swelling. Could he or she have had scarlet fever? The patient does not know what his or her pediatrician called the disease nor whether anyone thought that he or she had scarlet fever.
- A physician listens to the heart of an asthmatic child and thinks that she hears a heart murmur—but is not certain because of the patient's loud wheezing.
- A radiologist looking at a shadow on a chest X-ray film is not sure whether it represents overlapping blood vessels or a lung tumor.
- A confused patient is able to respond to simple questions about his or her illness, but under the circumstances the physician is uncertain how much of the history being reported is reliable.

<sup>1</sup> Note that it was the tendency to record such dates in computers as “14FEB12” that led to the end-of-century complexities that were called the *Year 2K problem*. It was shortsighted to think that it was adequate to encode the year of an event with only two digits.

As described in ► Chaps. 3 and 4, there are a variety of possible responses to deal with

incomplete data, the uncertainty in them, and in their interpretation. One technique is to collect additional data that will either confirm or eliminate the concern raised by the initial observation. This solution is not always appropriate, however, because the costs of data collection must be considered. The additional observation might be expensive, risky for the patient, or wasteful of time during which treatment could have been instituted. The idea of trade-offs in data collection thus becomes extremely important in guiding health care decision making.

### 2.1.1 What Are the Types of Clinical Data?

The examples in the previous section suggest that there is a broad range of data types in the practice of medicine and the allied health sciences. They range from narrative, textual data to numerical measurements, genetic information, recorded signals, drawings, and photographs or other images.

Narrative data account for a large component of the information that is gathered in the care of patients. For example, the patient's description of his or her present illness, including responses to focused questions from the physician, generally is gathered verbally and is recorded as text in the medical record. The same is true of the patient's social and family history, the general review of systems that is part of most evaluations of new patients, and the clinician's report of physical examination findings. Such narrative data were traditionally handwritten by clinicians and then placed in the patient's medical record (■ Fig. 2.1a). Increasingly, however, the narrative summaries were dictated and then transcribed by typists who produced printed summaries or electronic copies for inclusion in paper or electronic medical records. Now, physicians and staff largely enter narrative text directly into electronic health records (EHRs), usually through keyboard, mouse-driven, or voice-driven interfaces (■ Fig. 2.1b). Electronic narrative data often include not only patient histories and physical examinations, but also other narrative descrip-

tions such as reports of specialty consultations, surgical procedures, pathologic examinations of tissues, and hospitalization summaries when a patient is discharged.

Some narrative data are loosely coded with shorthand conventions known to health personnel, particularly data collected during the physical examination, in which recorded observations reflect the stereotypic examination process taught to all practitioners. It is common, for example, to find the notation "PERRLA" under the eye examination in a patient's medical record. This encoded form indicates that the patient's "Pupils are Equal (in size), Round, and Reactive to Light and Accommodation (the process of focusing on near objects)."

Note that there are significant problems associated with the use of such abbreviations. Many are not standard and can have different meanings depending on the context in which they are used. For example, "MI" can mean "mitral insufficiency" (leakage in one of the heart's valves) or "myocardial infarction" (the medical term for what is commonly called a heart attack). Many hospitals try to establish a set of "acceptable" abbreviations with meanings, but the enforcement of such standardization is often unsuccessful. Other hospitals approach this challenge by not permitting use of abbreviations in the medical record, and instead require use of full-length narrative descriptions.

Standard narrative expressions have often become loose standards of communication among medical personnel. Examples include "mild dyspnea (shortness of breath) on exertion," "pain relieved by antacids or milk," and "failure to thrive." Such standardized expressions are attempts to use conventional text notation as a form of summarization for otherwise heterogeneous conditions that together characterize a simple concept about a patient.

Many data used in medicine take on discrete numeric values. These include such parameters as laboratory tests, vital signs (such as temperature and pulse rate), and certain measurements taken during the physical examination. When such numerical data are interpreted, however, the issue of precision becomes important. Can physicians distinguish reliably between a 9-cm and a 10-cm liver span when they examine a

2

**a**

**Present Illness:** (date) June 3, 1989 **Chief Complaint:**

Admission Note

ID: 1st admission for this 42 y/o Mexican American F who presents with

CC: headache for one week

HPI: On 5/25 pt noted the onset of myalgias, severe headache, nausea, neck pain, and shaking chills. She consulted her private MD for these problems, and he diagnosed migraines & prescribed a combination med (Ibuprofen, alkaloids, phenobarbital, and ergotamine tartrate) plus meprobamate. However, her sx worsened over the next week until 6/3 when she presented to our ER. She denies photophobia, diplopia, & other neurologic symptoms. She has noted a nonproductive cough but is a nonsmoker and she denies hemoptysis. She denies exposure to diseased individuals, specifically including meningococcal disease or TB.

PMH: No hx of illnesses other than NCD's. Meds only as above. Allergies: ⊕ Surgery ⊕ One daughter, age 12, by NVD.

Social: Married 14 yrs. Works in home. Has never lived in San Joaquin Valley. Last travelled to Mexico by car in 1974.

RDS: Gen'l: well until 10 days PTA  
Skin: ⊕  
Head: ⊕ 7 yrs HPT.

**NARRATIVE PHYSICAL EXAMINATION**

Fig. 2.1 Much of the information gathered during a physician–patient encounter is written in the medical record. This was traditionally done using a paper notes, and now increasingly using b electronic health records

patient's abdomen? Does it make sense to report a serum sodium level to two-decimal-place accuracy? Is a 1-kg fluctuation in weight from 1 week to the next significant? Was the patient weighed on the same scale both times (i.e., could the different values reflect variation between measure-

ment instruments rather than changes in the patient)?

In some fields of medicine, analog data in the form of continuous signals are particularly important (see ► Chap. 23). Perhaps the best-known example is an electrocardiogram

**b****Signed**

Patient presents for followup following recent pneumonia. He is feeling much improved although still complains of mild fatigue and occasional cough productive of clear to cloudy white sputum. He lost about five pounds, but has gained about half of that back again.

Patient admits to being poorly compliant with his hypertension regimen over the past several months. He was concerned that the medication was making him tired and cut back his dosage to every other day. He has not been monitoring his blood pressure at home. He denies palpitations, anginal symptoms, or peripheral edema.

Patient indicates that he has been taking his thyroid medication regularly. Review of his prescriptions suggested he should have run out but he indicates that he had some extra tablets on hand. He is clinically euthyroid. Denies problems with constipation, dry skin, or unusual cold intolerance.

Current prescriptions:  
 CARDIZEM CD CPR 240 MG/24HR OR, 1 CAPSULE DAILY, D: 60, R: 5  
 SYNTHROID TABS 0.1 MG OR, 1 TABLET DAILY, D: 60, R: 5  
 PEPCID TABS 20 MG OR, 1 TABLET AT BEDTIME PRN, D: 30, R: 3

Review of patient's allergies indicates:  
 Penicillins Hives

**OBJECTIVE:**

BP 150/98 | Pulse 88 | Temp 99.1 | Resp 16 | Wt 182 lbs (82.55 kg)  
 Alert, cooperative, and well hydrated. TMs clear. Nose clear rhinorrhea. Oropharynx displays moderate erythema. Neck supple without adenopathy. Once a few scattered expiratory rhonchi which partially clear with coughing. Heart regular rate and rhythm without extra signs or murmurs. Abdomen soft, nontender, no organomegaly.

■ **Fig. 2.1** (continued)

(ECG), a tracing of the electrical activity from a patient's heart. When such data are stored in medical records, a graphical tracing frequently is included, with a written interpretation of its meaning. There are clear challenges in determining how such data are best managed in computer-based storage systems.

Visual images—acquired from machines or sketched by the physician—are another important category of data. Radiologic images or photographs of skin lesions are obvious examples. It has traditionally been common for physicians to draw simple pictures to represent abnormalities that they have observed; such drawings may serve as a basis for comparison when they or another physician next see the patient. For example, a sketch is a concise way of conveying the location and size of a nodule in the prostate gland (■ Fig. 2.2). In electronic health record systems, these hand drawings are increasingly being replaced in the medical record by text-based descriptions or photographs (Sanders et al. 2013).

As should be clear from these examples, the idea of data is inextricably bound to the idea of **data recording**. Physicians and other health care personnel are taught from the outset that it is crucial that they do not trust their memory when caring for patients. They must record their observations, as well as the actions they have

taken and the rationales for those actions, for later communication to themselves and other people. A glance at a medical record will quickly reveal the wide variety of data-recording techniques that have evolved. The range goes from narrative text to commonly understood shorthand notation to cryptic symbols that only specialists can understand; for example, few physicians without specialized training know how to interpret the data-recording conventions of an ophthalmologist (■ Fig. 2.3). The notations may be highly structured records with brief text or numerical information, machine-generated tracings of analog signals, photographic images (of the patient or of radiologic or other studies), or drawings. This range of data-recording conventions presents significant challenges to the person implementing electronic health record systems.

### 2.1.2 Who Collects the Data?

Health data on patients and populations are gathered by a variety of health professionals. Although conventional ideas of the **healthcare team** evoke images of coworkers treating ill patients, the team has much broader responsibilities than treatment per se; data collection and recording are a central part of its task.

2

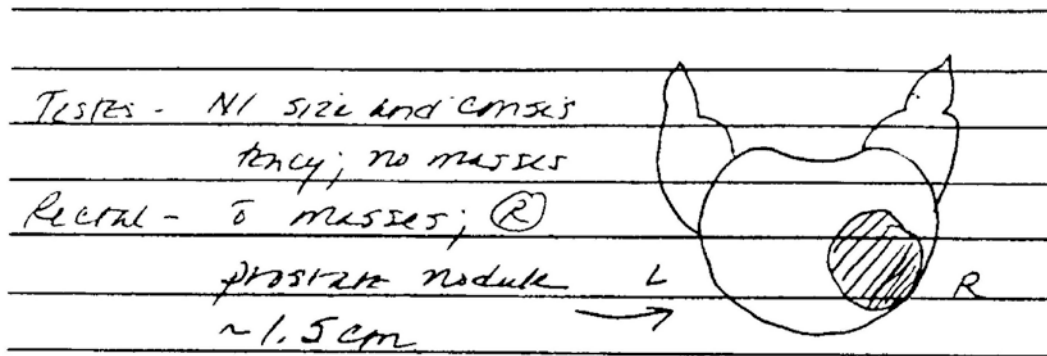

Fig. 2.2 A physician’s hand-drawn sketch of a prostate nodule. Drawings may convey precise information more easily and compactly than a textual description,

but are less common in electronic health records compared to paper charts

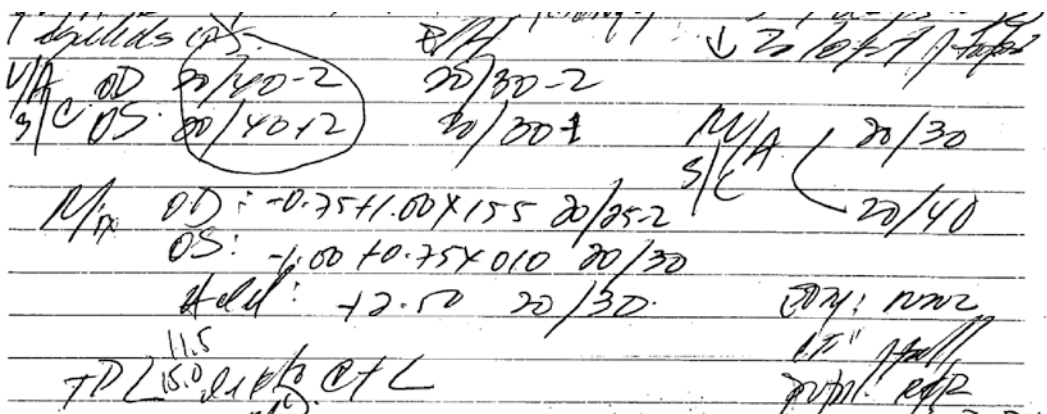

Fig. 2.3 An ophthalmologist’s report of an eye examination. Most physicians trained in other specialties would have difficulty deciphering the symbols that

the ophthalmologist has used. (Image courtesy of Nita Valikodath, MD, with permission)

Physicians are key players in the process of data collection and interpretation. They converse with a patient to gather narrative descriptive data on the chief complaint, past illnesses, family and social information, and the system review. They examine the patient, collecting pertinent data and recording them during or at the end of the visit. In addition, they generally decide what additional data to collect by ordering laboratory or radiologic studies and by observing the patient’s response to therapeutic interventions (yet another form of data that contributes to patient assessment).

In both outpatient and hospital settings, nurses play a central role in making observa-

tions and recording them for future reference. The data that they gather contribute to nursing care plans as well as to the assessment of patients by physicians and by other health care staff. Thus, nurses’ training includes instruction in careful and accurate observation, history taking, and examination of the patient. Because nurses typically spend more time with patients than physicians do, especially in the hospital setting, nurses often build relationships with patients that uncover information and insights that contribute to proper diagnosis, to understanding of pertinent psychosocial issues, or to proper planning of therapy or discharge management (Fig. 2.4). The role of

■ **Fig. 2.4** Nurses often develop close relationships with patients. These relationships may allow the nurse to make observations that are missed by other staff. This ability is just one of the ways in which nurses play a key role in data collection and recording. (Photograph courtesy of Susan Ostmo, with permission)

information systems in contributing to patient care tasks such as care planning by nurses is the subject of ► Chap. 19.

Various other health care workers contribute to the data-collection process. Office staff and admissions personnel gather demographic and financial information. Physical or respiratory therapists record the results of their treatments and often make suggestions for further management. Laboratory personnel perform tests on biological samples, such as blood or urine, and record the results for later use by physicians and nurses. Radiology technicians perform X-ray examinations; radiologists interpret the resulting data and report their findings to the patients' physicians. Pharmacists may interview patients about their medications or about drug allergies and then monitor the patients' use of prescription drugs. Increasingly, health professionals such as physician assistants, nurse practitioners, nurse anesthetists, nurse midwives, psychologists, chiropractors, and optometrists are assuming patient care

responsibilities. As these examples suggest, many different individuals employed in health care settings gather, record, and make use of patient data in their work.

Finally, there are the technological devices that generate data—laboratory instruments, imaging machines, monitoring equipment in intensive care units, and measurement devices that take a single reading (such as thermometers, ECG machines, sphygmomanometers for taking blood pressure, and spirometers for testing lung function). Sometimes such a device produces a paper report suitable for inclusion in a traditional medical record. Sometimes the device indicates a result on a gauge or traces a result that must be read by an operator and then recorded in the patient's chart. Sometimes a trained specialist must interpret the output. Increasingly, however, the devices feed their results directly into computer equipment so that the data can be analyzed or formatted for electronic storage in the electronic health record (see ► Chap. 16), thereby allowing access to information is through computer workstations, hand-held tablets, or even mobile devices.

## 2.2 Uses of Health Data

Health data are recorded for a variety of purposes. Clinical data may be needed to support the proper care of the patient from whom they were obtained, but they also may contribute to the good of society through the aggregation and analysis of data regarding populations of individuals (supporting clinical research or public health assessments; see ► Chaps. 20 and 28). Traditional data-recording techniques and a paper record may have worked reasonably well when care was given by a single physician over the life of a patient. However, given the increased complexity of modern health care, the broadly trained team of individuals who are involved in a patient's care, the need for multiple providers to access a patient's data and to communicate effectively with one another through the chart, and the need for aggregating clinical data from multiple individuals to support population health, the electronic health record has created new possibilities for improv-

ing the health care delivery process that were not feasible a generation ago. We will discuss these topics in more detail later in this chapter and in ► Chaps. 16 and 20.

### 2.2.1 Create the Basis for the Historical Record

---

Any student of science learns the importance of collecting and recording data meticulously when carrying out an experiment. Just as a scientific laboratory notebook provides a record of precisely what an investigator has done, the experimental data observed, and the rationale for intermediate decision points, medical records are intended to provide a detailed compilation of information about individual patients:

- What is the patient’s history (development of a current illness; other diseases that coexist or have resolved; pertinent family, social, and demographic information)?
- What symptoms has the patient reported? When did they begin, what has seemed to aggravate them, and what has provided relief?
- What physical signs have been noted on examination?
- How have signs and symptoms changed over time?
- What laboratory results have been, or are now, available?
- What radiologic and other special studies have been performed?
- What medications are being taken and are there any allergies?
- What other interventions have been undertaken?
- What is the reasoning behind the management decisions?

Each new patient problem and its management can be viewed as a therapeutic experiment, inherently confounded by uncertainty, with the goal of answering three questions when the experiment is over:

1. What was the nature of the disease or symptom?
2. What was the treatment decision?
3. What was the outcome of that treatment?

As is true for all experiments, one purpose is to learn from experience through careful observation and recording of data. The lessons learned in a given encounter may be highly individualized (e.g., the physician may learn how a specific patient tends to respond to pain or how family interactions tend to affect the patient’s response to disease). On the other hand, the value of some experiments may be derived only by pooling of data from many patients who have similar problems and through the analysis of the results of various treatment options to determine efficacy.

Although laboratory research has contributed dramatically to our knowledge of human disease and treatment, it is careful observation and recording by skilled health care personnel that has always been fundamental to the effective generation of new knowledge about patient care. We learn from the aggregation of information from large numbers of patients; thus, the historical record for individual patients is of inestimable importance to clinical research.

### 2.2.2 Support Communication Among Providers

---

A central function of structured data collection and recording in health care settings is to assist personnel in providing coordinated care to a patient over time. Most patients who have significant medical conditions are seen over months or years on several occasions for one or more problems that require ongoing evaluation and treatment. Given the increasing numbers of elderly patients in many cultures and health care settings, the care given to a patient is less oriented to diagnosis and treatment of a single disease episode and increasingly focused on management of one or more chronic disorders—possibly over many years.

It was once common for patients to receive essentially all their care from a single provider: the family doctor who tended both children and adults, often seeing the patient over many or all the years of that person’s life. We tend to picture such physicians as having especially close relationships with their patients—knowing the family and sharing in many of the patient’s life events, especially in smaller communities. Such

doctors nonetheless kept records of all encounters so that they could refer to data about past illnesses and treatments as a guide to evaluating future care issues.

In the world of modern medicine, the emergence of subspecialization and the increasing provision of care by teams of health professionals have placed new emphasis on the central role of the medical record. Over the past several decades, shared access to a paper chart (■ Fig. 2.5) has largely been replaced by clinicians accessing electronic records, sometimes conferring as they look at the same computer screen (■ Fig. 2.6). Now the record not only contains observations by a physician for reference on the next visit but also serves as a communication mechanism among physicians and other medical personnel, such as physical or respiratory therapists, nursing staff, radiology technicians, social workers, or discharge planners. In many outpatient settings, patients receive care over time from a variety of physicians—colleagues covering for the primary physician, or specialists to whom the patient has been referred, or a managed care organization’s case manager. It is not uncommon to hear complaints from patients who remember the days when it was possible to receive essentially all their care from a single physician whom they had come to trust and who knew them well. Physicians are sensitive to this issue

■ Fig. 2.5 One role of the medical record: a communication mechanism among health professionals who work together to plan patient care. (Photograph courtesy of Janice Anne Rohn)

■ Fig. 2.6 Today similar communication sessions occur around a computer screen rather than a paper chart (see ■ Fig. 2.5). (Photograph courtesy of Susan Ostmo with permission)

and therefore recognize the importance of the medical record in ensuring quality and **continuity of care** through adequate recording of the details and logic of past interventions and ongoing treatment plans. This idea is of particular importance in a health care system in which chronic diseases rather than care for trauma or acute infections increasingly dominate the basis for interactions between patients and their doctors.

### 2.2.3 Anticipate Future Health Problems

Providing high-quality health care involves more than responding to patients’ acute or chronic health problems. It also requires educating patients about the ways in which their environment and lifestyles can contribute to, or reduce the risk of, future development of disease. Similarly, data gathered routinely in the ongoing care of a patient may suggest that he or she is at high risk of developing a specific problem even though he or she may feel well and be without symptoms at present. Clinical

data therefore are important in screening for risk factors, following patients' risk profiles over time, and providing a basis for specific patient education or preventive interventions, such as diet, medication, or exercise. Perhaps the most common examples of such ongoing risk assessment in our society are routine monitoring for excess weight, high blood pressure, and elevated serum cholesterol levels. In these cases, abnormal data may be predictive of later symptomatic disease; optimal care requires early intervention before the complications have an opportunity to develop fully.

#### 2.2.4 Record Standard Preventive Measures

---

The medical record also serves as a source of data on interventions that have been performed to prevent common or serious disorders. Sometimes the interventions involve counseling or educational programs (for example, regarding smoking cessation, measures for stopping drug abuse, safe sex practices, or dietary changes). Other important preventive interventions include immunizations: the vaccinations that begin in early childhood and continue throughout life, including special treatments administered when a person will be at particularly high risk (e.g., injections to protect people from certain highly communicable diseases, administered before travel to areas where such diseases are endemic). When a patient comes to his local hospital emergency room with a laceration, the physicians routinely check for an indication of when he most recently had a tetanus immunization. When easily accessible in the record (or from the patient), such data can prevent unnecessary treatments (in this case, a repeat injection) that may be associated with risk or significant cost.

#### 2.2.5 Identify Deviations from Expected Trends

---

Data often are useful in medical care only when viewed as part of a continuum over time. An example is the routine monitoring of

children for normal growth and development by pediatricians (■ Fig. 2.7). Single data points regarding height and weight may have limited use by themselves; it is the trend in such data points observed over months or years that may provide the first clue to a medical problem. It is accordingly common for such parameters to be recorded on special charts or forms that make the trends easy to discern at a glance. Women who want to have a child often keep similar records of body temperature. By measuring temperature daily and recording the values on special charts, women can identify the slight increase in temperature that accompanies ovulation and thus may discern the days of maximum fertility. Many physicians will ask a patient to keep such graphical records so that they can later discuss the data with the patient and include the scanned or photographed graph in the electronic record for ongoing reference. Such graphs are increasingly captured and displayed for viewing by clinicians as a feature of a patient's medical record.

#### 2.2.6 Provide a Legal Record

---

Another use of health data, once they are charted and analyzed, is as the foundation for a legal record to which the courts can refer if necessary. The medical record is a legal document; the responsible individual must certify or sign most of the clinical information that is recorded. In addition, the chart generally should describe and justify both the presumed diagnosis for a patient and the choice of management.

We emphasized earlier the importance of recording data; in fact, data do not exist in a generally useful form unless they are recorded. The legal system stresses this point as well. Providers' unsubstantiated memories of what they observed or why they took some action are of little value in the courtroom. The medical record is the foundation for determining whether proper care was delivered. Thus, a well-maintained record is a source of protection for both patients and their physicians.

### 2.2.7 Support Clinical Research

Although experience caring for individual patients provides physicians with special skills and enhanced judgment over time, it is only by formally analyzing data collected from large numbers of patients that researchers can develop and validate new clinical knowledge of general applicability. Thus, another use of clinical data is to support research through the aggregation and statistical or other analysis of observations gathered from populations of patients (see ► Chap. 1).

A **randomized clinical trial (RCT)** (see also ► Chaps. 15 and 29) is a common method by which specific clinical questions are addressed experimentally. RCTs typically involve the random assignment of matched groups of patients to alternate treatments when there is uncertainty about how best to manage the patients' problem. The variables that might affect a patient's course (e.g., age, gender, weight, coexisting medical problems) are measured and recorded. As the study progresses, data are collected meticulously to provide a record of how each patient fared under treatment and precisely how the treatment was administered. By pooling such data, sometimes after years of experimentation (depending on the time course of the disease under consideration), researchers may be able to demonstrate a statistical difference among the study groups depending on precise characteristics present when patients entered the study or on the details of how patients were managed. Such results then help investigators to define the standard of care for future patients with the same or similar problems.

Medical knowledge also can be derived from the analysis of large patient data sets or registries, even when the patients were not specifically enrolled in an RCT, often referred to as **retrospective studies**. Much of the research in the field of epidemiology involves analysis of population-based data of this type. Our knowledge of the risks associated with cigarette smoking, for example, is based on irrefutable statistics derived from large populations of individuals with and without lung cancer, other pulmonary problems, and heart disease.

## 2.3 Rationale for the Transition from Paper to Electronic Documentation

The preceding description of medical data and their uses emphasizes the positive aspects of information storage and retrieval in the record. During the past several decades, the United States and many other countries have gradually transitioned from traditional paper records to electronic health records. The rationale for this transition has largely been to create the potential for enhancing the record's effectiveness for its intended uses, as summarized in the previous section.

### 2.3.1 Pragmatic and Logistical Issues

Recall, first, that data cannot effectively serve the delivery of health care unless they are recorded. Their optimal use depends on positive responses to the following questions:

- Can I find the data I need when I need them?
- Can I find the medical record in which they are recorded?
- Can I find the data within the record?
- Can I find what I need quickly?
- Can I read and interpret the data once I find them?
- Can I update the data reliably with new observations in a form consistent with the requirements for future access by me or other people?

The traditional paper record created situations in which people too often answered such questions in the negative. For example:

- The patient's paper chart was too often unavailable when the health care professional needed it. It could be in use by someone else at another location; it might have been misplaced despite the record-tracking system of the hospital, clinic, or office (► Fig. 2.8); or it might have been taken by someone unintentionally and is now buried on a desk.

■ **Fig. 2.8** Storage room for paper-based medical records. These paper repositories have largely been replaced as EHRs have become more standard. (Photograph courtesy of Janice Anne Rohn)

- It could be difficult to find the information required in either the paper or electronic record. The data might have been known previously but never recorded due to an oversight by a physician or other health professional. Poor organization or sheer size of either the paper or electronic record may lead the user to spend an inordinate time searching for the data, especially for patients who have long and complicated histories.
- Paper records were notoriously difficult to read. It was not uncommon to hear one physician asking another as they peered together into a chart: “What is that word?” “Is that a two or a five?” “Whose signature is that?” Illegible and sloppy entries was too often a major obstruction to effective use of the paper chart (■ Fig. 2.9).
- When a paper chart was unavailable, the health care professional still had to provide patient care. Thus, providers would often make do without past data, basing their decisions instead on what the patient could tell them and on what their examination revealed. They then wrote a note for inclusion in the chart—when the chart was located! In a large institution with thousands of medical records, it is not surprising that such loose notes often failed to make it to the patient’s chart or were filed out of sequence so that the actual chronology of management was disrupted in the record.

■ **Fig. 2.9** Written entries were standard in paper records, yet handwritten notes could be illegible. Notes that cannot be interpreted by other people due to illegibility may cause delays in treatment or inappropriate care—an issue that is largely eliminated when EHRs are used. (Image courtesy of Emily Cole, MD, with permission)

- When patients who have chronic or frequent diseases are seen over months or years, their paper records grew so large that the charts had to be broken up into multiple volumes. When a hospital clinic or emergency room ordered the patient’s chart, only the most recent volume typically was provided. Old but pertinent data might have been in early volumes that were stored offsite or are otherwise unavailable. Alternatively, an early volume could be mistaken for the most recent volume, misleading its users and resulting in documents being inserted out of sequence.
- ▶ Chapter 16 describes approaches that electronic health record systems have taken toward addressing these practical problems in the use of the paper record. It is for this reason that almost all hospitals, health systems, and individual practitioners have implemented EHRs—further encouraged in the US by Federal incentive programs that helped to cover the costs of EHR acquisition and maintenance (see ▶ Chaps. 1 and 31). That said, one challenge is that electronic health records in the US have been criticized for being composed of bloated, lengthy documentation that

is often focused on billing and compliance over clinical care (► Chaps. 16 and 31).

2

### 2.3.2 Redundancy and Inefficiency

To be able to find data quickly in the medical record, health professionals developed a variety of techniques in paper documentation that provided redundant recording to match alternate modes of access. For example, the result of a radiologic study typically was entered on a standard radiology reporting form, which was filed in the portion of the chart labeled “X-ray.” For complicated procedures, the same data often were summarized in brief notes by radiologists in the narrative part of the chart, which they entered at the time of studies because they knew that the formal report would not make it back to the chart for 1 or 2 days. In addition, the study results often were mentioned in notes written by the patient’s admitting and consulting physicians and by the nursing staff. Although there may have been good reasons for recording such information multiple times in different ways and in different locations within the paper chart, the combined bulk of these notes accelerated the

physical growth of the document and, accordingly, complicated the chart’s logistical management. Furthermore, it became increasingly difficult to locate specific patient data as the chart succumbed to “obesity”. The predictable result was that someone would write yet another redundant entry, summarizing information that it took hours to track down – and creating potential sources for transcription error.

A similar inefficiency occurred because of a tension between opposing goals in the design of reporting forms used by many laboratories. Most health personnel preferred a consistent, familiar form, often with color-coding, because it helped them to find information more quickly (■ Fig. 2.10). For example, a physician might know that a urinalysis report form is printed on yellow paper and records the bacteria count halfway down the middle column of the form. This knowledge allowed the physician to work backward quickly in the laboratory section of the chart to find the most recent urinalysis sheet and to check at a glance the bacterial count. The problem is that such forms typically stored only sparse information. It was clearly suboptimal if a rapidly growing physical chart was filled with sheets of paper that reported only a single data element.

### 2.3.3 Influence on Clinical Research

Anyone involved in a clinical research project based on retrospective data review from paper records can attest to the tediousness of flipping through myriad medical records. For all the reasons described in ► Chap. 1, it is arduous to sit with stacks of patient records, extracting data and formatting them for structured statistical analysis, and the process is vulnerable to transcription errors. Observers often wonder how much medical knowledge is sitting untapped in old paper medical records because there is no easy way to analyze experience across large populations of patients from the past without first extracting pertinent data from those charts.

Let's contrast such retrospective review with paper and electronic medical records. Suppose, for example, that physicians on a medical consultation service notice that patients receiving a certain common oral medication for diabetes (call it drug X) seem to be more likely to have significant postoperative hypotension (low blood pressure) than do surgical patients receiving other medications for diabetes. The doctors have based this hypothesis—that drug X influences postoperative blood pressure—on only a few recent observations, however, so they decide to look into existing hospital records to see whether this correlation has occurred with sufficient frequency to warrant a formal investigation. One efficient way to follow up on their theory from existing medical data would be to examine the hospital records of all patients who have diabetes and also have been admitted for surgery. The task would then be to examine those records (difficult and arduous with paper charts as will be discussed shortly, but subject to automated analysis in the case of EHRs) and to note for all patients (1) whether they were taking drug X when admitted and (2) whether they had postoperative hypotension. If the statistics showed that patients receiving drug X were more likely to have low blood pressure after surgery than were similar diabetic patients receiving alternate treatments, a controlled trial (prospective observation and data gathering) might well be appropriate.

Note the distinction between **retrospective chart review** to investigate a question that was

not a subject of study at the time the data were collected and **prospective studies** in which the clinical hypothesis is known in advance and the **research protocol** is designed specifically to collect future data that are relevant to the question under consideration (see also ► Chaps. 15 and 29). Subjects are assigned **randomly** to different study groups to help prevent researchers—who are bound to be biased, having developed the hypothesis—from unintentionally skewing the results by assigning a specific class of patients all to one group. For the same reason, to the extent possible, the studies are **double blind**; i.e., neither the researchers nor the subjects know which treatment is being administered. Such blinding is of course impractical when it is obvious to patients or physicians what therapy is being given (such as surgical procedures versus drug therapy). Prospective, randomized, double-blind studies are considered the best method for determining optimal management of disease, but it is often impractical to carry out such studies, and then methods such as retrospective chart review may be used.

Returning to our example, consider the problems in paper chart review that the researchers used to encounter in addressing the postoperative hypotension question retrospectively. First, they would have to identify the charts of interest: the subset of medical records dealing with surgical patients who are also diabetic. In a hospital record room filled with thousands of charts, the task of chart selection was often overwhelming. Medical records departments generally did keep indexes of diagnostic and procedure codes cross-referenced to specific patients (see ► Sect. 2.5.1). Thus, it sometimes was possible to use such an index to find all charts in which the discharge diagnoses included diabetes and the procedure codes included major surgical procedures. The researcher might then have compiled a list of patient identification numbers and have the individual charts pulled from the file room for review.

The researchers' next task was to examine each paper chart serially to find out what treatment each patient was receiving for diabetes at the time of the surgery and to determine whether the patient had postoperative hypotension. Finding such information tended to be

extremely time-consuming. Where should the researcher look for it? The admission drug orders might have shown what the patient received for diabetes control, but it would also have been wise to check the medication sheets to see whether the therapy was also administered (as well as ordered) and the admission history to see whether a routine treatment for diabetes, taken right up until the patient entered the hospital, was not administered during the inpatient stay. Information about hypotensive episodes might be similarly difficult to locate. The researchers might start with nursing notes from the recovery room or with the anesthesiologist's datasheets from the operating room, but the patient might not have been hypotensive until after leaving the recovery room and returning to the ward. So the nursing notes from the ward would need to be checked too, as well as vital signs sheets, physicians' progress notes, and the discharge summary.

It should be clear from this example that retrospective paper chart review was a laborious and tedious process and that people performing it were prone to make transcription errors and to overlook key data. EHRs offer an enormous opportunity (► Chap. 16) to facilitate the chart review and clinical research process. They have obviated the need to retrieve hard copy charts; instead, researchers are increasingly using computer-based data retrieval and analysis techniques to do most of the work (finding relevant patients, locating pertinent data, and formatting the information for statistical analyses). Researchers can use similar techniques to harness computer assistance with data management in prospective clinical trials (► Chap. 29).

### 2.3.4 The Passive Nature of Paper Records

The traditional manual system has another limitation that would have been meaningless until the emergence of the computer age. A manual archival system is inherently passive; the charts sit waiting for something to be done with them. They are insensitive to the characteristics of the data recorded within their pages,

such as legibility, accuracy, or implications for patient management. They cannot take an active role in responding appropriately to those implications.

EHR systems have changed our perspective on what health professionals can expect from the medical chart. Automated record systems introduce new opportunities for dynamic responses to the data that are recorded in them. As described in many of the chapters to follow, computational techniques for data storage, retrieval, and analysis make it feasible to develop record systems that (1) monitor their contents and generate warnings or advice for providers based on single observations or on logical combinations of data; (2) provide automated quality control, including the flagging of potentially erroneous data; or (3) provide feedback on patient-specific or population-based deviations from desirable standards.

## 2.4 New Kinds of Data and the Resulting Challenges

The revolution in human genetics that emerged with the **Human Genome Project** in the 1990s already has had a profound effect on the diagnosis, prognosis, and treatment of disease (Vamathevan and Birney 2017). The vast amounts of data that are generated in biomedical research (see ► Chaps. 11 and 28), and that can be pooled from patient datasets to support clinical research (► Chap. 29) and public health (► Chap. 20), have created new opportunities as well as challenges. Researchers are finding that the amount of data that they must manage and assess has become so large that they often find that they lack either the capabilities or expertise to handle the analytics that are required. This problem, sometimes dubbed the “big data” problem, has gathered the attention of government agencies as well.<sup>2</sup>

2 Big Data Senior Steering Group. The Federal Big Data Research and Development Strategic Plan. Available at: ► [https://obamawhitehouse.archives.gov/sites/default/files/microsites/ostp/NSTC/bigdatardstrategicplan-nitrd\\_final-051916.pdf](https://obamawhitehouse.archives.gov/sites/default/files/microsites/ostp/NSTC/bigdatardstrategicplan-nitrd_final-051916.pdf) (Accessed 6/28/2019).

Some suggest that the genetic material itself will become our next-generation method for storing large amounts of data (Erlich and Zielinski 2017). Data analytics, and the management of large amounts of genomic/proteomic or clinical/public-health data, have accordingly become major research topics and key opportunities for new methodology development by biomedical informatics and **data scientists** (Adler-Milstein and Jha 2013; Brennan et al. 2018; Bycroft et al. 2018).

The issues that arise are practical as well as scientifically interesting. For example, developers of EHRs have begun to grapple with questions regarding how they might store an individual's personal genome within the electronic health record. New standards will be required, and tactical questions need answering regarding, for example, whether to store an entire genome or only those components (e.g., genetic markers) that are already reasonably well understood (Masys et al. 2012; Haendel et al. 2018). In cancer, for example, where mutations in cell lines can occur, an individual may actually have many genomes represented among his or her cells. These issues will undoubtedly influence the evolution of data systems and EHRs, as well as the growth of **precision medicine** (see ► Chap. 30), in the years ahead (Relling and Evans 2015).

## 2.5 The Structure of Clinical Data

Scientific disciplines generally develop a precise terminology or notation that is standardized and accepted by all workers in the field. Consider, for example, the universal language of chemistry embodied in chemical formulae, the precise definitions and mathematical equations used by physicists, the predicate calculus used by logicians, or the conventions for describing circuits used by electrical engineers. Medicine is remarkable for its failure to develop a widely accepted standardized vocabulary and **nomenclature**, and many observers believe that a true “scientific” basis for the field will be impossible until this problem is addressed (see ► Chap. 8). Other people argue that common references to the “art” of medicine reflect an important distinction between medicine and the “hard” sci-

ences; these people question whether it is possible to introduce too much standardization into a field that prides itself in humanism.

The debate has been accentuated by the introduction of computers for data management, because such machines tend to demand conformity to data standards and definitions. Otherwise, issues of data retrieval and analysis are confounded by discrepancies between the meanings intended by the observers or recorders and those intended by the individuals retrieving information or doing data analysis. What is an “upper respiratory infection”? Does it include infections of the trachea or of the main stem bronchi? How large does the heart have to be before we can refer to “cardiomegaly”? How should we deal with the plethora of disease names based on eponyms (e.g., Alzheimer's disease, Hodgkin's disease) that are not descriptive of the illness and may not be familiar to all practitioners? What do we mean by an “acute abdomen”? Are the boundaries of the abdomen well agreed on? What are the time constraints that correspond to “acuteness” of abdominal pain? Is an “ache” a pain? What about “occasional” cramping?

Imprecision and the lack of a standardized vocabulary are particularly problematic when we wish to aggregate data recorded by multiple health professionals or to analyze trends over time. Without a controlled, predefined vocabulary, data interpretation is inherently complicated, and the automatic summarization of data may be impossible. For example, one physician might note that a patient has “shortness of breath.” Later, another physician might note that she has “dyspnea.” Unless these terms are designated as synonyms, an automated program will fail to indicate that the patient had the same problem on both occasions.

Regardless of arguments regarding the “artistic” elements in medicine, the need for health personnel to communicate effectively is clear both in acute care settings and when patients are seen over long periods. Both high-quality care and scientific progress depend on some standardization in terminology. Otherwise, differences in intended meaning or in defining criteria will lead to miscommunication, improper interpretation, and potentially negative consequences for the patients involved.

Given the lack of formal definitions for many medical terms, it is remarkable that medical workers communicate as well as they do. Only occasionally is the care for a patient clearly compromised by miscommunication. If EHRs are to become dynamic and responsive manipulators of patient data, however, their encoded logic must be able to presume a specific meaning for the terms and data elements entered by the observers. This point is discussed in greater detail in ► Chap. 8, which deals in part with the multiple efforts to develop health-care computing standards, including a shared, controlled terminology for biomedicine.

### 2.5.1 Coding Systems

We are used to seeing figures regarding the growing incidences of certain types of tumors, deaths from influenza during the winter months, and similar health statistics that we tend to take for granted. How are such data accumulated? Their role in health planning and health care financing is clear, but electronic health records provide the infrastructure for aggregating individual patient data to learn more about the health status of the populations in various communities (see ► Chap. 20).

Because of the needs to know about health trends for populations and to recognize epidemics in their early stages, there are various health-reporting requirements for hospitals (as well as other public organizations) and practitioners. For example, cases of gonorrhea, syphilis, and tuberculosis generally must be reported to local public-health organizations, which code the data to allow trend analyses over time. The Centers for Disease Control and Prevention in Atlanta (CDC) then pool regional data and report national as well as local trends in disease incidence, bacterial-resistance patterns, etc.

Another kind of reporting involves the coding of all discharge diagnoses for hospitalized patients, plus coding of certain procedures (e.g., type of surgery) that were performed during the hospital stay. Such codes are reported to state and federal health-planning and analysis agencies and also are used internally at the institution for case-mix analysis (determining the relative frequencies of various disorders in the

hospitalized population and the average length of stay for each disease category), for quality improvement, and for research. For such data to be useful, the codes must be well defined as well as uniformly applied and accepted.

The World Health Organization publishes a diagnostic coding scheme called the International Classification of Disease (ICD). The 10th revision of this standard, ICD-10-CM (clinical modification),<sup>3</sup> is currently in use in much of the world (see ► Chap. 8). ICD-10-CM is used by all nonmilitary hospitals in the United States for discharge coding, and must be reported on the bills submitted to most insurance companies (► Fig. 2.11). Pathologists have developed another widely used diagnostic coding scheme; originally known as Systematized Nomenclature of Pathology (SNOP), it was expanded to the Systematized Nomenclature of Medicine (SNOMED) and then merged with the Read Clinical Terms from Great Britain to become SNOMED-CT (Stearns et al. 2001; Lee et al. 2014). In recent years, support for SNOMED-CT was assumed by the International Health Terminology Standards Development Organization, based in Copenhagen, now renamed SNOMED International and relocated to London.<sup>4</sup> Another coding scheme, developed by the American Medical Association, is the Current Procedural Terminology (CPT) (Hirsch et al. 2015). It is similarly widely used in producing bills for services rendered to patients. More details on such schemes are provided in ► Chap. 8. What warrants emphasis here, however, is the motivation for the codes' development: health care personnel need standardized terms that can support pooling of data for analysis and can provide criteria for determining charges for individual patients.

The historical roots of a coding system reveal themselves as limitations or idiosyncrasies when the system is applied in more general clinical settings. For example, ICD-10-CM was derived from a classification scheme developed for epidemiologic reporting. Consequently, it has over 60 separate codes for describing tuber-

Human Services, ► <https://www.cms.gov/Medicare/Coding/ICD10/2018-ICD-10-CM-and-GEMs.html>, accessed June 28, 2019)

culosis infections. SNOMED versions have long permitted coding of pathologic findings in exquisite detail but only in later years began to introduce codes for expressing the dimensions of a patient's functional status. In a particular clinical setting, none of the common coding schemes is likely to be completely satisfactory. In some cases, the granularity of the code will be too coarse; on the one hand, a hematologist

(person who studies blood diseases) may want to distinguish among a variety of hemoglobinopathies (disorders of the structure and function of hemoglobin) lumped under a single code in ICD-10-CM. On the other hand, another practitioner may prefer to aggregate many individual codes—e.g., those for active tuberculosis—into a single category to simplify the coding and retrieval of data.

Such schemes cannot be effective unless health care providers accept them. There is an inherent tension between the need for a coding system that is general enough to cover many different patients and the need for precise and unique terms that accurately apply to a specific patient and do not unduly constrain physicians' attempts to describe what they observe. Yet if physicians view the EHR as a blank sheet of paper on which any unstructured information can be written, the data they record will be unsuitable for dynamic processing, clinical research, and health planning. The challenge is to learn how to meet all these needs. Researchers at many institutions worked for over two decades to develop a unified medical language system (UMLS), a common structure that ties together the various vocabularies that have been created. At the same time, the developers of specific terminologies are continually working to refine and expand their independent coding schemes (Humphreys et al. 1998) (see ► Chap. 8).

### 2.5.2 The Data-to-Knowledge Spectrum

A central focus in biomedical informatics is the information base that constitutes the “substance of medicine.” Workers in the field have tried to clarify the distinctions among three terms frequently used to describe the content of computer-based systems: data, information, and knowledge (Blum 1986; Bernstam et al. 2010). These terms are often used interchangeably. In this volume, we shall refer to a **datum** as a single observational point that characterizes a relationship. It generally can be regarded as the value of a specific parameter for a particular object (e.g., a patient) at a given point in time. The term **information** refers to analyzed data that have been suitably curated and organized so that they have meaning. Data do not constitute information until they have been organized in some way, e.g., for analysis or display. **Knowledge**, then, is derived through the formal or informal analysis (or interpretation) of information that was in turn derived from data. Thus, knowledge includes the results of formal studies and also common sense facts, assumptions, heuristics (strategic rules of thumb), and models—any of

which may reflect the experience or biases of people who interpret the primary data and the resulting information.

The observation that patient Brown has a blood pressure of 180/110 is a *datum*, as is the report that the patient has had a myocardial infarction (heart attack). When researchers pool such data, creating information, subsequent analysis may determine that patients with high blood pressure are more likely to have heart attacks than are patients with normal or low blood pressure. This analysis of organized data (information) has produced a piece of knowledge about the world. A physician's belief that prescribing dietary restriction of salt is unlikely to be effective in controlling high blood pressure in patients of low economic standing (because the latter are less likely to be able to afford special low-salt foods) is an additional personal piece of *knowledge*—a **heuristic** that guides physicians in their decision making. Note that the appropriate interpretation of these definitions depends on the context. Knowledge at one level of abstraction may be considered data at higher levels. A blood pressure of 180/110 mmHg is a raw piece of data; the statement that the patient has hypertension is an interpretation of several such data and thus represents a higher level of information. As input to a diagnostic decision aid, however, the presence or absence of hypertension may be requested, in which case the presence of hypertension is treated as a data item.

A **database** is a collection of individual observations without any summarizing analysis. An EHR system is thus primarily viewed as a database—the place where patient data are stored. When properly collated and pooled with other data, these elements in the EHR provide *information* about the patient. A **knowledge base**, on the other hand, is a collection of facts, heuristics, and models that can be used for problem solving and analysis of organized data (information). If the knowledge base provides sufficient structure, including semantic links among knowledge items, the computer itself may be able to apply that knowledge as an aid to case-based problem solving. Many decision-support systems have been called knowledge-based systems, reflect-

ing this distinction between knowledge bases and databases (see ► Chap. 26).

## 2.6 Strategies of Clinical Data Selection and Use

---

It is illusory to conceive of a “complete clinical data set.” All medical databases, and medical records, are necessarily incomplete because they reflect the selective collection and recording of data by the health care personnel responsible for the patient. There can be marked interpersonal differences in both style and problem solving that account for variations in the way practitioners collect and record data for the same patient under the same circumstances. Such variations do not necessarily reflect good practices, however, and much of medical education is directed at helping physicians and other health professionals to learn what observations to make, how to make them (generally an issue of technique), how to interpret them, and how to decide whether they warrant formal recording.

An example of this phenomenon is the difference between the first medical history, physical examination, and summarizing report developed by a medical student and the similar process undertaken by a seasoned clinician examining the same patient. Medical students tend to work from comprehensive mental outlines of questions to ask, physical tests to perform, and additional data to collect. Because they have not developed skills of selectivity, the process of taking a medical history and performing a physical examination may take more than 1 h, after which students develop extensive reports of what they observed and how they have interpreted their observations. It clearly would be impractical, inefficient, and inappropriate for physicians in practice to spend this amount of time assessing every new patient. Thus, part of the challenge for the neophyte is to learn how to ask only the questions that are necessary, to perform only the examination components that are required, and to record only those data that will be pertinent in justifying the ongoing diagnostic approach and in guiding the future management of the patient.

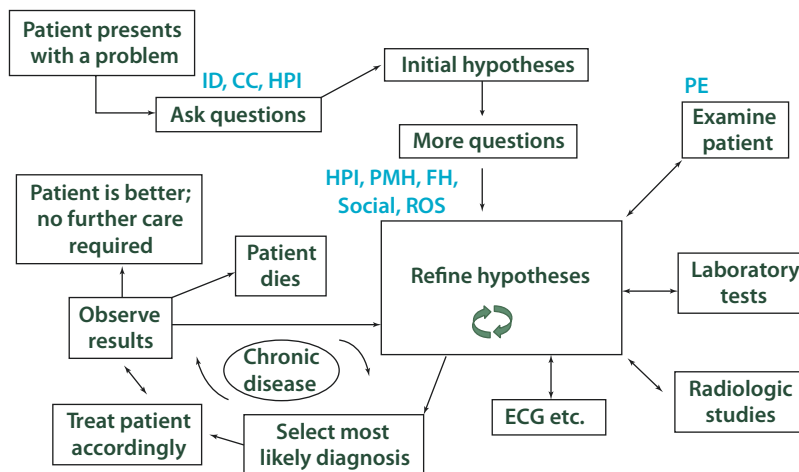

What do we mean by **selectivity** in data collection and recording? It is precisely this process that often is viewed as a central part of the “art” of medicine, an element that accounts for individual styles and the sometimes marked distinctions among clinicians. As is discussed with numerous clinical examples in ► Chaps. 3 and 4, the idea of selectivity implies an ongoing decision-making process that guides data collection and interpretation. Attempts to understand how expert clinicians internalize this process, and to formalize the ideas so that they can better be taught and explained, are central in biomedical informatics research. Improved guidelines for such decision making, derived from research activities in biomedical informatics, not only are enhancing the teaching and practice of medicine (Shortliffe 2010) but also are providing insights that suggest methods for developing computer-based decision-support tools.

### 2.6.1 The Hypothetico-Deductive Approach

---

Studies of clinical decision makers have shown that strategies for data collection and interpretation may be imbedded in an iterative process known as the **hypothetico-deductive approach** (Elstein et al. 1978; Kassirer and Gorry 1978). As medical students learn this process, their data collection becomes more focused and efficient, and their medical records become more compact. The central idea is one of sequential, staged data collection, followed by data interpretation and the generation of hypotheses, leading to hypothesis-directed selection of the next most appropriate data to be collected. As data are collected at each stage, they are added to the growing database of observations and are used to reformulate or refine the active hypotheses. This process is iterated until one hypothesis reaches a threshold level of certainty (e.g., it is proved to be true, or at least the uncertainty is reduced to a satisfactory level). At that point, a management, disposition, or therapeutic decision can be made.

The diagram in ► Fig. 2.12 clarifies this process. As is shown, data collection begins

■ Fig. 2.12 A schematic view of the hypothetico-deductive approach. The process of medical data collection and treatment is intimately tied to an ongoing process of hypothesis generation and refinement. See text

for full discussion. *ID* patient identification, *CC* chief complaint, *HPI* history of present illness, *PMH* past medical history, *FH* family history, *Social* social history, *ROS* review of systems, *PE* physical examination

when the patient presents to the physician with some issue (a symptom or disease, or perhaps the need for routine care). The physician generally responds with a few questions that allow one to focus rapidly on the nature of the problem. In the written report, the data collected with these initial questions typically are recorded as the patient identification, chief complaint, and initial portion of the history of the present illness. Studies have shown that an experienced physician will have an initial set of hypotheses (theories) in mind after hearing the patient's response to the first six or seven questions (Elstein et al. 1978). These hypotheses then serve as the basis for selecting additional questions. As shown in ■ Fig. 2.12, answers to these additional questions allow the physician to refine hypotheses about the source of the patient's problem. Physicians refer to the set of active hypotheses as the **differential diagnosis** for a patient; the differential diagnosis comprises the set of possible diagnoses among which the physician must distinguish to determine how best to administer treatment.

Note that the question selection process is inherently heuristic; e.g., it is personalized and efficient, but it is not guaranteed to collect every piece of information that might be per-

tent. Human beings use heuristics all the time in their decision making because it often is impractical or impossible to use an exhaustive problem-solving approach. A common example of heuristic problem solving is the playing of a complex game such as chess. Because it would require an enormous amount of time to define all the possible moves and countermoves that could ensue from a given board position, expert chess players develop personal heuristics for assessing the game at any point and then selecting a strategy for how best to proceed. Differences among such heuristics account in part for variations in observed expertise.

Physicians have developed safety measures, however, to help them to avoid missing important issues that they might not discover when collecting data in a hypothesis-directed fashion when taking the history of a patient's present illness (Pauker et al. 1976). These measures tend to be focused in four general categories of questions that follow the collection of information about the chief complaint: past medical history, family history, social history, and a brief **review of systems** in which the physician asks some general questions about the state of health of each of the major organ systems in the

body. Occasionally, the physician discovers entirely new problems or finds important information that modifies the hypothesis list or modulates the treatment options available (e.g., if the patient reports a serious past drug reaction or allergy).

When physicians have finished asking questions, the refined hypothesis list (which may already be narrowed to a single diagnosis) then serves as the basis for a focused physical examination. By this time, physicians may well have expectations of what they will find on examination or may have specific tests in mind that will help them to distinguish among still active hypotheses about diseases based on the questions that they have asked. Once again, as in the question-asking process, focused hypothesis-directed examination is augmented with general tests that occasionally turn up new abnormalities and generate hypotheses that the physician did not expect on the basis of the medical history alone. In addition, unexplained findings on examination may raise issues that require additional history taking. Thus, the asking of questions generally is partially integrated with the examination process.

When physicians have completed the physical examination, their refined hypothesis list may be narrowed sufficiently for them to undertake specific treatment. Additional data gathering may still be necessary, however. Such testing is once again guided by the current hypotheses. The options available include laboratory tests (of blood, urine, other body fluids, or biopsy specimens), radiologic studies (X-ray examinations, nuclear-imaging scans, computed tomography (CT) studies, magnetic resonance scans, sonograms, or any of a number of other imaging modalities), and other specialized tests (electrocardiograms (ECGs), electroencephalograms, nerve conduction studies, and many others), as well as returning to the patient to ask further questions or perform additional physical examination. As the results of such studies become available, physicians constantly revise and refine their hypothesis list.

Ultimately, physicians are sufficiently certain about the source of a patient's problem to be able to develop a specific management plan. Treatments are administered, and the patient

is observed. Note data collected to measure response to treatment may themselves be used to synthesize information that affects the hypotheses about a patient's illness. If patients do not respond to treatment, it may mean that their disease is resistant to that therapy and that their physicians should try an alternate approach, or it may mean that the initial diagnosis was incorrect and that physicians should consider alternate explanations for the patient's problem.

The patient may remain in a cycle of treatment and observation for a long time, as shown in [Fig. 2.12](#). This long cycle reflects the nature of chronic-disease management—an aspect of medical care that is accounting for an increasing proportion of the health care community's work (and an increasing proportion of health care cost). Alternatively, the patient may recover and no longer need therapy, or he or she may die. Although the process outlined in [Fig. 2.12](#) is oversimplified in many regards, it is generally applicable to the process of data collection, diagnosis, and treatment in most areas of medicine.

Note that the hypothesis-directed process of data collection, diagnosis, and treatment is inherently knowledge-based. It is dependent not only on a significant fact base that permits proper interpretation of data and selection of appropriate follow-up questions and tests but also on the effective use of heuristic techniques that characterize individual expertise.

Another important issue, addressed in [Chap. 3](#), is the need for physicians to balance financial costs and health risks of data collection against the perceived benefits to be gained when those data become available. It costs nothing but time to examine the patient at the bedside or to ask an additional question, but if the data being considered require, for example, X-ray exposure, coronary angiography, or a CT scan of the head (all of which have associated risks and costs), then it may be preferable to proceed with treatment in the absence of full information. Differences in the assessment of cost-benefit trade-offs in data collection, and variations among individuals in their willingness to make decisions under uncertainty, often account for differences of opinion among collaborating physicians.

## 2.6.2 The Relationship Between Data and Hypotheses

2

We wrote rather glibly in ▶ Sect. 2.6.1 about the “generation of hypotheses from data”; now we need to ask: What precisely is the nature of that process? As is discussed in ▶ Chap. 4, researchers with a psychological orientation have spent much time trying to understand how expert problem solvers evoke hypotheses (Elstein et al. 1978; Arocha et al. 2005) and the traditional probabilistic decision sciences have much to say about that process as well. We provide only a brief introduction to these ideas here; they are discussed in greater detail in ▶ Chaps. 3 and 4.

When an observation evokes a hypothesis (e.g., when a clinical finding makes a specific diagnosis come to mind), the observation presumably has some close association with the hypothesis. What might be the characteristics of that association? Perhaps the finding is almost always observed when the hypothesis turns out to be true. Is that enough to explain hypothesis generation? A simple example will show that such a simple relationship is not enough to explain the evocation process. Consider the hypothesis that a patient is pregnant and the observation that the patient is biologically female. Clearly, all pregnant patients are female. When a new patient is observed to be female, however, the possibility that the patient is pregnant is not immediately evoked. Thus, female gender is a highly sensitive indicator of pregnancy (there is a 100% certainty that a pregnant patient is female), but it is not a good predictor of pregnancy (most females are not pregnant). The idea of **sensitivity**—the likelihood that a given datum will be observed in a patient with a given disease or condition—is an important one, but it will not alone account for the process of hypothesis generation in medical diagnosis.

Perhaps the clinical manifestation seldom occurs unless the hypothesis turns out to be true; is that enough to explain hypothesis generation? This idea seems to be a little closer to the mark. Suppose a given datum is never seen unless a patient has a specific disease. For example, a Pap smear (a smear of cells swabbed from the cervix, at the opening to the uterus, treated with

Papanicolaou’s stain, and then examined under the microscope) with grossly abnormal cells (called class IV findings) is never seen unless the woman has cancer of the cervix or uterus. Such tests are called **pathognomonic**. Not only do they evoke a specific diagnosis but they also immediately prove it to be true. Unfortunately, there are few pathognomonic tests in medicine and they are often of relatively low sensitivity (that is, although having a particular test result makes the diagnosis, few patients with the condition may actually have that finding).

More commonly, a feature is seen in one disease or disease category more frequently than it is in others, but the association is not absolute. For example, there are few disease entities other than infections that elevate a patient’s white blood cell count. Certainly it is true, for example, that leukemia can raise the white blood cell count, as can the use of certain medications, but most patients who do not have infections will have normal white blood cell counts. An elevated white count therefore does not prove that a patient has an infection, but it does tend to evoke or support the hypothesis that an infection is present. The word used to describe this relationship is **specificity**. An observation is highly specific for a disease if it is generally not seen in patients who do not have that disease. A pathognomonic observation is 100% specific for a given disease. When an observation is highly specific for a disease, it tends to evoke that disease during the diagnostic or data-gathering process.

By now, you may have realized that there is a substantial difference between a physician viewing test results that evoke a disease hypothesis and that physician being willing to act on the disease hypothesis. Yet even experienced physicians sometimes fail to recognize that, although they have made an observation that is highly specific for a given disease, it may still be more likely that the patient has other diseases (and does not have the suspected one) unless (1) the finding is pathognomonic or (2) the suspected disease is considerably more common than are the other diseases that can cause the observed abnormality. This mistake is one of the most common errors of intuition in the medical decision-making process. To explain the basis for this confusion in

more detail, we must introduce two additional terms: prevalence and predictive value.

The **prevalence** of a disease is simply the percentage of a population of interest that has the disease at any given time. A particular disease may have a prevalence of only 5% in the general population (1 person in 20 will have the disease) but have a higher prevalence in a specially selected subpopulation. For example, black-lung disease has a low prevalence in the general population but has a much higher prevalence among coal miners, who develop black lung from inhaling coal dust. The task of diagnosis therefore involves updating the probability that a patient has a disease from the **baseline rate** (the prevalence in the population from which the patient was selected) to a post-test probability that reflects the test results. For example, the probability that any given person in the United States has lung cancer is low (i.e., the prevalence of the disease is low), but the chance increases if his or her chest X-ray examination shows a possible tumor. If the patient were a member of the population composed of cigarette smokers in the United States, however, the prevalence of lung cancer would be higher. In this case, the identical chest X-ray

report would result in an even higher updated probability of lung cancer than it would had the patient been selected from the population of all people in the United States.

The **predictive value (PV) of a test** is simply the post-test (updated) probability that a disease is present based on the results of a test. If an observation supports the presence of a disease, the PV will be greater than the prevalence (also called the pretest risk). If the observation tends to argue against the presence of a disease, the PV will be lower than the prevalence. For any test and disease, then, there is one PV if the test result is positive and another PV if the test result is negative. These values are typically abbreviated PV+ (the PV of a positive test) and PV− (the PV of a negative test).

The process of hypothesis generation in medical diagnosis thus involves both the evocation of hypotheses and the assignment of a likelihood (probability) to the presence of a specific disease or disease category. The PV of a positive test depends on the test's sensitivity and specificity, as well as the prevalence of the disease. The formula that describes the relationship precisely is:

$$PV+ = \frac{(\text{sensitivity})(\text{prevalence})}{(\text{sensitivity})(\text{prevalence}) + (1 - \text{specificity})(1 - \text{prevalence})}$$

There is a similar formula for defining PV− in terms of sensitivity, specificity, and prevalence. Both formulae can be derived from simple probability theory. Note that positive tests with high sensitivity and specificity may still lead to a low post-test probability of the disease (PV+) if the prevalence of that disease is low. You should substitute values in the PV+ formula to convince yourself that this assertion is true. It is this relationship that tends to be poorly understood by practitioners and that often is viewed as counterintuitive (which shows that your intuition can misguide you!). Note also (by substitution into the formula) that test sensitivity and disease prevalence can be ignored only when a test is pathognomonic (i.e., when its specificity is 100%, which mandates that PV+ be 100%). The PV+ formula is one of many forms of **Bayes' theorem**,

a rule for combining probabilistic data that is generally attributed to the work of Reverend Thomas Bayes in the 1700s. Bayes' theorem is discussed in greater detail in ► Chap. 3.

### 2.6.3 Methods for Selecting Questions and Comparing Tests

We have described the process of hypothesis-directed sequential data collection and have asked how an observation might evoke or refine the physician's hypotheses about what abnormalities account for the patient's illness. The complementary question is: Given a set of current hypotheses, how does the physician decide what additional data should be collect-

ed? This question also has been analyzed at length (Elstein et al. 1978; Arocha et al. 2005) and is pertinent for computer programs that gather data efficiently to assist clinicians with diagnosis or with therapeutic decision making (see ► Chap. 26). Because understanding issues of test selection and data interpretation is crucial to understanding medical data and their uses, we devote ► Chap. 3 to these and related issues of medical decision making. In ► Sect. 3.6, for example, we discuss the use of decision-analytic techniques in deciding whether to treat a patient on the basis of available information or to perform additional diagnostic tests.

## 2.7 The Computer and Collection of Medical Data

Although this chapter has not directly discussed computer systems, the role of the computer in medical data storage, retrieval, and interpretation should be clear. Much of the rest of this book deals with specific applications in which the computer's primary role is data management. One question is pertinent to all such applications: What are the best approaches for getting data into the computer in the first place?

The need for data entry by physicians has posed a problem for medical-computing systems since the earliest days of the field. Awkward or nonintuitive interactions at computing devices—particularly ones requiring keyboard typing or confusing movement through multiple display screens by the physician—have perhaps done more to frustrate clinicians than have any other factor.

A variety of approaches have been used to try to finesse this problem. One is to design systems such that clerical staff can do essentially all the data entry and much of the data retrieval as well. Many clinical research systems (see ► Chap. 29) have taken this approach. Physicians may be asked to fill out structured paper data-sheets, or such sheets may be filled out by data abstractors who review patient charts, but the actual entry of data into the database is done by paid transcriptionists. Other physicians have adopted “scribes” (staff whose role is to follow physicians in examination rooms and to enter

data into the electronic health record) to reduce the data entry burden on physicians while they interact with patients.

In some applications, data are entered automatically into the computer by the device that measures or collects them. For example, monitors in intensive care or coronary care units, pulmonary function or ECG machines, and measurement equipment in the clinical chemistry laboratory can interface directly with a computer in which a database is stored. Certain data can be entered directly by patients; there are systems, for example, that take the patient's history by presenting on a computer screen or tablet multiple-choice questions that follow a branching logic. The patient's responses to the questions are used to generate electronic or hard copy reports for physicians and also may be stored directly in a computer database for subsequent use in other settings.

When physicians or other health personnel do use the machine themselves, specialized devices often allow rapid and intuitive operator-machine interaction. Most of these devices use a variant of the “point-and-select” approach—e.g., touch-sensitive computer screens, mouse-pointing devices, and increasingly the clinician's finger on a mobile tablet or smart phone (see ► Chaps. 5 and 6). When conventional computer workstations are used, specialized keypads can be helpful. Designers frequently permit logical selection of items from menus displayed on the screen so that the user does not need to learn a set of specialized commands to enter or review data. There were clear improvements when handheld tablets using pen-based or finger-based mechanisms for data entry were introduced. With ubiquitous wireless data services, such devices are allowing clinicians to maintain normal mobility (in and out of examining rooms or inpatient rooms) while accessing and entering data that are pertinent to a patient's care.

These issues arise in essentially all application areas, and, because they can be crucial to the successful implementation and use of a system, they warrant particular attention in system design. As more physicians are comfortable with computers in daily life, they will likely find the use of computers in their practice less of a hindrance. We encourage you to consider human-computer interaction, and

the cognitive issues that arise in dealing with computer systems (see ► Chap. 4), as you learn about the application areas and the specific systems described in later chapters.

This articles reviews the latest trends and major developments in translational bioinformatics. This includes work applying findings from national genome sequencing initiatives to health care delivery. There is a discussion of current challenges and emerging technologies that bridge research with clinical care. See also Chap. 28.

### Questions for Discussion

1. You check your pulse and discover that your heart rate is 100 beats per minute. Is this rate normal or abnormal? What additional information would you use in making this judgment? How does the context in which data are collected influence the interpretation of those data?
2. Given the imprecision of many medical terms, why do you think that serious instances of miscommunication among health care professionals are not more common? Why is greater standardization of terminology necessary if computers rather than humans are to manipulate patient data?
3. Based on the discussion of coding schemes for representing clinical information, discuss three challenges you foresee in

attempting to construct a standardized terminology to be used in hospitals, physicians' offices, and research institutions.

4. How would medical practice change if nonphysicians were to collect and enter all medical data into EHRs? What problems or unintended consequences would you anticipate?
5. Consider what you know about the typical daily schedule of a busy clinician. What are the advantages of wireless devices, connected to the Internet, as tools for such clinicians? Can you think of disadvantages as well? Be sure to consider the safety and protection of information as well as workflow and clinical needs.
6. To decide whether a patient has a significant urinary tract infection, physicians commonly use a calculation of the number of bacterial organisms in a milliliter of the patient's urine. Physicians generally assume that a patient has a urinary tract infection if there are at least 10,000 bacteria per milliliter. Although laboratories can provide such quantification with reasonable accuracy, it is obviously unrealistic for the physician explicitly to count large numbers of bacteria by examining a milliliter of urine under the microscope. As a result, one article offers the following guideline to physicians: "When interpreting ... microscopy of ... stained centrifuged urine, a threshold of one organism per field yields a 95% sensitivity and five organisms per field a 95% specificity for bacteriuria [bacteria in the urine] at a level of at least 10,000 organisms per ml." (Senior Medical Review 1987, p. 4)
  - (a) Describe an experiment that would have allowed the researchers to determine the sensitivity and specificity of the microscopy.
  - (b) How would you expect specificity to change as the number of bacteria per microscopic field increases from one to five?
  - (c) How would you expect sensitivity to change as the number of bacteria

per microscopic field increases from one to five?

- (d) Why does it take more organisms per microscopic field to obtain a specificity of 95% than it does to achieve a sensitivity of 95%?

## 🏠 Learning Objectives

After reading this chapter, you should know the answers to these questions:

- How is the concept of probability useful for understanding test results and for making medical decisions that involve uncertainty?
- How can we characterize the ability of a test to discriminate between disease and health?
- What information do we need to interpret test results accurately?
- What is expected-value decision making? How can this methodology help us to understand particular medical problems?
- What are utilities, and how can we use them to represent patients' preferences?
- What is a sensitivity analysis? How can we use it to examine the robustness of a decision and to identify the important variables in a decision?
- What are influence diagrams? How do they differ from decision trees?

### 3.1 The Nature of Clinical Decisions: Uncertainty and the Process of Diagnosis

Because clinical data are imperfect and outcomes of treatment are uncertain, health professionals often are faced with difficult choices. In this chapter, we introduce probabilistic medical reasoning, an approach that can help health care providers to deal with the uncertainty inherent in many medical decisions. Medical decisions are made by a variety of methods; our approach is neither necessary nor appropriate for all decisions. Throughout the chapter, we provide simple clinical examples that illustrate a broad range of problems for which probabilistic medical reasoning does provide valuable insight.

As discussed in ▶ Chap. 2, medical practice is medical decision making. In this chapter, we look at the process of medical decision making. Together, ▶ Chaps. 2 and 3 lay the groundwork for the rest of the book. In the remaining chapters, we discuss ways that computers can help clinicians with the decision-making process, and we emphasize the relationship be-

tween information needs and system design and implementation.

The material in this chapter is presented in the context of the decisions made by an individual clinician. The concepts, however, are more broadly applicable. Sensitivity and specificity are important parameters of laboratory systems that flag abnormal test results, of patient monitoring systems (▶ Chap. 21), and of information-retrieval systems (▶ Chap. 23). An understanding of what probability is and of how to adjust probabilities after the acquisition of new information is a foundation for our study of clinical decision-support systems (▶ Chap. 24). The importance of probability in medical decision making was noted as long ago as 1922:

- » [G]ood medicine does not consist in the indiscriminate application of laboratory examinations to a patient, but rather in having so clear a comprehension of the probabilities and possibilities of a case as to know what tests may be expected to give information of value (Peabody 1922).

#### ▶ Example 3.1

You are the director of a blood bank. All potential blood donors are tested to ensure that they are not infected with the human immunodeficiency virus (HIV), the causative agent of acquired immunodeficiency syndrome (AIDS). You ask whether use of the polymerase chain reaction (PCR), a gene-amplification technique that can diagnose HIV, would be useful to identify people who have HIV. The PCR test is positive 98% of the time when antibody is present, and negative 99% of the time antibody is absent.<sup>1</sup> ◀

If the test is positive, what is the likelihood that a donor actually has HIV? If the test is negative, how sure can you be that the person does not have HIV? On an intuitive level, these questions

1 The test sensitivity and specificity used in ▶ Example 3.1 are consistent with the reported values of the sensitivity and specificity of the PCR test for diagnosis of HIV early in its development (Owens et al. 1996b); the test now has higher sensitivity and specificity.

do not seem particularly difficult to answer. The test appears accurate, and we would expect that, if the test is positive, the donated blood specimen is likely to contain the HIV. Thus, we are surprised to find that, if only one in 1000 donors actually is infected, the test is more often mistaken than it is correct. In fact, of 100 donors with a positive test, fewer than 10 would be infected. There would be ten wrong answers for each correct result. How are we to understand this result? Before we try to find an answer, let us consider a related example.

#### ► Example 3.2

Ms. Kamala is a 66-year-old woman with coronary artery disease (narrowing or blockage of the blood vessels that supply the heart tissue). When the heart muscle does not receive enough oxygen (hypoxia) because blood cannot reach it, the patient often experiences chest pain (angina). Ms. Kamala has twice undergone coronary artery bypass graft (CABG) surgery, a procedure in which new vessels, often taken from the leg, are grafted onto the old ones such that blood is shunted past the blocked region. Unfortunately, she has again begun to have chest pain, which becomes progressively more severe, despite medication. If the heart muscle is deprived of oxygen, the result can be a heart attack (myocardial infarction), in which a section of the muscle dies. ◀

Should Ms. Kamala undergo a third operation? The medications are not working; without surgery, she runs a high risk of suffering a heart attack, which may be fatal. On the other hand, the surgery is hazardous. Not only is the surgical mortality rate for a third operation higher than that for a first or second one but also the chance that surgery will relieve the chest pain is lower than that for a first operation. All choices in ► Example 3.2 entail considerable uncertainty. Furthermore, the risks are grave; an incorrect decision may substantially increase the chance that Ms. Kamala will die. The decision will be difficult even for experienced clinicians.

These examples illustrate situations in which intuition is either misleading or inadequate. Although the test results in ► Example 3.1 are appropriate for the blood bank, a clinician who uncritically reports these results would erroneously inform many people that they had

HIV—a mistake with profound emotional and social consequences. In ► Example 3.2, the decision-making skill of the clinician will affect a patient's quality and length of life. Similar situations are commonplace in medicine. Our goal in this chapter is to show how the use of probability and decision analysis can help to make clear the best course of action.

Decision making is one of the quintessential activities of the healthcare professional. Some decisions are made on the basis of deductive reasoning or of physiological principles. Many decisions, however, are made on the basis of knowledge that has been gained through collective experience: the clinician often must rely on empirical knowledge of associations between symptoms and disease to evaluate a problem. A decision that is based on these usually imperfect associations will be, to some degree, uncertain. In ► Sects. 3.1.1, 3.1.2 and 3.1.3, we examine decisions made under uncertainty and present an overview of the diagnostic process. As Smith (1985, p. 3) said: “Medical decisions based on probabilities are necessary but also perilous. Even the most astute physician will occasionally be wrong.”

### 3.1.1 Decision Making Under Uncertainty

#### ► Example 3.3

Ms. Kirk, a 33-year-old woman with a history of a previous blood clot (thrombus) in a vein in her left leg, presents with the complaint of pain and swelling in that leg for the past 5 days. On physical examination, the leg is tender and swollen to midcalf—signs that suggest the possibility of deep vein thrombosis.<sup>2</sup> A test (ultrasonography) is performed, and the flow of blood in the veins of Ms. Kirk's leg is evaluated. The blood flow is abnormal, but the radiologist cannot tell whether there is a new blood clot. ◀

2 In medicine, a sign is an objective physical finding (something observed by the clinician) such as a temperature of 101.2 °F. A symptom is a subjective experience of the patient, such as feeling hot or feverish. The distinction may be blurred if the patient's experience also can be observed by the clinician.

Should Ms. Kirk be treated for blood clots? The main diagnostic concern is the recurrence of a blood clot in her leg. A clot in the veins of the leg can dislodge, flow with the blood, and cause a blockage in the vessels of the lungs, a potentially fatal event called a pulmonary embolus. Of patients with a swollen leg, about one-half actually have a blood clot; there are numerous other causes of a swollen leg. Given a swollen leg, therefore, a clinician cannot be sure that a clot is the cause. Thus, the physical findings leave considerable uncertainty. Furthermore, in ► Example 3.3, the results of the available diagnostic test are equivocal. The treatment for a blood clot is to administer anticoagulants (drugs that inhibit blood clot formation), which pose the risk of excessive bleeding to the patient. Therefore, clinicians do not want to treat the patient unless they are confident that a thrombus is present. But how much confidence should be required before starting treatment? We will learn that it is possible to answer this question by calculating the benefits and harms of treatment.

This example illustrates an important concept: Clinical data are imperfect. The degree of imperfection varies, but all clinical data—including the results of diagnostic tests, the history given by the patient, and the findings on physical examination—are uncertain.

### 3.1.2 Probability: An Alternative Method of Expressing Uncertainty

The language that clinicians use to describe a patient's condition often is ambiguous—a factor that further complicates the problem of uncertainty in medical decision making. Clinicians use words such as “probable” and “highly likely” to describe their beliefs about the likelihood of disease. These words have strikingly different meanings to different individuals. Because of the widespread disagreement about the meaning of common descriptive terms, there is ample opportunity for miscommunication.

The problem of how to express degrees of uncertainty is not unique to medicine. How is it handled in other contexts? Horse racing has

its share of uncertainty. If experienced gamblers are deciding whether to place bets, they will find it unsatisfactory to be told that a given horse has a “high chance” of winning. They will demand to know the odds.

The odds are simply an alternate way to express a probability. The use of probability or odds as an expression of uncertainty avoids the ambiguities inherent in common descriptive terms.

### 3.1.3 Overview of the Diagnostic Process

In ► Chap. 2, we described the hypothetico-deductive approach, a diagnostic strategy comprising successive iterations of hypothesis generation, data collection, and interpretation. We discussed how observations may evoke a hypothesis and how new information subsequently may increase or decrease our belief in that hypothesis. Here, we review this process briefly in light of a specific example. For the purpose of our discussion, we separate the diagnostic process into three stages.

The first stage involves making an initial judgment about whether a patient is likely to have a disease. After an interview and physical examination, a clinician intuitively develops a belief about the likelihood of disease. This judgment may be based on previous experience or on knowledge of the medical literature. A clinician's belief about the likelihood of disease usually is implicit; he or she can refine it by making an explicit estimation of the probability of disease. This estimated probability, made before further information is obtained, is the **prior probability** or **pretest probability** of disease.

#### ► Example 3.4

Mr. Smith, a 60-year-old man, complains to his clinician that he has pressure-like chest pain that occurs when he walks quickly. After taking his history and examining him, his clinician believes there is a high enough chance that he has heart disease to warrant ordering an exercise stress test. In the stress test, an electrocardiogram (ECG) is taken while Mr. Smith exercises. Because the heart must pump more blood per stroke and must beat faster (and thus

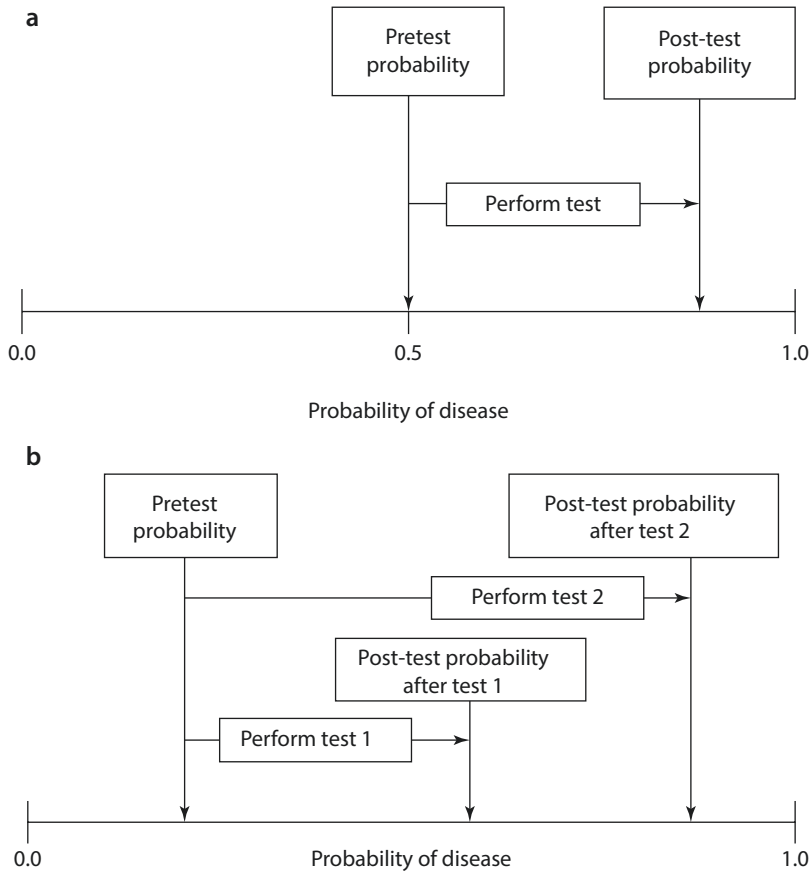

requires more oxygen) during exercise, many heart conditions are evident only when the patient is physically stressed. Mr. Smith’s results show abnormal changes in the ECG during exercise—a sign of heart disease. ◀

3

How would the clinician evaluate this patient? The clinician would first talk to the patient about the quality, duration, and severity of his or her pain. Traditionally, the clinician would then decide what to do next based on his or her intuition about the etiology (cause) of the chest pain. Our approach is to ask the clinician to make his or her initial intuition explicit by estimating the pretest probability of disease. The clinician in this example, based on what he or she knows from talking with the patient, might assess the pretest or prior probability of heart disease as 0.5 (50% chance or 1:1 odds; see ▶ Sect. 3.2). We

explore methods used to estimate pretest probability accurately in ▶ Sect. 3.2.

After the pretest probability of disease has been estimated, the second stage of the diagnostic process involves gathering more information, often by performing a diagnostic test. The clinician in ▶ Example 3.4 ordered a test to reduce the uncertainty about the diagnosis of heart disease. The positive test result supports the diagnosis of heart disease, and this reduction in uncertainty is shown in ◻ Fig. 3.1a. Although the clinician in ▶ Example 3.4 chose the exercise stress test, there are many tests available to diagnose heart disease, and the clinician would like to know which test he or she should order next. Some tests reduce uncertainty more than do others (see ◻ Fig. 3.1b), but may cost more. The more a test reduces uncertainty, the more useful it is. In ▶ Sect. 3.3, we explore ways to measure

◻ Fig. 3.1 The effect of test results on the probability of disease. **a** A positive test result increases the probability of disease. **b** Test 2 reduces uncertainty about presence of disease (increases the probability of disease) more than test 1 does

how well a test reduces uncertainty, expanding the concepts of test sensitivity and specificity first introduced in ► Chap. 2.

Given new information provided by a test, the third step is to update the initial probability estimate. The clinician in ► Example 3.4 must ask: “What is the probability of disease given the abnormal stress test?” The clinician wants to know the **posterior probability**, or **post-test probability**, of disease (see ■ Fig. 3.1a). In ► Sect. 3.4, we reexamine Bayes’ theorem, introduced in ► Chap. 2, and we discuss its use for calculating the post-test probability of disease. As we noted, to calculate post-test probability, we must know the pretest probability, as well as the sensitivity and specificity, of the test.<sup>3</sup>

### 3.2 Probability Assessment: Methods to Assess Pretest Probability

In this section, we explore the methods that clinicians can use to make judgments about the probability of disease before they order tests. **Probability** is our preferred means of expressing uncertainty. In this framework, probability ( $p$ ) expresses a clinician’s opinion about the likelihood of an event as a number between 0 and 1. An event that is certain to occur has a probability of 1; an event that is certain not to occur has a probability of 0.<sup>4</sup>

The probability of event A is written  $p[A]$ . The sum of the probabilities of all possible, collectively exhaustive outcomes of a chance event must be equal to 1. Thus, in a coin flip,

$$p[\text{heads}] + p[\text{tails}] = 1.0.$$

The probability of event A and event B occurring together is denoted by  $p[A\&B]$  or by  $p[A,B]$ .

Events A and B are considered **independent** if the occurrence of one does not influence the probability of the occurrence of the other. The probability of two independent events A and B both occurring is given by the product of the individual probabilities:

$$p[A,B] = p[A] \times p[B].$$

Thus, the probability of heads on two consecutive coin tosses is  $0.5 \times 0.5 = 0.25$ . (Regardless of the outcome of the first toss, the probability of heads on the second toss is 0.5).

The probability that event A will occur given that event B is known to occur is called the **conditional probability** of event A given event B, denoted by  $p[A|B]$  and read as “the probability of A given B.” Thus a post-test probability is a conditional probability predicated on the test or finding. For example, if 30% of patients who have a swollen leg have a blood clot, we say the probability of a blood clot given a swollen leg is 0.3, denoted:

$$p[\text{blood clot}|\text{swollen leg}] = 0.3.$$

Before the swollen leg is noted, the pretest probability is simply the prevalence of blood clots in the leg in the population from which the patient was selected—a number likely to be much smaller than 0.3.

Now that we have decided to use probability to express uncertainty, how can we estimate probability? We can do so by either subjective or objective methods; each approach has advantages and limitations.

#### 3.2.1 Subjective Probability Assessment

Most assessments that clinicians make about probability are based on personal experience. The clinician may compare the current problem to similar problems encountered previously and then ask: “What was the frequency of disease in similar patients whom I have seen?”

To make these subjective assessments of probability, people rely on several discrete, often unconscious mental processes that have been de-

3 Note that pretest and post-test probabilities correspond to the concepts of prevalence and predictive value. The latter terms were used in ► Chap. 2 because the discussion was about the use of tests for screening populations of patients; in a population, the pretest probability of disease is simply that disease’s prevalence in that population.

4 We assume a Bayesian interpretation of probability; there are other statistical interpretations of probability.

scribed and studied by cognitive psychologists (Tversky and Kahneman 1974). These processes are termed **cognitive heuristics**.

More specifically, a cognitive heuristic is a mental process by which we learn, recall, or process information; we can think of heuristics as rules of thumb. Knowledge of heuristics is important because it helps us to understand the underpinnings of our intuitive probability assessment. Both naive and sophisticated decision makers (including clinicians and statisticians) misuse heuristics and therefore make systematic—often serious—errors when estimating probability. So, just as we may underestimate distances on a particularly clear day (Tversky and Kahneman 1974), we may make mistakes in estimating probability in deceptive clinical situations. Three heuristics have been identified as important in estimation of probability:

1. **Representativeness.** One way that people estimate probability is to ask themselves: What is the probability that object A belongs to class B? For instance, what is the probability that this patient who has a swollen leg belongs to the class of patients who have blood clots? To answer, we often rely on the **representativeness** heuristic in which probabilities are judged by the degree to which A is representative of, or similar to, B. The clinician will judge the probability of the development of a blood clot (thrombosis) by the degree to which the patient with a swollen leg resembles the clinician's mental image of patients with a blood clot. If the patient has all the classic findings (signs and symptoms) associated with a blood clot, the clinician judges that the patient is highly likely to have a blood clot. Difficulties occur with the use of this heuristic when the disease is rare (very low prior probability, or prevalence); when the clinician's previous experience with the disease is atypical, thus giving an incorrect mental representation; when the patient's clinical profile is atypical; and when the probability of certain findings depends on whether other findings are present.
2. **Availability.** Our estimate of the probability of an event is influenced by the ease with which we remember similar events. Events more easily remembered are judged more probable; this rule is the **availability**

heuristic, and it is often misleading. We remember dramatic, atypical, or emotion-laden events more easily and therefore are likely to overestimate their probability. A clinician who had cared for a patient who had a swollen leg and who then died from a blood clot would vividly remember thrombosis as a cause of a swollen leg. The clinician would remember other causes of swollen legs less easily, and he or she would tend to overestimate the probability of a blood clot in patients with a swollen leg.

3. **Anchoring and adjustment.** Another common heuristic used to judge probability is **anchoring and adjustment**. A clinician makes an initial probability estimate (the anchor) and then adjusts the estimate based on further information. For instance, the clinician in ▶ Example 3.4 makes an initial estimate of the probability of heart disease as 0.5. If he or she then learns that all the patient's brothers had died of heart disease, the clinician should raise the estimate because the patient's strong family history of heart disease increases the probability that he or she has heart disease, a fact the clinician could ascertain from the literature. The usual mistake is to adjust the initial estimate (the anchor) insufficiently in light of the new information. Instead of raising his or her estimate of prior probability to, say, 0.8, the clinician might adjust it to only 0.6.

Heuristics often introduce error into our judgments about prior probability. Errors in our initial estimates of probabilities will be reflected in the posterior probabilities even if we use quantitative methods to derive those posterior probabilities. An understanding of heuristics is thus important for medical decision making. The clinician can avoid some of these difficulties by using published research results to estimate probabilities.

### 3.2.2 Objective Probability Estimates

Published research results can serve as a guide for more objective estimates of probabilities. We can use the prevalence of disease in the popula-

tion or in a subgroup of the population, or clinical prediction rules, to estimate the probability of disease.

As we discussed in ► Chap. 2, the **prevalence** is the frequency of an event in a population; it is a useful starting point for estimating probability. For example, if you wanted to estimate the probability of prostate cancer in a 50-year-old man, the prevalence of prostate cancer in men of that age (5–14%) would be a useful anchor point from which you could increase or decrease the probability depending on your findings. Estimates of disease prevalence in a defined population often are available in the medical literature.

Symptoms, such as difficulty with urination, or signs, such as a palpable prostate nodule, can be used to place patients into a **clinical subgroup** in which the probability of disease is known. For patients referred to a urologist for evaluation of a prostate nodule, the prevalence of cancer is about 50%. This approach may be limited by difficulty in placing a patient in the correct clinically defined subgroup, especially if the criteria for classifying patients are ill-defined. A trend has been to develop guidelines, known as clinical prediction rules, to help clinicians assign patients to well-defined subgroups in which the probability of disease is known.

**Clinical prediction rules** are developed from systematic study of patients who have a particular diagnostic problem; they define how clinicians can use combinations of clinical findings to estimate probability. The symptoms or signs that make an independent contribution to the probability that a patient has a disease are identified and assigned numerical weights based on statistical analysis of the finding's contribution. The result is a list of symptoms and signs for an individual patient, each with a corresponding numerical contribution to a total score. The total score places a patient in a subgroup with a known probability of disease.

#### ► Example 3.5

Ms. Troy, a 65-year-old woman who had a heart attack 4 months ago, has abnormal heart rhythm (arrhythmia), is in poor medical condition, and is about to undergo elective surgery. ◀

What is the probability that Ms. Troy will suffer a cardiac complication? Clinical prediction rules have been developed to help clinicians to assess this risk (Palda and Detsky 1997). ■ Table 3.1 lists clinical findings and their corresponding diagnostic weights. We add the diagnostic weights for each of the patient's clinical findings to obtain the total score. The total score places the patient in a group with a defined probability of cardiac complications, as shown in ■ Table 3.2. Ms. Troy receives a score of 20; thus, the clinician can estimate that the patient has a 27% chance of developing a severe cardiac complication.

Objective estimates of pretest probability are subject to error because of bias in the studies on which the estimates are based. For

■ **Table 3.1** Diagnostic weights for assessing risk of cardiac complications from noncardiac surgery

Clinical finding	Diagnostic weight
Age greater than 70 years	5
Recent documented heart attack	
>6 months previously	5
<6 months previously	10
Severe angina	20
Pulmonary edema <sup>a</sup>	
Within 1 week	10
Ever	5
Arrhythmia on most recent ECG 5	
>5 PVCs	5
Critical aortic stenosis	20
Poor medical condition	5
Emergency surgery	10

*ECG* electrocardiogram, *PVCs* premature ventricular contractions on preoperative electrocardiogram

<sup>a</sup>Fluid in the lungs due to reduced heart function

**Table 3.2** Clinical prediction rule for diagnostic weights in **Table 3.1**

Total score	Prevalence (%) of cardiac complications <sup>a</sup>
0–15	5
20–30	27
>30	60

<sup>a</sup>Cardiac complications defined as death, heart attack, or congestive heart failure

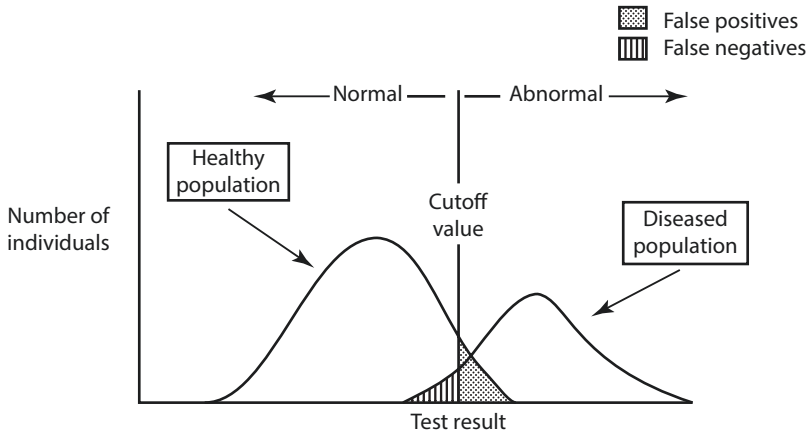

instance, published prevalence data may not apply directly to a particular patient. A clinical illustration is that early studies indicated that a patient found to have microscopic evidence of blood in the urine (microhematuria) should undergo extensive tests because a significant proportion of the patients would be found to have cancer or other serious diseases. The tests involve some risk, discomfort, and expense to the patient. Nonetheless, the approach of ordering tests for any patient with microhematuria was widely practiced for some years. A later study, however, suggested that the probability of serious disease in asymptomatic patients with only microscopic evidence of blood was only about 2%. In the past, many patients may have undergone unnecessary tests, at considerable financial and personal cost.

What explains the discrepancy in the estimates of disease prevalence? The initial studies that showed a high prevalence of disease in patients with microhematuria were performed on patients referred to urologists, who are specialists. The primary care clinician refers patients whom he or she suspects have a disease in the specialist's sphere of expertise. Because of this initial screening by primary care clinicians, the specialists seldom see patients with clinical findings that imply a low probability of disease. Thus, the prevalence of disease in the patient population in a specialist's practice often is much higher than that in a primary care practice; studies performed with the former patients therefore almost always overestimate disease probabilities. This example demonstrates

**referral bias.** Referral bias is common because many published studies are performed on patients referred to specialists. Thus, one may need to adjust published estimates before one uses them to estimate pretest probability in other clinical settings.

We now can use the techniques discussed in this part of the chapter to illustrate how the clinician in **Example 3.4** might estimate the pretest probability of heart disease in his or her patient, Mr. Smith, who has pressure-like chest pain. We begin by using the objective data that are available. The prevalence of heart disease in 60-year-old men could be our starting point. In this case, however, we can obtain a more refined estimate by placing the patient in a clinical subgroup in which the prevalence of disease is known. The prevalence in a clinical subgroup, such as men with symptoms typical of coronary heart disease, will predict the pretest probability more accurately than would the prevalence of heart disease in a group that is heterogeneous with respect to symptoms, such as the population at large. We assume that large studies have shown the prevalence of coronary heart disease in men with typical symptoms of angina pectoris to be about 0.9; this prevalence is useful as an initial estimate that can be adjusted based on information specific to the patient. Although the prevalence of heart disease in men with typical symptoms is high, 10% of patients with this history do not have heart disease.

The clinician might use subjective methods to adjust his or her estimate further based on other specific information about the patient. For example, the clinician might adjust his or her initial estimate of 0.9 upward to 0.95 or higher based on information about family history of heart disease. The clinician should be careful, however, to avoid the mistakes that can occur when one uses heuristics to make subjective probability estimates. In particular, he or she should be aware of the tendency to stay too close to the initial estimate when adjusting for additional information. By combining subjective and objective methods for assessing pretest probability, the clinician can arrive at a reasonable estimate of the pretest probability of heart disease.

**Fig. 3.2** Distribution of test results in healthy and diseased individuals. Varying the cutoff between “normal” and “abnormal” across the continuous range of

possible values changes the relative proportions of false positives (FPs) and false negatives (FNs) for the two populations

In this section, we summarized subjective and objective methods to determine the pretest probability, and we learned how to adjust the pretest probability after assessing the specific subpopulation of which the patient is representative. The next step in the diagnostic process is to gather further information, usually in the form of formal diagnostic tests (laboratory tests, X-ray studies, etc.). To help you to understand this step more clearly, we discuss in the next two sections how to measure the accuracy of tests and how to use probability to interpret the results of the tests.

### 3.3 Measurement of the Operating Characteristics of Diagnostic Tests

The first challenge in assessing any test is to determine criteria for deciding whether a result is normal or abnormal. In this section, we present the issues that you need to consider when making such a determination.

#### 3.3.1 Classification of Test Results as Abnormal

Most biological measurements in a population of healthy people are continuous variables that assume different values for different

individuals. The distribution of values often is approximated by the normal (gaussian, or bell-shaped) distribution curve (Fig. 3.2). Thus, 95% of the population will fall within two standard deviations of the mean. About 2.5% of the population will be more than two standard deviations from the mean at each end of the distribution. The distribution of values for ill individuals may be normally distributed as well. The two distributions usually overlap (see Fig. 3.2).

How is a test result classified as abnormal? Most clinical laboratories report an “upper limit of normal,” which usually is defined as two standard deviations above the mean. Thus, a test result greater than two standard deviations above the mean is reported as abnormal (or positive); a test result below that cutoff is reported as normal (or negative). As an example, if the mean cholesterol concentration in the blood is 180 mg/dl, a clinical laboratory might choose as the upper limit of normal 220 mg/dl because it is two standard deviations above the mean. Note that a cutoff that is based on an arbitrary statistical criterion may not have biological significance.

An ideal test would have no values at which the distribution of diseased and non-diseased people overlap. That is, if the cutoff value were set appropriately, the test would be normal in all healthy individuals and abnormal in all individuals with disease. Few tests meet this standard. If a test result is defined as

abnormal by the statistical criterion, 2.5% of healthy individuals will have an abnormal test. If there is an overlap in the distribution of test results in healthy and diseased individuals, some diseased patients will have a normal test (see [■ Fig. 3.2](#)). You should be familiar with the terms used to denote these groups:

- A **true positive** (TP) is a positive test result obtained for a patient in whom the disease is present (the test result correctly classifies the patient as having the disease).
- A **true negative** (TN) is a negative test result obtained for a patient in whom the disease is absent (the test result correctly classifies the patient as not having the disease).
- A **false positive** (FP) is a positive test result obtained for a patient in whom the disease is absent (the test result incorrectly classifies the patient as having the disease).
- A **false negative** (FN) is a negative test result obtained for a patient in whom the disease is present (the test result incorrectly classifies the patient as not having the disease).

[■](#) Figure 3.2 shows that varying the cutoff point (moving the vertical line in the figure) for an abnormal test will change the relative proportions of these groups. As the cutoff is moved further up from the mean of the normal values, the number of FNs increases and the number of FPs decreases. Once we have chosen a cutoff point, we can conveniently summarize test performance—the ability to discriminate disease from nondisease—in a  $2 \times 2$  **contingency table**, as shown in [■ Table 3.3](#). The table summarizes the number of patients in each group: TP, FP, TN, and FN. Note that the sum of the first column is the total number of diseased patients, TP + FN. The sum of the second column is the total number of nondiseased patients, FP + TN. The sum of the first row, TP + FP, is the total number of patients with a positive test result. Likewise, FN + TN gives the total number of patients with a negative test result.

A perfect test would have no FN or FP results. Erroneous test results do occur, however, and you can use a  $2 \times 2$  contingency table to define the measures of test performance that reflect these errors.

### 3.3.2 Measures of Test Performance

Measures of test performance are of two types: measures of agreement between tests or **measures of concordance**, and measures of disagreement or **measures of discordance**. Two types of **concordant test results** occur in the  $2 \times 2$  table in [■ Table 3.3](#): TPs and TNs. The relative frequencies of these results form the basis of the measures of concordance. These measures correspond to the ideas of the sensitivity and specificity of a test, which we introduced in [▶ Chap. 2](#). We define each measure in terms of the  $2 \times 2$  table and in terms of conditional probabilities.

The **true-positive rate** (TPR), or **sensitivity**, is the likelihood that a diseased patient has a positive test. In conditional-probability notation, sensitivity is expressed as the probability of a positive test given that disease is present:

$$p[\text{positive test}|\text{disease}].$$

Another way to think of the TPR is as a ratio. The likelihood that a diseased patient has a positive test is given by the ratio of diseased

[■ Table 3.3](#) A  $2 \times 2$  contingency table for test results

Results of test	Disease present	Disease absent	Total
Positive result	TP	FP	TP + FP
Negative result	FN	TN	FN + TN
	TP + FN	FP + TN	

*TP* true positive, *TN* true negative, *FP* false positive, *FN* false negative

patients with a positive test to all diseased patients:

$$\text{TPR} = \left( \frac{\text{number of diseased patients with positive test}}{\text{total number of diseased patients}} \right).$$

We can determine these numbers for our example from the  $2 \times 2$  table (see Table 3.3). The number of diseased patients with a positive test is TP. The total number of diseased patients is the sum of the first column, TP + FN. So,

$$\text{TPR} = \frac{\text{TP}}{\text{TP} + \text{FN}}.$$

The **true-negative rate** (TNR), or **specificity**, is the likelihood that a nondiseased patient has a negative test result. In terms of conditional probability, specificity is the probability of a negative test given that disease is absent:

$$p[\text{negative test} | \text{no disease}].$$

Viewed as a ratio, the TNR is the number of nondiseased patients with a negative test divided by the total number of nondiseased patients:

$$\text{TNR} = \left( \frac{\text{Number of nondiseased patients with negative test}}{\text{Total number of nondiseased patients}} \right)$$

From the  $2 \times 2$  table (see Table 3.3),

$$\text{TNR} = \frac{\text{TN}}{\text{TN} + \text{FP}}$$

The measures of discordance—the **false-positive rate** (FPR) and the **false-negative rate** (FNR)—are defined similarly. The FNR is the likelihood that a diseased patient has a negative test result. As a ratio,

$$\begin{aligned} \text{FNR} &= \left( \frac{\text{Number of diseased patients with negative test}}{\text{Total number of diseased patients}} \right) \\ &= \frac{\text{FN}}{\text{FN} + \text{TP}}. \end{aligned}$$

Table 3.4 A  $2 \times 2$  contingency table for HIV antibody EIA

EIA test result	Antibody present	Antibody absent	Total
Positive EIA	98	3	101
Negative EIA	2	297	299
	100	300	

*EIA* enzyme-linked immunoassay

The FPR is the likelihood that a nondiseased patient has a positive test result:

$$\begin{aligned} \text{FPR} &= \left( \frac{\text{Number of nondiseased patients with positive test}}{\text{Total number of nondiseased patients}} \right) \\ &= \frac{\text{FP}}{\text{FP} + \text{TN}} \end{aligned}$$

#### Example 3.6

Consider again the problem of screening blood donors for HIV. One test used to screen blood donors for HIV antibody is an enzyme-linked immunoassay (EIA). So that the performance of the EIA can be measured, the test is performed on 400 patients; the hypothetical results are shown in the  $2 \times 2$  table in Table 3.4.<sup>5</sup> ◀

To determine test performance, we calculate the TPR (sensitivity) and TNR (specificity) of the EIA antibody test. The TPR, as defined previously, is:

$$\frac{\text{TP}}{\text{TP} + \text{FN}} = \frac{98}{98 + 2} = 0.98$$

Thus, the likelihood that a patient with the HIV antibody will have a positive EIA test is

5 This example assumes that we have a perfect method (different from EIA) for determining the presence or absence of antibody. We discuss the idea of gold-standard tests in ▶ Sect. 3.3.4. We have chosen the numbers in the example to simplify the calculations. In practice, the sensitivity and specificity of the HIV EIAs are greater than 99%.

0.98. If the test were performed on 100 patients who truly had the antibody, we would expect the test to be positive in 98 of the patients. Conversely, we would expect two of the patients to receive incorrect, negative results, for an FNR of 2%. (You should convince yourself that the sum of TPR and FNR by definition must be 1:  $TPR + FNR = 1$ ).

And the TNR is:

$$\frac{TN}{TN + FP} = \frac{297}{297 + 3} = 0.99$$

The likelihood that a patient who has no HIV antibody will have a negative test is 0.99. Therefore, if the EIA test were performed on 100 individuals who had not been infected with HIV, it would be negative in 99 and incorrectly positive in 1. (Convince yourself that the sum of TNR and FPR also must be 1:  $TNR + FPR = 1$ ).

### 3.3.3 Implications of Sensitivity and Specificity: How to Choose Among Tests

It may be clear to you already that the calculated values of sensitivity and specificity for a continuous-valued test depend on the particular cutoff value chosen to distinguish normal and abnormal results. In Fig. 3.2, note that increasing the cutoff level (moving it to the right) would decrease significantly the number of FP tests but also would increase the number of FN tests. Thus, the test would have become more specific but less sensitive. Similarly, a lower cutoff value would increase the FPs and decrease the FNs, thereby increasing sensitivity while decreasing specificity. Whenever a decision is made about what cutoff to use in calling a test abnormal, an inherent philosophical decision is being made about whether it is better to tolerate FNs (missed cases) or FPs (nondiseased people inappropriately classified as diseased). The choice of cutoff depends on the disease in question and on the purpose of testing. If the disease is serious and if lifesaving therapy is available, we should try to minimize the number of FN results. On the other hand, if the disease is not serious

and the therapy is dangerous, we should set the cutoff value to minimize FP results.

We stress the point that sensitivity and specificity are characteristics not of a test per se but rather of the test and a criterion for when to call that test abnormal. Varying the cutoff in Fig. 3.2 has no effect on the test itself (the way it is performed, or the specific values for any particular patient); instead, it trades off specificity for sensitivity. Thus, the best way to characterize a test is by the range of values of sensitivity and specificity that it can take on over a range of possible cutoffs. The typical way to show this relationship is to plot the test's sensitivity against 1 minus specificity (i.e., the TPR against the FPR), as the cutoff is varied and the two test characteristics are traded off against each other (Fig. 3.3). The resulting curve, known as a **receiver-operating characteristic (ROC) curve**, was originally described by researchers investigating methods of electromagnetic-signal detection and was later applied to the field of psychology (Peterson and Birdsall 1953; Swets 1973). Any given point along a ROC curve for a test corresponds to the test sensitivity and specificity for a given threshold of "abnormality." Similar curves can be drawn for any test used to associate ob-

Fig. 3.3 Receiver operating characteristic (ROC) curves for two hypothetical tests. Test B is more discriminative than test A because its curve is higher (e.g., the false-positive rate (FPR) for test B is lower than the FPR for test A at any value of true-positive rate (TPR)). However, the more discriminative test may not always be preferred in clinical practice (see text)

served clinical data with specific diseases or disease categories.

Suppose a new test were introduced that competed with the current way of screening for the presence of a disease. For example, suppose a new radiologic procedure for assessing the presence or absence of pneumonia became available. This new test could be assessed for trade-offs in sensitivity and specificity, and an ROC curve could be drawn. As shown in  Fig. 3.3, a test has better discriminating power than a competing test if its ROC curve lies above that of the other test. In other words, test B is more discriminating than test A when its specificity is greater than test A's specificity for any level of sensitivity (and when its sensitivity is greater than test A's sensitivity for any level of specificity).

Understanding ROC curves is important in understanding test selection and data interpretation. Clinicians should not necessarily, however, always choose the test with the most discriminating ROC curve. Matters of cost, risk, discomfort, and delay also are important in the choice about what data to collect and what tests to perform. When you must choose among several available tests, you should select the test that has the highest sensitivity and specificity, provided that other factors, such as cost and risk to the patient, are equal. The higher the sensitivity and specificity of a test, the more the results of that test will reduce uncertainty about probability of disease.

### 3.3.4 Design of Studies of Test Performance

In  Sect. 3.3.2, we discussed measures of test performance: a test's ability to discriminate disease from no disease. When we classify a test result as TP, TN, FP, or FN, we assume that we know with certainty whether a patient is diseased or healthy. Thus, the validity of any test's results must be measured against a gold standard: a test that reveals the patient's true disease state, such as a biopsy of diseased tissue or a surgical operation. A **gold-standard test** is a procedure that is used to define unequivocally the presence or absence of disease. The test whose discrimination is being measured is called the

**index test**. The gold-standard test usually is more expensive, riskier, or more difficult to perform than is the index test (otherwise, the less precise test would not be used at all).

The performance of the index test is measured in a small, select group of patients enrolled in a study. We are interested, however, in how the test performs in the broader group of patients in which it will be used in practice. The test may perform differently in the two groups, so we make the following distinction: the **study population** comprises those patients (usually a subset of the clinically relevant population) in whom test discrimination is measured and reported; the **clinically relevant population** comprises those patients in whom a test typically is used.

### 3.3.5 Bias in the Measurement of Test Characteristics

We mentioned earlier the problem of referral bias. Published estimates of disease prevalence (derived from a study population) may differ from the prevalence in the clinically relevant population because diseased patients are more likely to be included in studies than are nondiseased patients. Similarly, published values of sensitivity and specificity are derived from study populations that may differ from the clinically relevant populations in terms of average level of health and disease prevalence. These differences may affect test performance, so the reported values may not apply to many patients in whom a test is used in clinical practice.

#### Example 3.7

In the early 1970s, a blood test called the carcinoembryonic antigen (CEA) was touted as a screening test for colon cancer. Reports of early investigations, performed in selected patients, indicated that the test had high sensitivity and specificity. Subsequent work, however, proved the CEA to be completely valueless as a screening blood test for colon cancer. Screening tests are used in unselected populations, and the differences between the study and clinically relevant populations were partly responsible for the original miscalculations of the CEA's TPR and TNR (Ransohoff and Feinstein 1978). 

The experience with CEA has been repeated with numerous tests. Early measures of test discrimination are overly optimistic, and subsequent test performance is disappointing. Problems arise when the TPR and TNR, as measured in the study population, do not apply to the clinically relevant population. These problems usually are the result of bias in the design of the initial studies—notably spectrum bias, test referral bias, or test interpretation bias.

**Spectrum bias** occurs when the study population includes only individuals who have advanced disease (“sickest of the sick”) and healthy volunteers, as is often the case when a test is first being developed. Advanced disease may be easier to detect than early disease. For example, cancer is easier to detect when it has spread throughout the body (metastasized) than when it is localized to, say, a small portion of the colon. In contrast to the study population, the clinically relevant population will contain more cases of early disease that are more likely to be missed by the index test (FNs). Thus, the study population will have an artifactually low FNR, which produces an artifactually high TPR ( $TPR = 1 - FNR$ ). In addition, healthy volunteers are less likely than are patients in the clinically relevant population to have other diseases that may cause FP results<sup>6</sup>; the study population will have an artifactually low FPR, and therefore the specificity will be overestimated ( $TNR = 1 - FPR$ ). Inaccuracies in early estimates of the TPR and TNR of the CEA were partly due to spectrum bias.

**Test-referral bias** (sometimes referred to as referral bias) occurs when a positive index test is a criterion for ordering the gold standard test. In clinical practice, patients with negative index tests are less likely to undergo the gold

standard test than are patients with positive tests. In other words, the study population, comprising individuals with positive index–test results, has a higher percentage of patients with disease than does the clinically relevant population. Therefore, both TN and FN tests will be underrepresented in the study population. The result is overestimation of the TPR and underestimation of the TNR in the study population.

**Test-interpretation bias** develops when the interpretation of the index test affects that of the gold standard test or vice versa. This bias causes an artificial concordance between the tests (the results are more likely to be the same) and spuriously increases measures of concordance—the sensitivity and specificity—in the study population. (Remember, the relative frequencies of TPs and TNs are the basis for measures of concordance). To avoid these problems, the person interpreting the index test should be unaware of the results of the gold standard test.

To counter these three biases, you may need to adjust the TPR and TNR when they are applied to a new population. All the biases result in a TPR that is higher in the study population than it is in the clinically relevant population. Thus, if you suspect bias, you should adjust the TPR (sensitivity) downward when you apply it to a new population.

Adjustment of the TNR (specificity) depends on which type of bias is present. Spectrum bias and test interpretation bias result in a TNR that is higher in the study population than it will be in the clinically relevant population. Thus, if these biases are present, you should adjust the specificity downward when you apply it to a new population. Test-referral bias, on the other hand, produces a measured specificity in the study population that is lower than it will be in the clinically relevant population. If you suspect test referral bias, you should adjust the specificity upward when you apply it to a new population.

### 3.3.6 Meta-Analysis of Diagnostic Tests

Often, there are many studies that evaluate the sensitivity and specificity of the same diagnostic test. If the studies come to similar conclusions

6 Volunteers are often healthy, whereas patients in the clinically relevant population often have several diseases in addition to the disease for which a test is designed. These other diseases may cause FP test results. For example, patients with benign (rather than malignant) enlargement of their prostate glands are more likely than are healthy volunteers to have FP elevations of prostate-specific antigen (Meigs et al. 1996), a substance in the blood that is elevated in men who have prostate cancer. Measurement of prostate-specific antigen is often used to detect prostate cancer.

about the sensitivity and specificity of the test, you can have increased confidence in the results of the studies. But what if the studies disagree? For example, by 1995, over 100 studies had assessed the sensitivity and specificity of the PCR for diagnosis of HIV (Owens et al. 1996a, b); these studies estimated the sensitivity of PCR to be as low as 10% and to be as high as 100%, and they assessed the specificity of PCR to be between 40 and 100%. Which results should you believe? One approach that you can use is to assess the quality of the studies and to use the estimates from the highest-quality studies.

For evaluation of PCR, however, even the high-quality studies did not agree. Another approach is to perform a **meta-analysis**: a study that combines quantitatively the estimates from individual studies to develop a **summary ROC curve** (Moses et al. 1993; Owens et al. 1996a, b; Hellmich et al. 1999; Leeflang et al. 2008; Leeflang 2014). Investigators develop a summary ROC curve by using estimates from many studies, in contrast to the type of ROC curve discussed in ► Sect. 3.3.3, which is developed from the data in a single study. Summary ROC curves provide the best available approach to synthesizing data from many studies.

► Section 3.3 dealt with the second step in the diagnostic process: acquisition of further information with diagnostic tests. We have learned how to characterize the performance of a test with sensitivity (TPR) and specificity (TNR). These measures reveal the probability of a test result given the true state of the patient. They do not, however, answer the clinically relevant question posed in the opening example: Given a positive test result, what is the probability that this patient has the disease? To answer this question, we must learn methods to calculate the post-test probability of disease.

### 3.4 Post-test Probability: Bayes' Theorem and Predictive Value

The third stage of the diagnostic process (see ► Fig. 3.1a) is to adjust our probability estimate to take into account the new information gained from diagnostic tests by calculating the post-test probability.

#### 3.4.1 Bayes' Theorem

As we noted earlier in this chapter, a clinician can use the disease prevalence in the patient population as an initial estimate of the pretest risk of disease. Once clinicians begin to accumulate information about a patient, however, they revise their estimate of the probability of disease. The revised estimate (rather than the disease prevalence in the general population) becomes the pretest probability for the test that they perform. After they have gathered more information with a diagnostic test, they can calculate the post-test probability of disease with Bayes' theorem.

**Bayes' theorem** is a quantitative method for calculating post-test probability using the pretest probability and the sensitivity and specificity of the test. The theorem is derived from the definition of conditional probability and from the properties of probability (see the Appendix to this chapter for the derivation).

Recall that a conditional probability is the probability that event A will occur given that event B is known to occur (see ► Sect. 3.2). In general, we want to know the probability that disease is present (event A), given that the test is known to be positive (event B). We denote the presence of disease as D, its absence as  $-D$ , a test result as R, and the pretest probability of disease as  $p[D]$ . The probability of disease, given a test result, is written  $p[D|R]$ . Bayes' theorem is:

$$p[D|R] = \frac{p[D] \times p[R|D]}{p[D] \times p[R|D] + p[-D] \times p[R|-D]}$$

We can reformulate this general equation in terms of a positive test, (+), by substituting  $p[D|+]$  for  $p[D|R]$ ,  $p[+|D]$  for  $p[R|D]$ ,  $p[+|-D]$  for  $p[R|-D]$ , and  $1 - p[D]$  for  $p[-D]$ . From ► Sect. 3.3, recall that  $p[+|D] = \text{TPR}$  and  $p[+|-D] = \text{FPR}$ . Substitution provides Bayes' theorem for a positive test:

$$p[D|+] = \frac{p[D] \times \text{TPR}}{p[D] \times \text{TPR} + (1 - p[D]) \times \text{FPR}}$$

We can use a similar derivation to develop Bayes' theorem for a negative test:

$$p[D|-] = \frac{p[D] \times \text{FNR}}{p[D] \times \text{FNR} + (1 - p[D]) \times \text{TNR}}$$

► Example 3.8

We are now able to calculate the clinically important probability in ► Example 3.4: the post-test probability of heart disease after a positive exercise test. At the end of ► Sect. 3.2.2, we estimated the pretest probability of heart disease as 0.95, based on the prevalence of heart disease in men who have typical symptoms of heart disease and on the prevalence in people with a family history of heart disease. Assume that the TPR and FPR of the exercise stress test are 0.65 and 0.20, respectively. Substituting in Bayes' formula for a positive test, we obtain the probability of heart disease given a positive test result:

$$p[D|+] = \frac{0.95 \times 0.65}{0.95 \times 0.65 + 0.05 \times 0.20} = 0.98 \quad \blacktriangleleft$$

Thus, the positive test raised the post-test probability to 0.98 from the pretest probability of 0.95. The change in probability is modest because the pretest probability was high (0.95) and because the FPR also is high (0.20). If we repeat the calculation with a pretest probability of 0.75, the post-test probability is 0.91. If we assume the FPR of the test to be 0.05 instead of 0.20, a pretest probability of 0.95 changes to 0.996.

### 3.4.2 The Odds-Ratio Form of Bayes' Theorem and Likelihood Ratios

Although the formula for Bayes' theorem is straightforward, it is awkward for mental calculations. We can develop a more convenient form of Bayes' theorem by expressing probability as odds and by using a different measure of test discrimination. Probability and odds are related as follows:

$$\text{odds} = \frac{p}{1-p},$$

$$p = \frac{\text{odds}}{1 + \text{odds}}.$$

Thus, if the probability of rain today is 0.75, the odds are 3:1. Thus, on similar days, we should expect rain to occur three times for each time it does not occur.

A simple relationship exists between pre-test odds and post-test odds:

post-test odds = pretest odds × likelihood ratio

or

$$\frac{p[D|R]}{p[-D|R]} = \frac{p[D]}{p[-D]} \times \frac{p[R|D]}{p[R|-D]}.$$

This equation is the **odds-ratio form** of Bayes' theorem.<sup>7</sup> It can be derived in a straightforward fashion from the definitions of Bayes' theorem and of conditional probability that we provided earlier. Thus, to obtain the post-test odds, we simply multiply the pre-test odds by the **likelihood ratio** (LR) for the test in question.

The LR of a test combines the measures of test discrimination discussed earlier to give one number that characterizes the discriminatory power of a test, defined as:

$$LR = \frac{p[R|D]}{p[R|-D]}$$

or

$$LR = \frac{\text{probability of result in diseased people}}{\text{probability of result in nondiseased people}}$$

The LR indicates the amount that the odds of disease change based on the test result. We can use the LR to characterize clinical findings (such as a swollen leg) or a test result. We describe the performance of a test that has only two possible outcomes (e.g., positive or negative) by two LRs: one corresponding to a positive test result and the other corresponding to a negative test. These ratios are abbreviated LR+ and LR−, respectively.

$$LR+ = \left( \frac{\text{probability that test is positive in diseased people}}{\text{probability that test is positive in nondiseased people}} \right) = \frac{TPR}{FPR}$$

<sup>7</sup> Some authors refer to this expression as the odds-likelihood form of Bayes' theorem.

In a test that discriminates well between disease and nondisease, the TPR will be high, the FPR will be low, and thus LR+ will be much greater than 1. A LR of 1 means that the probability of a test result is the same in diseased and nondiseased individuals; the test has no value. Similarly,

$$\text{LR-} = \frac{\left( \begin{array}{l} \text{probability that test} \\ \text{is negative in} \\ \text{diseased people} \end{array} \right)}{\left( \begin{array}{l} \text{probability that test} \\ \text{is negative in} \\ \text{nondiseased people} \end{array} \right)} = \frac{\text{FNR}}{\text{TNR}}$$

A desirable test will have a low FNR and a high TNR; therefore, the LR- will be much less than 1.

#### ► Example 3.9

We can calculate the post-test probability for a positive exercise stress test in a 70 year-old woman whose pretest probability is 0.75. The pretest odds are:

$$\text{odds} = \frac{p}{1-p} = \frac{0.75}{1-0.75} = \frac{0.75}{0.25} = 3, \text{ or } 3:1$$

The LR for the stress test is:

$$\text{LR+} = \frac{\text{TPR}}{\text{FPR}} = \frac{0.65}{0.20} = 3.25$$

We can calculate the post-test odds of a positive test result using the odds-ratio form of Bayes' theorem:

$$\text{post-test odds} = 3 \times 3.25 = 9.75 : 1$$

We can then convert the odds to a probability:

$$p = \frac{\text{odds}}{1 + \text{odds}} = \frac{9.75}{1 + 9.75} = 0.91 \quad \blacktriangleleft$$

As expected, this result agrees with our earlier answer (see the discussion of ► Example 3.8).

The odds-ratio form of Bayes' theorem allows rapid calculation. The LR is a powerful method for characterizing the operating characteristics of a test: if you know the pretest odds, you can calculate the post-test odds in one step. The LR demonstrates that a useful test is one that changes the odds of disease.

### 3.4.3 Predictive Value of a Test

An alternative approach for estimation of the probability of disease in a person who has a positive or negative test is to calculate the predictive value of the test. The **positive predictive value** (PV+) of a test is the likelihood that a patient who has a positive test result also has disease. Thus, PV+ can be calculated directly from a 2 × 2 contingency table:

$$\text{PV+} = \frac{\begin{array}{l} \text{number of diseased patients} \\ \text{with positive test} \end{array}}{\begin{array}{l} \text{total number of patients} \\ \text{with a positive test} \end{array}}$$

From the 2 × 2 contingency table in ■ Table 3.3,

$$\text{PV+} = \frac{\text{TP}}{\text{TP} + \text{FP}}$$

The **negative predictive value** (PV-) is the likelihood that a patient with a negative test does not have disease:

$$\text{PV-} = \frac{\begin{array}{l} \text{number of nondiseased patients} \\ \text{with negative test} \end{array}}{\begin{array}{l} \text{Total number of patients} \\ \text{with a negative test} \end{array}}$$

From the 2 × 2 contingency table in ■ Table 3.3,

$$\text{PV-} = \frac{\text{TN}}{\text{TN} + \text{FN}}$$

#### ► Example 3.10

We can calculate the PV of the EIA test from the 2 × 2 table that we constructed in ► Example 3.6 (see ■ Table 3.4) as follows:

$$\text{PV+} = \frac{98}{98 + 3} = 0.97$$

$$\text{PV-} = \frac{297}{297 + 2} = 0.99 \quad \blacktriangleleft$$

The probability that antibody is present in a patient who has a positive index test (EIA) in this study is 0.97; about 97 of 100 patients with a positive test will have antibody. The likelihood that a patient with a negative index test does not have antibody is about 0.99. ◀

It is worth reemphasizing the difference between PV and sensitivity and specificity, given that both are calculated from the  $2 \times 2$  table and they often are confused. The sensitivity and specificity give the probability of a particular test result in a patient who has a particular disease state. The PV gives the probability of true disease state once the patient's test result is known.

The PV+ calculated from Table 3.4 is 0.97, so we expect 97 of 100 patients with a positive index test actually to have antibody. Yet, in Example 3.1, we found that fewer than one of ten patients with a positive test were expected to have antibody. What explains the discrepancy in these examples? The sensitivity and specificity (and, therefore, the LR<sub>s</sub>) in the two examples are identical. The discrepancy is due to an extremely important and often overlooked characteristic of PV: the PV of a test depends on the prevalence of disease in the study population (the prevalence can be calculated as TP + FN divided by the total number of patients in the  $2 \times 2$  table). The PV cannot be generalized to a new population because the prevalence of disease may differ between the two populations.

The difference in PV of the EIA in Example 3.1 and in Example 3.6 is due to a difference in the prevalence of disease in the examples. The prevalence of antibody was given as 0.001 in Example 3.1 and as 0.25 in Example 3.6. These examples should remind us that the PV+ is not an intrinsic property of a test. Rather, it represents the post-test probability of disease only when the prevalence is identical to that in the  $2 \times 2$  contingency table from which the PV+ was calculated. Bayes' theorem provides a method for calculation of the post-test probability of disease for any prior probability. For that reason, we prefer the use of Bayes' theorem to calculate the post-test probability of disease.

### 3.4.4 Implications of Bayes' Theorem

In this section, we explore the implications of Bayes' theorem for test interpretation. These ideas are extremely important, yet they often are misunderstood.

Figure 3.4 illustrates one of the most essential concepts in this chapter: The post-test

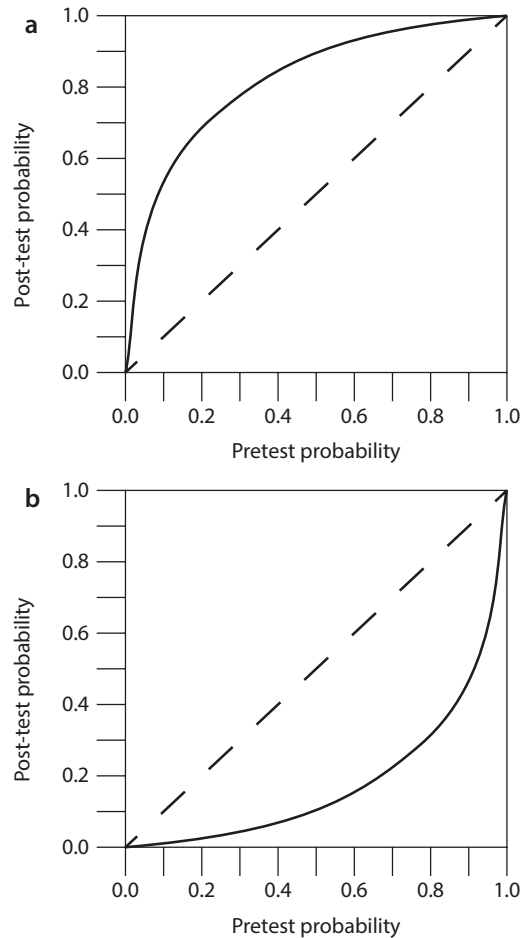

Fig. 3.4 Relationship between pretest probability and post-test probability of disease. The dashed lines correspond to a test that has no effect on the probability of disease. Sensitivity and specificity of the test were assumed to be 0.90 for the two examples. a The post-test probability of disease corresponding to a positive test result (solid curve) was calculated with Bayes' theorem for all values of pretest probability. b The post-test probability of disease corresponding to a negative test result (solid curve) was calculated with Bayes' theorem for all values of pretest probability. (Source: Adapted from Sox (1987), with permission)

probability of disease increases as the pretest probability of disease increases. We produced Fig. 3.4a by calculating the post-test probability after a positive test result for all possible pretest probabilities of disease. We similarly derived Fig. 3.4b for a negative test result.

The 45-degree line in each figure denotes a test in which the pretest and post-test probability are equal (LR = 1), indicating a test that

is useless. The curve in [Fig. 3.4a](#) relates pretest and post-test probabilities in a test with a sensitivity and specificity of 0.9. Note that, at low pretest probabilities, the post-test probability after a positive test result is much higher than is the pretest probability. At high pretest probabilities, the post-test probability is only slightly higher than the pretest probability.

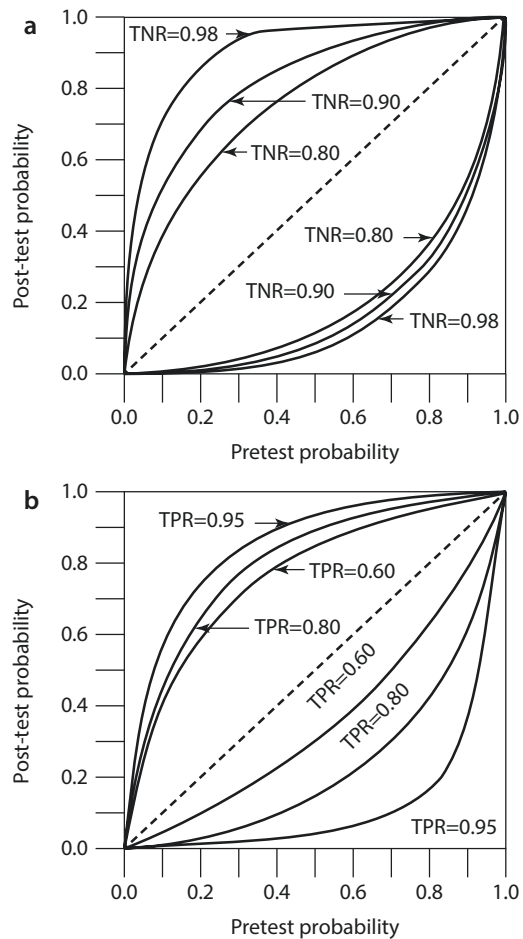

[Figure 3.4b](#) shows the relationship between the pretest and post-test probabilities after a negative test result. At high pretest probabilities, the post-test probability after a negative test result is much lower than is the pretest probability. A negative test, however, has little effect on the post-test probability if the pretest probability is low.

This discussion emphasizes a key idea of this chapter: the interpretation of a test result depends on the pretest probability of disease. If the pretest probability is low, a positive test result has a large effect, and a negative test result has a small effect. If the pretest probability is high, a positive test result has a small effect, and a negative test result has a large effect. In other words, when the clinician is almost certain of the diagnosis before testing (pretest probability nearly 0 or nearly 1), a confirmatory test has little effect on the posterior probability (see [Example 3.8](#)). If the pretest probability is intermediate or if the result contradicts a strongly held clinical impression, the test result will have a large effect on the post-test probability.

Note from [Fig. 3.4a](#) that, if the pretest probability is very low, a positive test result can raise the post-test probability into only the intermediate range. Assume that [Fig. 3.4a](#) represents the relationship between the pretest and post-test probabilities for the exercise stress test. If the clinician believes the pretest probability of coronary artery disease is 0.1, the post-test probability will be about 0.5. Although there has been a large change in the probability, the post-test probability is in an intermediate range, which leaves considerable uncertainty about the diagnosis. Thus, if the pretest probability is low, it is unlikely that a positive test result will raise the probability of disease sufficiently for the clinician to make that diagnosis with confidence. An exception to this statement occurs when a test has a very high specificity (or a large LR+); e.g., HIV an-

tibody tests have a specificity greater than 0.99, and therefore a positive test is convincing. Similarly, if the pretest probability is very high, it is unlikely that a negative test result will lower the post-test probability sufficiently to exclude a diagnosis.

[Figure 3.5](#) illustrates another important concept: test specificity affects primarily the in-

**Fig. 3.5** Effects of test sensitivity and specificity on post-test probability. The curves are similar to those shown in [Fig. 3.4](#) except that the calculations have been repeated for several values of the sensitivity ( $TPR$  true-positive rate) and specificity ( $TNR$  true-negative rate) of the test. **a** The sensitivity of the test was assumed to be 0.90, and the calculations were repeated for several values of test specificity. **b** The specificity of the test was assumed to be 0.90, and the calculations were repeated for several values of the sensitivity of the test. In both panels, the top family of curves corresponds to positive test results, and the bottom family of curves corresponds to negative test results. (Source: Adapted from Sox (1987), with permission)

3 interpretation of a positive test; test sensitivity affects primarily the interpretation of a negative test. In both parts (a) and (b) of **Fig. 3.5**, the top family of curves corresponds to positive test results and the bottom family to negative test results. **Figure 3.5a** shows the post-test probabilities for tests with varying specificities (TNR). Note that changes in the specificity produce large changes in the top family of curves (positive test results) but have little effect on the lower family of curves (negative test results). That is, an increase in the specificity of a test markedly changes the post-test probability if the test is positive but has relatively little effect on the post-test probability if the test is negative. Thus, if you are trying to rule in a diagnosis,<sup>8</sup> you should choose a test with high specificity or a high LR+. **Figure 3.5b** shows the post-test probabilities for tests with varying sensitivities. Note that changes in sensitivity produce large changes in the bottom family of curves (negative test results) but have little effect on the top family of curves. Thus, if you are trying to exclude a disease, choose a test with a high sensitivity or a high LR-.

### 3.4.5 Cautions in the Application of Bayes' Theorem

Bayes' theorem provides a powerful method for calculating post-test probability. You should be aware, however, of the possible errors you can make when you use it. Common problems

are inaccurate estimation of pretest probability, faulty application of test-performance measures, and violation of the assumptions of conditional independence and of mutual exclusivity.

Bayes' theorem provides a means to adjust an estimate of pretest probability to take into account new information. The accuracy of the calculated post-test probability is limited, however, by the accuracy of the estimated pretest probability. Accuracy of estimated prior probability is increased by proper use of published prevalence rates, heuristics, and clinical prediction rules. In a decision analysis, as we shall see, a range of prior probability often is sufficient. Nonetheless, if the pretest probability assessment is unreliable, Bayes' theorem will be of little value.

A second potential mistake that you can make when using Bayes' theorem is to apply published values for the test sensitivity and specificity, or LRs, without paying attention to the possible effects of bias in the studies in which the test performance was measured (see **► Sect. 3.3.5**). With certain tests, the LRs may differ depending on the pretest odds in part because differences in pretest odds may reflect differences in the spectrum of disease in the population.

A third potential problem arises when you use Bayes' theorem to interpret a sequence of tests. If a patient undergoes two tests in sequence, you can use the post-test probability after the first test result, calculated with Bayes' theorem, as the pretest probability for the second test. Then, you use Bayes' theorem a second time to calculate the post-test probability after the second test. This approach is valid, however, only if the two tests are conditionally independent. Tests for the same disease are **conditionally independent** when the probability of a particular result on the second test does not depend on the result of the first test, given (conditioned on) the disease state. Expressed in conditional probability notation for the case in which the disease is present,

8 In medicine, to *rule in* a disease is to confirm that the patient *does* have the disease; to *rule out* a disease is to confirm that the patient *does not* have the disease. A doctor who strongly suspects that his or her patient has a bacterial infection orders a culture to *rule in* his or her diagnosis. Another doctor is almost certain that his or her patient has a simple sore throat but orders a culture to rule out streptococcal infection (strep throat). This terminology oversimplifies a diagnostic process that is probabilistic. Diagnostic tests rarely, if ever, rule in or rule out a disease; rather, the tests raise or lower the probability of disease.

$$\begin{aligned}
 & p[\text{second test positive}|\text{first test positive and disease present}] \\
 &= p[\text{second test positive}|\text{first test negative and disease present}] \\
 &= p[\text{second test positive}|\text{disease present}].
 \end{aligned}$$

If the conditional independence assumption is satisfied, the post-test odds = pretest odds  $\times$  LR1  $\times$  LR2. If you apply Bayes' theorem sequentially in situations in which conditional independence is violated, you will obtain inaccurate post-test probabilities.

The fourth common problem arises when you assume that all test abnormalities result from one (and only one) disease process. The Bayesian approach, as we have described it, generally presumes that the diseases under consideration are **mutually exclusive**. If they are not, Bayesian updating must be applied with great care.

We have shown how to calculate post-test probability. In ▶ Sect. 3.5, we turn to the problem of decision making when the outcomes of a clinician's actions (e.g., of treatments) are uncertain.

### 3.5 Expected-Value Decision Making

Medical decision-making problems often cannot be solved by reasoning based on pathophysiology. For example, clinicians need a method for choosing among treatments when the outcome of the treatments is uncertain, as are the results of a surgical operation. You can

use the ideas developed in the preceding sections to solve such difficult decision problems. Here we discuss two methods: the decision tree, a method for representing and comparing the expected outcomes of each decision alternative; and the threshold probability, a method for deciding whether new information can change a management decision. These techniques help you to clarify the decision problem and thus to choose the alternative that is most likely to help the patient.

#### 3.5.1 Comparison of Uncertain Prospects

Like those of most biological events, the outcome of an individual's illness is unpredictable. How can a clinician determine which course of action has the greatest chance of success?

##### ▶ Example 3.11

There are two available therapies for a fatal illness. The length of a patient's life after either therapy is unpredictable, as illustrated by the frequency distribution shown in Fig. 3.6 and summarized in Table 3.5. Each therapy is associated with uncertainty: regardless of which therapy a patient receives, the patient will die by the end of the fourth year, but there is no way to know which

■ Fig. 3.6 Survival after therapy for a fatal disease. Two therapies are available; the results of either are unpredictable

**Table 3.5** Distribution of probabilities for the two therapies in [Fig. 3.7](#)

Years after therapy	Probability of death	
	Therapy A	Therapy B
1	0.20	0.05
2	0.40	0.15
3	0.30	0.45
4	0.10	0.35

year will be the patient's last. [Figure 3.6](#) shows that survival until the fourth year is more likely with therapy B, but the patient might die in the first year with therapy B or might survive to the fourth year with therapy A. ◀

Which of the two therapies is preferable? ▶ [Example 3.11](#) demonstrates a significant fact: a choice among therapies is a choice among gambles (i.e., situations in which chance determines the outcomes). How do we usually choose among gambles? More often than not, we rely on hunches or on a sixth sense. How should we choose among gambles? We propose a method for choosing called expected-value decision making: we characterize each gamble by a number, and we use that number to compare the gambles.<sup>9</sup> In [Example 3.11](#), therapy A and therapy B are both gambles with respect to duration of life after therapy. We want to assign a measure (or number) to each therapy that summarizes the outcomes such that we can decide which therapy is preferable.

The ideal criterion for choosing a gamble should be a number that reflects preferences (in medicine, often the patient's preferences) for the outcomes of the gamble. **Utility** is the name given to a measure of preference that has a desirable property for decision making: the gamble with the highest utility should be preferred. We shall discuss utility briefly ([Sect. 3.5.4](#)), but you can pursue this topic and

the details of decision analysis in other textbooks (see Suggested Readings at the end of this chapter).<sup>10</sup> We use the average duration of life after therapy (survival) as a criterion for choosing among therapies; remember that this model is oversimplified, used here for discussion only. Later, we consider other factors, such as the quality of life.

Because we cannot be sure of the duration of survival for any given patient, we characterize a therapy by the mean survival (average length of life) that would be observed in a large number of patients after they were given the therapy. The first step we take in calculating the mean survival for a therapy is to divide the population receiving the therapy into groups of patients who have similar survival rates. Then, we multiply the survival time in each group<sup>11</sup> by the fraction of the total population in that group. Finally, we sum these products over all possible survival values.

We can perform this calculation for the therapies in [Example 3.11](#). Mean survival for therapy A =  $(0.2 \times 1.0) + (0.4 \times 2.0) + (0.3 \times 3.0) + (0.1 \times 4.0) = 2.3$  years. Mean survival for therapy B =  $(0.05 \times 1.0) + (0.15 \times 2.0) + (0.45 \times 3.0) + (0.35 \times 4.0) = 3.1$  years.

Survival after a therapy is under the control of chance. Therapy A is a gamble characterized by an average survival equal to 2.3 years. Therapy B is a gamble characterized by an average survival of 3.1 years. If length of life is our criterion for choosing, we should select therapy B.

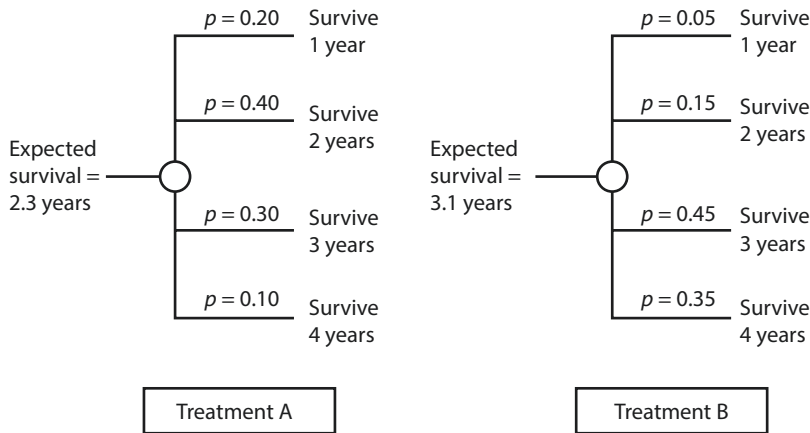

### 3.5.2 Representation of Choices with Decision Trees

The choice between therapies A and B is represented diagrammatically in [Fig. 3.7](#). Events that are under the control of chance can be represented by a **chance node**. By convention, a

<sup>9</sup> Expected-value decision making had been used in many fields before it was first applied to medicine.

<sup>10</sup> A more general term for expected-value decision making is expected utility decision making. Because a full treatment of utility is beyond the scope of this chapter, we have chosen to use the term expected value.

<sup>11</sup> For this simple example, death during an interval is assumed to occur at the end of the year.

**Fig. 3.7** A chance-node representation of survival after the two therapies in **Fig. 3.6**. The probabilities times the corresponding years of survival are summed to obtain the total expected survival

chance node is shown as a circle from which several lines emanate. Each line represents one of the possible outcomes. Associated with each line is the probability of the outcome occurring. For a single patient, only one outcome can occur. Some physicians object to using probability for just this reason: “You cannot rely on population data, because each patient is an individual.” In fact, we often must use the frequency of the outcomes of many patients experiencing the same event to inform our opinion about what might happen to an individual. From these frequencies, we can make patient-specific adjustments and thus estimate the probability of each outcome at a chance node.

A chance node can represent more than just an event governed by chance. The outcome of a chance event, unknowable for the individual, can be represented by the **expected value** at the chance node. The concept of expected value is important and is easy to understand. We can calculate the mean survival that would be expected based on the probabilities depicted by the chance node in **Fig. 3.7**. This average length of life is called the expected survival or, more generally, the expected value of the chance node. We calculate the expected value at a chance node by the process just described: we multiply the survival value associated with each possible outcome by the probability that that outcome will occur. We then sum the product of probability times survival over all outcomes. Thus, if sev-

eral hundred patients were assigned to receive either therapy A or therapy B, the expected survival would be 2.3 years for therapy A and 3.1 years for therapy B.

We have just described the basis of expected-value decision making. The term expected value is used to characterize a chance event, such as the outcome of a therapy. If the outcomes of a therapy are measured in units of duration of survival, units of sense of well-being, or dollars, the therapy is characterized by the expected duration of survival, expected sense of well-being, or expected monetary cost that it will confer on, or incur for, the patient, respectively.

To use expected-value decision making, we follow this strategy when there are therapy choices with uncertain outcomes: (1) calculate the expected value of each decision alternative and then (2) pick the alternative with the highest expected value.

### 3.5.3 Performance of a Decision Analysis

We clarify the concepts of expected-value decision making by discussing an example. There are four steps in decision analysis:

1. Create a decision tree; this step is the most difficult, because it requires formulating the decision problem, assigning probabilities, and measuring outcomes.

2. Calculate the expected value of each decision alternative.
3. Choose the decision alternative with the highest expected value.
4. Use sensitivity analysis to test the conclusions of the analysis.

3

Some health professionals hesitate when they first learn about the technique of decision analysis, because they recognize the opportunity for error in assigning values to both the probabilities and the utilities in a decision tree. They reason that the technique encourages decision making based on small differences in expected values that are estimates at best. The defense against this concern, which also has been recognized by decision analysts, is the technique known as sensitivity analysis. We discuss this important fourth step in decision analysis in ► Sect. 3.5.5. In addition, decision analysis helps make the assumptions underlying a decision explicit, so that the assumptions can be assessed carefully.

The first step in decision analysis is to create a **decision tree** that represents the decision problem. Consider the following clinical problem.

#### ► Example 3.12

The patient is Mr. Danby, a 66-year-old man who has been crippled with arthritis of both knees so severely that, while he can get about the house with the aid of two canes, he must otherwise use a wheelchair. His other major health problem is emphysema, a disease in which the lungs lose their ability to exchange oxygen and carbon dioxide between blood and air, which in turn causes shortness of breath (dyspnea). He is able to breathe comfortably when he is in a wheelchair, but the effort of walking with canes makes him breathe heavily and feel uncomfortable. Several years ago, he seriously considered knee replacement surgery but decided against it, largely because his internist told him that there was a serious risk that he would not survive the operation because of his lung disease. Recently, however, Mr. Danby's wife had a stroke and was partially paralyzed; she now requires a degree of assistance that the patient cannot supply given his present state of mobility. He tells his doctor that he is reconsidering knee replacement surgery.

Mr. Danby's internist is familiar with decision analysis. She recognizes that this problem is filled with uncertainty: Mr. Danby's ability to survive the operation is in doubt, and the surgery sometimes does not restore mobility to the degree required by such a patient. Furthermore, there is a small chance that the prosthesis (the artificial knee) will become infected, and Mr. Danby then would have to undergo a second risky operation to remove it. After removal of the prosthesis, Mr. Danby would never again be able to walk, even with canes. The possible outcomes of knee replacement include death from the first procedure and death from a second mandatory procedure if the prosthesis becomes infected (which we will assume occurs in the immediate postoperative period, if it occurs at all). Possible functional outcomes include recovery of full mobility or continued, and unchanged, poor mobility. Should Mr. Danby choose to undergo knee replacement surgery, or should he accept the status quo? ◀

Using the conventions of decision analysis, the internist sketches the decision tree shown in ■ Fig. 3.8. According to these conventions, a square box denotes a **decision node**, and each line emanating from a decision node represents an action that could be taken.

According to the methods of expected-value decision making, the internist first must assign a probability to each branch of each chance node. To accomplish this task, the internist asks several orthopedic surgeons for their estimates of the chance of recovering full function after surgery ( $p[\text{full recovery}] = 0.60$ ) and the chance of developing infection in the prosthetic joint ( $p[\text{infection}] = 0.05$ ). She uses her subjective estimate of the probability that the patient will die during or immediately after knee surgery ( $p[\text{operative death}] = 0.05$ ).

Next, she must assign a value to each outcome. To accomplish this task, she first lists the outcomes. As you can see from ■ Table 3.6, the outcomes differ in two dimensions: length of life (survival) and quality of life (functional status). To characterize each outcome accurately, the internist must develop a measure that takes into account these two dimensions. Simply using duration of survival is inadequate because Mr. Danby values 5 years of good health more than

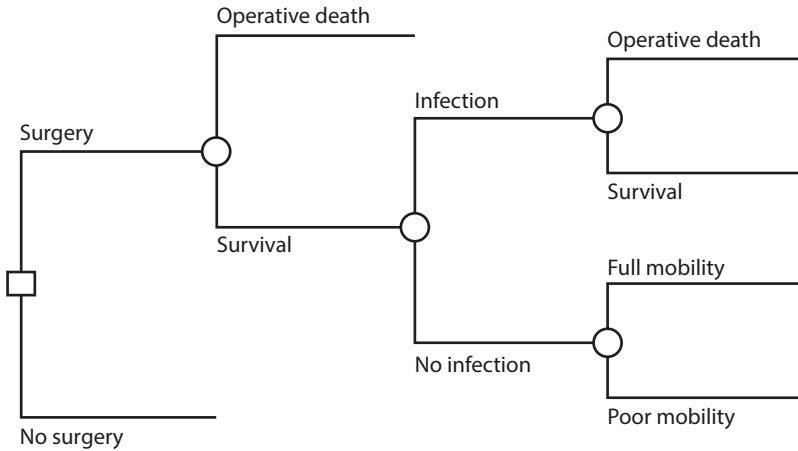

Fig. 3.8 Decision tree for knee replacement surgery. The box represents the decision node (whether to have surgery); the circles represent chance nodes

Table 3.6 Outcomes for Example 3.12

Survival (years)	Functional status	Years of full function equivalent to outcome
10	Full mobility (successful surgery)	10
10	Poor mobility (status quo or unsuccessful surgery)	6
10	Wheelchair-bound (the outcome if a second surgery is necessary)	3
0	Death	0

he values 10 years of poor health. The internist can account for this trade-off factor by converting outcomes with two dimensions into outcomes with a single dimension: duration of survival in good health. The resulting measure is called a **quality-adjusted life year (QALY)**.<sup>12</sup>

She can convert years in poor health into years in good health by asking Mr. Danby to indicate the shortest period in good health

(full mobility) that he would accept in return for his full expected lifetime (10 years) in a state of poor health (status quo). Thus, she asks Mr. Danby: “Many people say they would be willing to accept a shorter life in excellent health in preference to a longer life with significant disability. In your case, how many years with normal mobility do you feel is equivalent in value to 10 years in your current state of disability?” She asks him this question for each outcome. The patient’s responses are shown in the third column of Table 3.6. The patient decides that 10 years of limited mobility are equivalent to 6 years of normal mobility, whereas 10 years of wheelchair confinement are equivalent to only 3 years of full function. Figure 3.9 shows the final decision tree—complete with probability estimates and utility values for each outcome.<sup>13</sup>

The second task that the internist must undertake is to calculate the expected value, in healthy years, of surgery and of no surgery. She calculates the expected value at each chance node, moving from right (the tips of

12 QALYs commonly are used as measures of utility (value) in medical decision analysis and in health policy analysis.

13 In a more sophisticated decision analysis, the clinician also would adjust the utility values of outcomes that require surgery to account for the pain and inconvenience associated with surgery and rehabilitation. Other approaches to assessing utility are available and may be preferable in some circumstances.

**Fig. 3.9** Decision tree for knee-replacement surgery. Probabilities have been assigned to each branch of each chance node. The patient's valuations of outcomes

(measured in years of perfect mobility) are assigned to the tips of each branch of the tree

the tree) to left (the root of the tree). Let us consider, for example, the expected value at the chance node representing the outcome of surgery to remove an infected prosthesis (Node A in **Fig. 3.9**). The calculation requires three steps:

1. Calculate the expected value of operative death after surgery to remove an infected prosthesis. Multiply the probability of operative death (0.05) by the QALY of the outcome—death (0 years):  $0.05 \times 0 = 0$  QALY.
2. Calculate the expected value of surviving surgery to remove an infected knee prosthesis. Multiply the probability of surviving the operation (0.95) by the number of healthy years equivalent to 10 years of being wheelchair-bound (3 years):  $0.95 \times 3 = 2.85$  QALYs.
3. Add the expected values calculated in step 1 (0 QALY) and step 2 (2.85 QALYs) to obtain the expected value of developing an infected prosthesis:  $0 + 2.85 = 2.85$  QALYs.

Similarly, the expected value at chance node B is calculated:  $(0.6 \times 10) + (0.4 \times 6) = 8.4$  QALYs. To obtain the expected value of sur-

viving knee replacement surgery (Node C), she proceeds as follows:

1. Multiply the expected value of an infected prosthesis (already calculated as 2.85 QALYs) by the probability that the prosthesis will become infected (0.05):  $2.85 \times 0.05 = 0.143$  QALYs.
2. Multiply the expected value of never developing an infected prosthesis (already calculated as 8.4 QALYs) by the probability that the prosthesis will not become infected (0.95):  $8.4 \times 0.95 = 7.98$  QALYs.
3. Add the expected values calculated in step 1 (0.143 QALY) and step 2 (7.98 QALYs) to get the expected value of surviving knee replacement surgery:  $0.143 + 7.98 = 8.123$  QALYs.

The clinician performs this process, called **averaging out at chance nodes**, for node D as well, working back to the root of the tree, until the expected value of surgery has been calculated. The outcome of the analysis is as follows. For surgery, Mr. Danby's average life expectancy, measured in years of normal mobility, is 7.7. What does this value mean? It does not mean that, by accepting surgery,

Mr. Danby is guaranteed 7.7 years of mobile life. One look at the decision tree will show that some patients die in surgery, some develop infection, and some do not gain any improvement in mobility after surgery. Thus, an individual patient has no guarantees. If the clinician had 100 similar patients who underwent the surgery, however, the average number of mobile years would be 7.7. We can understand what this value means for Mr. Danby only by examining the alternative: no surgery.

In the analysis for no surgery, the average length of life, measured in years of normal mobility, is 6.0, which Mr. Danby considered equivalent to 10 years of continued poor mobility. Not all patients will experience this outcome; some who have poor mobility will live longer than, and some will live less than, 10 years. The average length of life, however, expressed in years of normal mobility, will be 6. Because 6.0 is less than 7.7, on average the surgery will provide an outcome with higher value to the patient. Thus, the internist recommends performing the surgery.

The key insight of expected-value decision making should be clear from this example: given the unpredictable outcome in an individual, the best choice for the individual is the alternative that gives the best result on the average in similar patients. Decision analysis can help the clinician to identify the therapy that will give the best results when averaged over many similar patients. The decision analysis is tailored to a specific patient in that both the utility functions and the probability estimates are adjusted to the individual. Nonetheless, the results of the analysis represent the outcomes that would occur on average in a population of patients who have similar utilities and for whom uncertain events have similar probabilities.

### 3.5.4 Representation of Patients' Preferences with Utilities

In ► Sect. 3.5.3, we introduced the concept of QALYs, because length of life is not the only outcome about which patients care. Patients' preferences for a health outcome may depend on the length of life with the outcome, on the

quality of life with the outcome, and on the risk involved in achieving the outcome (e.g., a cure for cancer might require a risky surgical operation). How can we incorporate these elements into a decision analysis? To do so, we can represent patients' preferences with utilities. The utility of a health state is a quantitative measure of the desirability of a health state from the patient's perspective. Utilities are typically expressed on a 0 to 1 scale, where 0 represents death and 1 represents ideal health. For example, a study of patients who had chest pain (angina) with exercise rated the utility of mild, moderate, and severe angina as 0.95, 0.92, and 0.82 (Nease et al. 1995), respectively. There are several methods for assessing utilities.

The **standard-gamble** technique has the strongest theoretical basis of the various approaches to utility assessment, as shown by Von Neumann and Morgenstern and described by Sox et al. (1988). To illustrate use of the standard gamble, suppose we seek to assess a person's utility for the health state of asymptomatic HIV infection. To use the standard gamble, we ask our subject to compare the desirability of asymptomatic HIV infection to those of two other health states whose utility we know or can assign. Often, we use ideal health (assigned a utility of 1) and immediate death (assigned a utility of 0) for the comparison of health states. We then ask our subject to choose between asymptomatic HIV infection and a gamble with a chance of ideal health or immediate death. We vary the probability of ideal health and immediate death systematically until the subject is indifferent between asymptomatic HIV infection and the gamble. For example, a subject might be indifferent when the probability of ideal health is 0.8 and the probability of death is 0.2. At this point of indifference, the utility of the gamble and that of asymptomatic HIV infection are equal. We calculate the utility of the gamble as the weighted average of the utilities of each outcome of the gamble  $[(1 \times 0.8) + (0 \times 0.2)] = 0.8$ . Thus in this example, the utility of asymptomatic HIV infection is 0.8. Use of the standard gamble enables an analyst to assess the utility of outcomes that differ in length or quality of life. Because the standard gamble involves chance events, it

also assesses a person's willingness to take risks—called the person's **risk attitude**.

A second common approach to utility assessment is the **time-trade-off** technique (Sox et al. 1988; Torrance and Feeny 1989). To assess the utility of asymptomatic HIV infection using the time-trade-off technique, we ask a person to determine the length of time in a better state of health (usually ideal health or best attainable health) that he or she would find equivalent to a longer period of time with asymptomatic HIV infection. For example, if our subject says that 8 months of life with ideal health was equivalent to 12 months of life with asymptomatic HIV infection, then we calculate the utility of asymptomatic HIV infection as  $8 \div 12 = 0.67$ . The time-trade-off technique provides a convenient method for valuing outcomes that accounts for gains (or losses) in both length and quality of life. Because the time trade-off does not include gambles, however, it does not assess a person's risk attitude. Perhaps the strongest assumption underlying the use of the time trade-off as a measure of utility is that people are risk neutral. A **risk-neutral** decision maker is indifferent between the expected value of a gamble and the gamble itself. For example, a risk-neutral decision maker would be indifferent between the choice of living 20 years (for certain) and that of taking a gamble with a 50% chance of living 40 years and a 50% chance of immediate death (which has an expected value of 20 years). In practice, of course, few people are risk-neutral. Nonetheless, the time-trade-off technique is used frequently to value health outcomes because it is relatively easy to understand.

Several other approaches are available to value health outcomes. To use the **visual analog scale**, a person simply rates the quality of life with a health outcome (e.g., asymptomatic HIV infection) on a scale from 0 to 100. Although the visual analog scale is easy to explain and use, it has no theoretical justification as a valid measure of utility. Ratings with the visual analog scale, however, correlate modestly well with utilities assessed by the standard gamble and time trade-off. For a demonstration of the use of standard gambles, time trade-offs, and the visual analog scale to assess utilities in patients with angina, see Nease et al.

(1995); in patient living with HIV, see Joyce et al. (2009) and (2012). Other approaches to valuing health outcomes include the Quality of Well-Being Scale, the Health Utilities Index, and the EuroQoL (see Neumann et al. 2017, ch. 7). Each of these instruments assesses how people value health outcomes and therefore may be appropriate for use in decision analyses or cost-effectiveness analyses.

In summary, we can use utilities to represent how patients value complicated health outcomes that differ in length and quality of life and in riskiness. Computer-based tools with an interactive format have been developed for assessing utilities; they often include text and multimedia presentations that enhance patients' understanding of the assessment tasks and of the health outcomes (Sumner et al. 1991; Nease and Owens 1994; Lenert et al. 1995).

### 3.5.5 Performance of Sensitivity Analysis

Sensitivity analysis is a test of the robustness of the conclusions of an analysis over a wide range of assumptions about the probabilities and the values, or utilities. The probability of an outcome at a chance node may be the best estimate that is available, but there often is a wide range of reasonable probabilities that a clinician could use with nearly equal confidence. We use sensitivity analysis to answer this question: Do my conclusions regarding the preferred choice change when the probability and outcome estimates are assigned values that lie within a reasonable range?

The knee-replacement decision in ► Example 3.12 illustrates the power of sensitivity analysis. If the conclusions of the analysis (surgery is preferable to no surgery) remain the same despite a wide range of assumed values for the probabilities and outcome measures, the recommendation is trustworthy. ■ Figures 3.10 and 3.11 show the expected survival in healthy years with surgery and without surgery under varying assumptions of the probability of operative death and the probability of attaining perfect mobility, respectively. Each point (value) on these lines represents one calculation of expected survival using the tree in

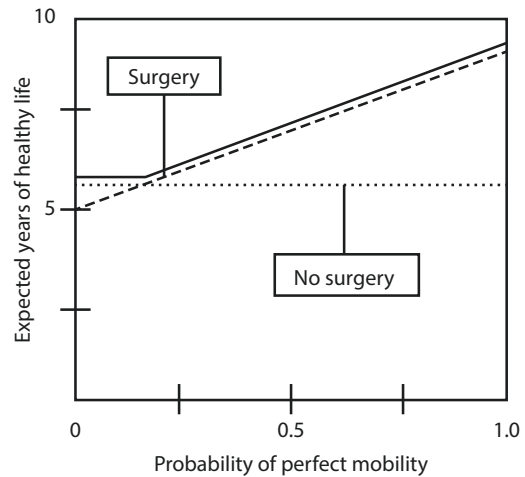

■ **Fig. 3.10** Sensitivity analysis of the effect of operative mortality on length of healthy life (► Example 3.12). As the probability of operative death increases, the relative values of surgery versus no surgery change. The point at which the two lines cross represents the probability of operative death at which no surgery becomes preferable. The solid line represents the preferred option at a given probability

■ **Fig. 3.8.** ■ Figure 3.10 shows that expected survival is higher with surgery over a wide range of operative mortality rates. Expected survival is lower with surgery, however, when the operative mortality rate exceeds 25%. ■ Figure 3.11 shows the effect of varying the probability that the operation will lead to perfect mobility. The expected survival, in healthy years, is higher for surgery as long as the probability of perfect mobility exceeds 20%, a much lower figure than is expected from previous experience with the operation. (In ► Example 3.12, the consulting orthopedic surgeons estimated the chance of full recovery at 60%). Thus, the internist can proceed with confidence to recommend surgery. Mr. Danby cannot be sure of a good outcome, but he has valid reasons for thinking that he is more likely to do well with surgery than he is without it.

Another way to state the conclusions of a sensitivity analysis is to indicate the range of probabilities over which the conclusions apply. The point at which the two lines in ■ Fig. 3.10 cross is the probability of operative death at which the two therapy options have the same expected survival. If expected survival is to be the basis for choosing therapy, the internist and the patient should be indifferent between

■ **Fig. 3.11** Sensitivity analysis of the effect of a successful operative result on length of healthy life (► Example 3.12). As the probability of a successful surgical result increases, the relative values of surgery versus no surgery change. The point at which the two lines cross represents the probability of a successful result at which surgery becomes preferable. The solid line represents the preferred option at a given probability

surgery and no surgery when the probability of operative death is 25%.<sup>14</sup> When the probability is lower, they should select surgery. When it is higher, they should select no surgery.

The approach to sensitivity analyses we have described enables the analyst to understand how uncertainty in one, two, or three parameters affects the conclusions of an analysis. But in a complex problem, a decision tree or decision model may have a 100 or more parameters. The analyst may have uncertainty about many parameters in a model. **Probabilistic sensitivity analysis** is an approach for understanding how the uncertainty in all (or a large number of) model parameters affects the conclusion of a decision analysis. To perform a probabilistic sensitivity analysis, the analyst must specify a probability distribution for each model parameter. The analytic software then chooses a value for each model parameter randomly from the

14 An operative mortality rate of 25% may seem high; however, this value is correct when we use QALYs as the basis for choosing treatment. A decision maker performing a more sophisticated analysis could use a utility function that reflects the patient's aversion to risking death.

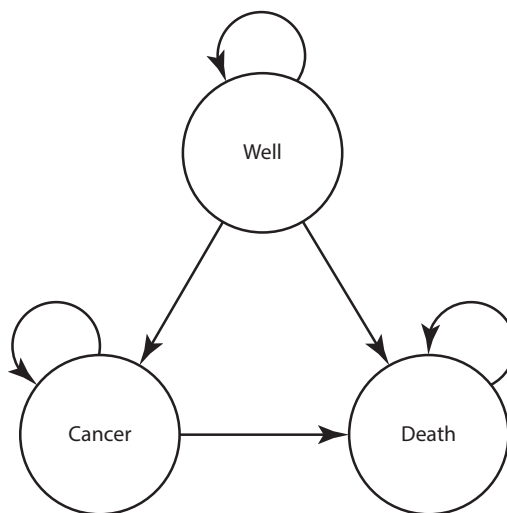

parameter's probability distribution. The software then uses this set of parameter values and calculates the outcomes for each alternative. For each evaluation of the model, the software will determine which alternative is preferred. The process is usually repeated 10,000–100,000 times. From the probabilistic sensitivity analysis, the analyst can determine the proportion of times an alternative is preferred, accounting for all uncertainty in model parameters simultaneously. For more information on this advanced topic, see the article by Briggs and colleagues referenced at the end of the chapter.

3

### 3.5.6 Representation of Long-Term Outcomes with Markov Models

In ▶ Example 3.12, we evaluated Mr. Danby's decision to have surgery to improve his mobility, which was compromised by arthritis. We assumed that each of the possible outcomes (full mobility, poor mobility, death, etc.) would occur shortly after Mr. Danby took action on his decision. But what if we want to model events that might occur in the distant future? For example, a patient with HIV infection might develop AIDS 10–15 years after infection; thus, a therapy to prevent or delay the development of AIDS could affect events that occur 10–15 years, or more, in the future. A similar problem arises in analyses of decisions regarding many chronic diseases: we must model events that occur over the lifetime of the patient. The decision tree representation is convenient for decisions for which all outcomes occur during a short time horizon, but it is not always sufficient for problems that include events that could occur in the future. How can we include such events in a decision analysis? The answer is to use Markov models (Beck and Pauker 1983; Sonnenberg and Beck 1993; Siebert et al. 2012).

To build a **Markov model**, we first specify the set of health states that a person could experience (e.g., Well, Cancer, and Death in ■ Fig. 3.12). We then specify the **transition probabilities**, which are the probabilities that a person will transit from one of these health states to another during a specified time period. This pe-

■ Fig. 3.12 A simple Markov model. The states of health that a person can experience are indicated by the circles; arrows represent allowed transitions between health states

riod—often 1 month or 1 year—is the length of the **Markov cycle**. The Markov model then simulates the transitions among health states for a person (or for a hypothetical cohort of people) for a specified number of cycles; by using a Markov model, we can calculate the probability that a person will be in each of the health states at any time in the future. As an illustration, consider a simple Markov model that has three health states: Well, Cancer, and Death (see ■ Fig. 3.12). We have specified each of the transition probabilities in ■ Table 3.7 for the cycle length of 1 year. Thus, we note from ■ Table 3.7 that a person who is in the well state will remain well with probability 0.9, will develop cancer with probability 0.06, and will die from non-cancer causes with probability 0.04 during 1 year. The calculations for a Markov model are performed by computer software. Based on the transition probabilities in ■ Table 3.7, the probabilities that a person remains well, develops cancer, or dies from non-cancer causes over time is shown in ■ Table 3.8. We can also determine from a Markov model the expected length of time that a person spends in each health state. Therefore, we can determine life expectancy, or quality-adjusted life expectancy, for any alternative represented by a Markov model.

In decision analyses that represent long-term outcomes, the analysts will often use a

Markov model in conjunction with a decision tree to model the decision (Owens et al. 1995; Salpeter et al. 1997; Sanders et al. 2005; Lin et al. 2018). The analyst models the effect of an intervention as a change in the probability of going from one state to another. For example, we could model a cancer-prevention intervention (such as screening for breast cancer with mammography) as a reduction in the transition probability from Well to Cancer in Fig. 3.12. (See the articles by Beck and Pauker (1983) and Sonnenberg and Beck (1993) for further explanation of the use of Markov models).

### 3.6 The Decision Whether to Treat, Test, or Do Nothing

The clinician who is evaluating a patient's symptoms and suspects a disease must choose among the following actions:

**Table 3.7** Transition probabilities for the Markov model in Fig. 3.13

Health state transition	Annual probability
Well to well	0.9
Well to cancer	0.06
Well to death	0.04
Cancer to well	0.0
Cancer to cancer	0.4
Cancer to death	0.6
Death to well	0.0
Death to cancer	0.0
Death to death	1.0

1. Do nothing further (neither perform additional tests nor treat the patient).
2. Obtain additional diagnostic information (test) before choosing whether to treat or do nothing.
3. Treat without obtaining more information.

When the clinician knows the patient's true state, testing is unnecessary, and the doctor needs only to assess the trade-offs among therapeutic options (as in Example 3.12). Learning the patient's true state, however, may require costly, time-consuming, and often risky diagnostic procedures that may give misleading FP or FN results. Therefore, clinicians often are willing to treat a patient even when they are not absolutely certain about a patient's true state. There are risks in this course: the clinician may withhold therapy from a person who has the disease of concern, or he may administer therapy to someone who does not have the disease yet may suffer undesirable side effects of therapy.

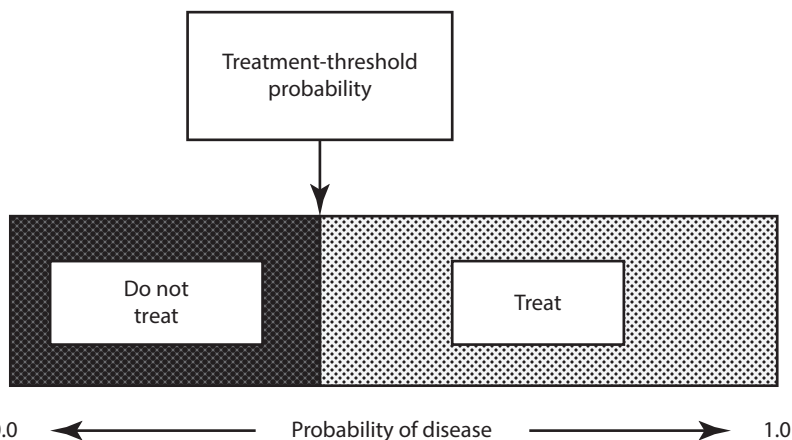

Deciding among treating, testing, and doing nothing sounds difficult, but you have already learned all the principles that you need to solve this kind of problem. There are three steps:

1. Determine the treatment threshold probability of disease.
2. Determine the pretest probability of disease.
3. Decide whether a test result could affect your decision to treat.

The **treatment threshold probability** of disease is the probability of disease at which you should be indifferent between treating and not treating (Pauker and Kassirer 1980). Below the treatment threshold, you should not treat. Above the treatment threshold, you should

**Table 3.8** Probability of future health states for the Markov model in Fig. 3.12

Health state	Probability of health state at end of year						
	Year 1	Year 2	Year 3	Year 4	Year 5	Year 6	Year 7
Well	0.9000	0.8100	0.7290	0.6561	0.5905	0.5314	0.4783
Cancer	0.0600	0.0780	0.0798	0.0757	0.0696	0.0633	0.0572
Death	0.0400	0.1120	0.1912	0.2682	0.3399	0.4053	0.4645

**Fig. 3.13** Depiction of the treatment threshold probability. At probabilities of disease that are less than the treatment threshold probability, the preferred action

is to withhold therapy. At probabilities of disease that are greater than the treatment threshold probability, the preferred action is to treat

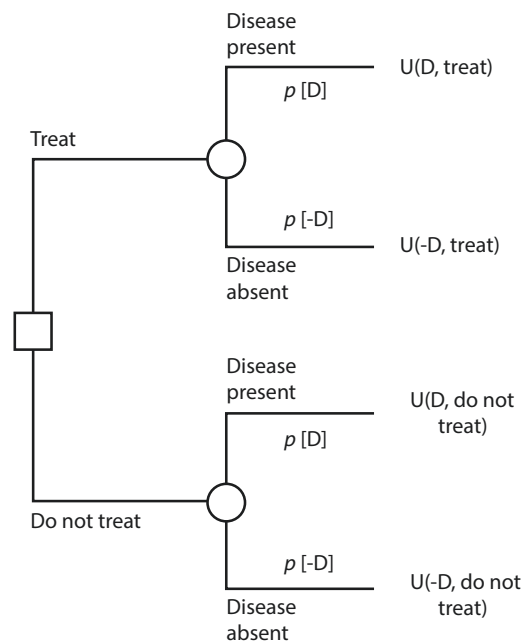

treat (Fig. 3.13). Whether to treat when the diagnosis is not certain is a problem that you can solve with a decision tree, such as the one shown in Fig. 3.14.

You can use this tree to learn the treatment threshold probability of disease by leaving the probability of disease as an unknown, setting the expected value of surgery equal to the expected value for medical (i.e., nonsurgical, such as drugs or physical therapy) treatment, and solving for the probability of disease. (In this example, surgery corresponds to the “treat” branch of the tree in Fig. 3.14, and nonsurgical intervention corresponds to the “do not treat” branch). Because you are indifferent between medical treatment and surgery at this probability, it is the treatment threshold probability. Using the tree completes step 1. In practice, people often determine the treatment threshold intuitively rather than analytically.

An alternative approach to determination of the treatment threshold probability is to use the equation:

$$p^* = \frac{H}{H + B},$$

where  $p^*$  = the treatment threshold probability,  $H$  = the harm associated with treatment of a nondiseased patient, and  $B$  = the benefit associated with treatment of a diseased patient (Pauker and Kassirer 1980; Sox et al. 1988). We define  $B$  as the difference between the utility ( $U$ ) of diseased patients who are treated and

**Fig. 3.14** Decision tree with which to calculate the treatment threshold probability of disease. By setting the utilities of the treat and do not treat choices to be equal, we can compute the probability at which the clinician and patient should be indifferent to the choice. Recall that  $p[-D] = 1 - p[D]$

diseased patients who are not treated ( $U[D, \text{treat}] - U[D, \text{do not treat}]$ ), as shown in Fig. 3.14). The utility of diseased patients who are treated should be greater than that of diseased patients who are not treated; therefore,  $B$  is

positive. We define  $H$  as the difference in utility of nondiseased patients who are not treated and nondiseased patients who are treated ( $U[-D, \text{do not treat}] - U[-D, \text{treat}]$ ), as shown in [Fig. 3.14](#). The utility of nondiseased patients who are not treated should be greater than that of nondiseased patients who are treated; therefore,  $H$  is positive. The equation for the treatment threshold probability fits with our intuition: if the benefit of treatment is small and the harm of treatment is large, the treatment threshold probability will be high. In contrast, if the benefit of treatment is large and the harm of treatment is small, the treatment threshold probability will be low.

Once you know the pretest probability, you know what to do in the absence of further information about the patient. If the pretest probability is below the treatment threshold, you should not treat the patient. If the pretest probability is above the threshold, you should treat the patient. Thus, you have completed step 2.

One of the guiding principles of medical decision making is this: do not order a test unless it could change your management of the patient. In our framework for decision making, this principle means that you should order a test only if the test result could cause the probability of disease to cross the treatment threshold or lead to another test that would do so. Thus, if the pretest probability is above the treatment threshold, a negative test result must lead to a post-test probability that is below the threshold. Conversely, if the pretest probability is below the threshold probability, a positive result must lead to a post-test probability that is above the threshold. In either case, the test result would alter your decision of whether to treat the patient. This analysis completes step 3.

To decide whether a test could alter management, we simply use Bayes' theorem. We calculate the post-test probability after a test result that would move the probability of disease toward the treatment threshold. If the pretest probability is above the treatment threshold, we calculate the probability of disease if the test result is negative. If the pretest probability is below the treatment threshold, we calculate the probability of disease if the test result is positive.

### ► Example 3.13

You are a pulmonary medicine specialist. You suspect that a patient of yours has a pulmonary embolus (blood clot lodged in the vessels of the lungs). One approach is to do a computed tomography angiography (CTA) scan, a test in which a computed tomography (CT) of the lung is done after a radiopaque dye is injected into a vein. The dye flows into the vessels of the lung. The CT scan can then assess whether the blood vessels are blocked. If the scan is negative, you do no further tests and do not treat the patient. ◀

To decide whether this strategy is correct, you take the following steps:

1. Determine the treatment threshold probability of pulmonary embolus.
2. Estimate the pretest probability of pulmonary embolus.
3. Decide whether a test result could affect your decision to treat for an embolus.

First, assume you decide that the treatment threshold should be 0.10 in this patient. What does it mean to have a treatment threshold probability equal to 0.10? If you could obtain no further information, you would treat for pulmonary embolus if the pretest probability was above 0.10 (i.e., if you believed that there was greater than a 1 in 10 chance that the patient had an embolus), and would withhold therapy if the pretest probability was below 0.10. A decision to treat when the pretest probability is at the treatment threshold means that you are willing to treat nine patients without pulmonary embolus to be sure of treating one patient who has pulmonary embolus. A relatively low treatment threshold is justifiable because treatment of a pulmonary embolism with blood-thinning medication substantially reduces the high mortality of pulmonary embolism, whereas there is only a relatively small danger (mortality of less than 1%) in treating someone who does not have pulmonary embolus. Because the benefit of treatment is high and the harm of treatment is low, the treatment threshold probability will be low, as discussed earlier. You have completed step 1.

You estimate the pretest probability of pulmonary embolus to be 0.05, which is equal to a pretest odds of 0.053. Because the pretest probability is lower than the treatment thresh-

old, you should do nothing unless a positive CTA scan result could raise the probability of pulmonary embolus to above 0.10. You have completed step 2.

To decide whether a test result could affect your decision to treat, you must decide whether a positive CTA scan result would raise the probability of pulmonary embolism to more than 0.10, the treatment threshold. You review the literature and learn that the LR for a positive CTA scan is approximately 21 (Stein et al. 2006).

A negative CTA scan result will move the probability of disease away from the treatment threshold and will be of no help in deciding what to do. A positive result will move the probability of disease toward the treatment threshold and could alter your management decision if the post-test probability were above the treatment threshold. You therefore use the odds-ratio form of Bayes' theorem to calculate the post-test probability of disease if the lung scan result is reported as high probability.

$$\begin{aligned}\text{post-test odds} &= \text{pretest odds} \times LR \\ &= 0.053 \times 21 = 1.11.\end{aligned}$$

A post-test odds of 1.1 is equivalent to a probability of disease of 0.53. Because the post-test probability of pulmonary embolus is higher than the treatment threshold, a positive CTA scan result would change your management of the patient, and you should order the lung scan. You have completed step 3.

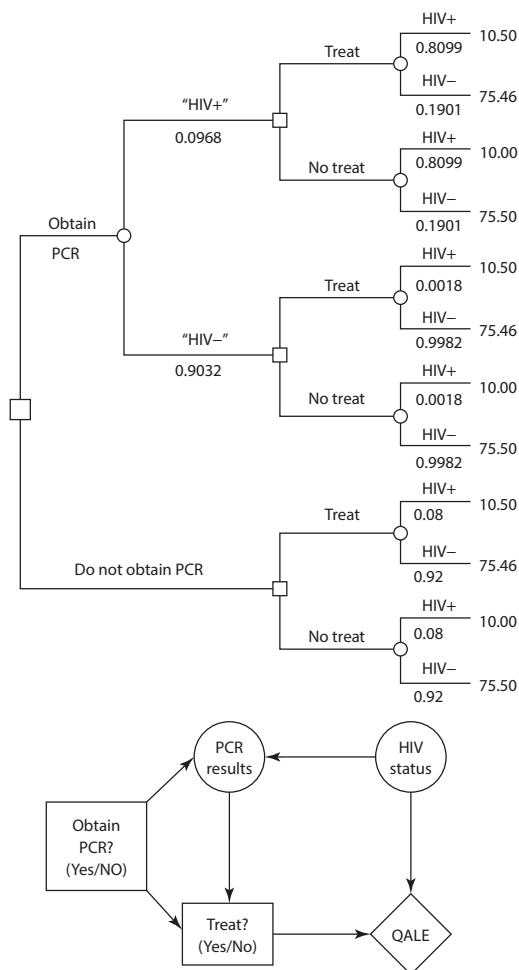

This example is especially useful for two reasons: first, it demonstrates one method for making decisions and second, it shows how the concepts that were introduced in this chapter all fit together in a clinical example of medical decision making.

### 3.7 Alternative Graphical Representations for Decision Models: Influence Diagrams and Belief Networks

In ▶ Sects. 3.5 and 3.6, we used decision trees to represent decision problems. Although decision trees are the most common graphical representation for decision problems, **influence diagrams** are an important alternative

representation for such problems (Nease and Owens 1997; Owens et al. 1997).

As shown in ■ Fig. 3.15, influence diagrams have certain features that are similar to decision trees, but they also have additional graphical elements. Influence diagrams represent decision nodes as squares and chance nodes as circles. In contrast to decision trees, however, the influence diagram also has arcs

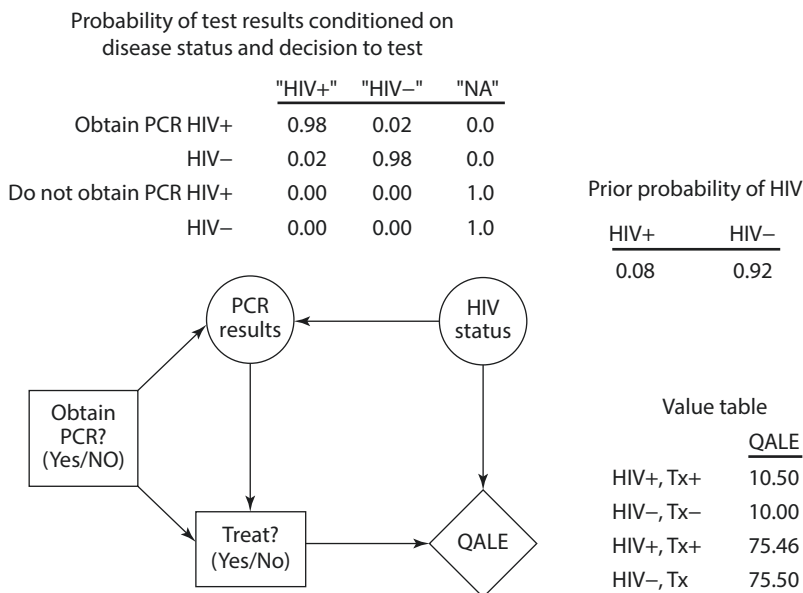

■ Fig. 3.15 A decision tree (*top*) and an influence diagram (*bottom*) that represent the decisions to test for, and to treat, HIV infection. The structural asymmetry of the alternatives is explicit in the decision tree. The influence diagram highlights probabilistic relationships. *HIV* human immunodeficiency virus, *HIV+* HIV infected, *HIV-* not infected with HIV, *QALE* quality-adjusted life expectancy, *PCR* polymerase chain reaction. Test results are shown in quotation marks (“HIV+”), whereas the true disease state is shown without quotation marks (HIV+). (Source: Owens et al. (1997). Reproduced with permission)

between nodes and a diamond-shaped value node. An arc between two chance nodes indicates that a probabilistic relationship may exist between the chance nodes (Owens et al. 1997). A **probabilistic relationship** exists when the occurrence of one chance event affects the probability of the occurrence of another chance event. For example, in Fig. 3.15, the probability of a positive or negative PCR test result (PCR result) depends on whether a person has HIV infection (HIV status); thus, these nodes have a probabilistic relationship, as indicated by the arc. The arc points from the **conditioning event** to the **conditioned event** (PCR test result is conditioned on HIV status in Fig. 3.15). The absence of an arc between two chance nodes, however, always indicates that the nodes are independent or conditionally independent. Two events are conditionally independent, given a third event, if the occurrence of one of the events does not affect the probability of the other event conditioned on the occurrence of the third event.

Unlike a decision tree, in which the events usually are represented from left to right in

the order in which the events are observed, influence diagrams use arcs to indicate the timing of events. An arc from a chance node to a decision node indicates that the chance event has been observed at the time the decision is made. Thus, the arc from PCR result to Treat? in Fig. 3.15 indicates that the decision maker knows the PCR test result (positive, negative, or not obtained) when he or she decides whether to treat. Arcs between decision nodes indicate the timing of decisions: the arc points from an initial decision to subsequent decisions. Thus, in Fig. 3.15, the decision maker must decide whether to obtain a PCR test before deciding whether to treat, as indicated by the arc from Obtain PCR? to Treat?

The probabilities and utilities that we need to determine the alternative with the highest expected value are contained in tables associated with chance nodes and the value node (Fig. 3.16). These tables contain the same information that we would use in a decision tree. With a decision tree, we can determine the expected value of each alternative by averaging out at chance nodes and folding back the tree (Sect. 3.5.3).

**Fig. 3.16** The influence diagram from Fig. 3.15, with the probability and value tables associated with the nodes. The information in these tables is the same as that associated with the branches and endpoints of the decision tree in Fig. 3.15. HIV human immunodeficiency virus, HIV+ HIV infected, HIV− not infected with HIV, QALE quality-

adjusted life expectancy, PCR polymerase chain reaction, NA not applicable, TX+ treated, TX− not treated. Test results are shown in quotation marks ("HIV+"), and the true disease state is shown without quotation marks (HIV+). (Source: Owens et al. (1997). Reproduced with permission)

For influence diagrams, the calculation of expected value is more complex (Owens et al. 1997), and generally must be performed with computer software. With the appropriate software, we can use influence diagrams to perform the same analyses that we would perform with a decision tree. Diagrams that have only chance nodes are called **belief networks**; we use them to perform probabilistic inference.

Why use an influence diagram instead of a decision tree? Influence diagrams have both advantages and limitations relative to decision trees. Influence diagrams represent graphically the probabilistic relationships among variables (Owens et al. 1997). Such representation is advantageous for problems in which probabilistic conditioning is complex or in which communication of such conditioning is important (such as may occur in large models). In an influence diagram, probabilistic conditioning is indicated by the arcs, and thus the conditioning is apparent immediately by inspection. In a decision tree, probabilistic conditioning is revealed by the probabilities in the branches of the tree. To determine whether events are conditionally independent in a decision tree requires that the analyst compare probabilities of events between branches of the tree. Influence diagrams also are particularly useful for discussion with content experts who can help to structure a problem but who are not familiar with decision analysis. In contrast, problems that have decision alternatives that are structurally different may be easier for people to understand when represented with a decision tree, because the tree shows the structural differences explicitly, whereas the influence diagram does not. The choice of whether to use a decision tree or an influence diagram depends on the problem being analyzed, the experience of the analyst, the availability of software, and the purpose of the analysis. For selected problems, influence diagrams provide a powerful graphical alternative to decision trees.

### 3.8 Other Modeling Approaches

---

We have described decision trees, Markov models and influence diagrams. An analyst also can choose several other approaches to modeling. The choice of modeling approach depends on

the problem and the objectives of the analysis. Although how to choose and design such models is beyond our scope, we note other type of models that analysts use commonly for medical decision making. **Microsimulation models** are individual-level health state transition models, similar to Markov models, that provide a means to model very complex events flexibly over time. They are useful when the clinical history of a problem is complex, such as might occur with cancer, heart disease, and other chronic diseases. They are also useful for modeling individual heterogeneity which may depend on combinations of individual characteristics (e.g. heterogeneity of response to treatment based on medical conditions or genetics). **Dynamic transmission models** are particularly well-suited for assessing the outcomes of infectious diseases. These models divide a population into compartments (for example, uninfected, infected, recovered, dead), and transitions between compartments are governed by differential or difference equations. The rate of transition between compartments depends in part on the number of individuals in the compartment, an important feature for infectious diseases in which the transmission may depend on the number of infected or susceptible individuals. **Discrete event simulation models** also are often used to model interactions between people. These models are composed of entities (a patient) that have attributes (clinical history), and that experience events (a heart attack). An entity can interact with other entities and use resources. Discrete event simulation models are also used when considering scarce resources such as queues for a diagnostic test or an operating room slot. For more information on these types of models, we suggest a recent series of papers on best modeling practices; the paper by Caro and colleagues noted in the suggested readings at the end of the chapter is an overview of this series of papers.

### 3.9 The Role of Probability and Decision Analysis in Medicine

---

You may be wondering how probability and decision analysis might be integrated smoothly into medical practice. An understanding of

probability and measures of test performance will prevent any number of misadventures. In ► Example 3.1, we discussed a hypothetical test that, on casual inspection, appeared to be an accurate way to screen blood donors for previous exposure to the AIDS virus. Our quantitative analysis, however, revealed that the hypothetical test results were misleading more often than they were helpful because of the low prevalence of HIV in the clinically relevant population. Fortunately, in actual practice, much more accurate tests are used to screen for HIV.

The need for knowledgeable interpretation of test results is widespread. The federal government screens civil employees in “sensitive” positions for drug use, as do many companies. If the drug test used by an employer had a sensitivity and specificity of 0.95, and if 10% of the employees used drugs, one-third of the positive tests would be FPs. An understanding of these issues should be of great interest to the public, and health professionals should be prepared to answer the questions of their patients.

Although we should try to interpret every kind of test result accurately, decision analysis has a more selective role in medicine. Not all clinical decisions require decision analysis. Some decisions depend on physiologic principles or on deductive reasoning. Other decisions involve little uncertainty. Nonetheless, many decisions must be based on imperfect data, and they will have outcomes that cannot be known with certainty at the time that the decision is made. Decision analysis provides a technique for managing these situations.

For many problems, simply drawing a tree that denotes the possible outcomes explicitly will clarify the question sufficiently to allow you to make a decision. When time is limited, even a “quick and dirty” analysis may be helpful. By using expert clinicians’ subjective probability estimates and asking what the patient’s utilities might be, you can perform an analysis quickly and learn which probabilities and utilities are the important determinants of the decision.

Health care professionals sometimes express reservations about decision analysis because the analysis may depend on probabilities that must be estimated, such as the pretest

probability. A thoughtful decision maker will be concerned that the estimate may be in error, particularly because the information needed to make the estimate often is difficult to obtain from the medical literature. We argue, however, that uncertainty in the clinical data is a problem for any decision-making method and that the effect of this uncertainty is explicit with decision analysis. The method for evaluating uncertainty is sensitivity analysis: we can examine any variable to see whether its value is critical to the final recommended decision. Thus, we can determine, for example, whether a change in pretest probability from 0.6 to 0.8 makes a difference in the final decision. In so doing, we often discover that it is necessary to estimate only a range of probabilities for a particular variable rather than a precise value. Thus, with a sensitivity analysis, we can decide whether uncertainty about a particular variable should concern us.

The growing complexity of medical decisions, coupled with the need to control costs, has led to major programs to develop clinical practice guidelines. Decision models have many advantages as aids to guideline development (Eddy 1992; Habbema et al. 2014; Owens et al. 2016): they make explicit the alternative interventions, associated uncertainties, and utilities of potential outcomes. Decision models can help guideline developers to structure guideline-development problems (Owens and Nease 1993), to incorporate patients’ preferences (Nease and Owens 1994; Owens 1998), and to tailor guidelines for specific clinical populations (Owens and Nease 1997). The U.S. Preventive Services Task Force, which develops national prevention guidelines, has used decision models in the development of guidelines on breast, lung, cervical, and colorectal cancer screening. In addition, Web-based interfaces for decision models can provide distributed decision support for guideline developers and users by making the decision model available for analysis to anyone who has access to the Web (Sanders et al. 1999).

We have not emphasized computers in this chapter, although they can simplify many aspects of decision analysis (see ► Chap. 24). MEDLINE and other bibliographic retrieval systems (see ► Chap. 23) make it easier to ob-

tain published estimates of disease prevalence and test performance. Computer programs for performing statistical analyses can be used on data collected by hospital information systems. Decision analysis software, available for personal computers, can help clinicians to structure decision trees, to calculate expected values, and to perform sensitivity analyses. Researchers continue to explore methods for computer-based automated development of practice guidelines from decision models and use of computer-based systems to implement guidelines (Musen et al. 1996). With the growing maturity of this field, there are now companies that offer formal analytical tools to assist with clinical outcome assessment and interpretation of population datasets.

Medical decision making often involves uncertainty for the clinician and risk for the patient. Most health care professionals would welcome tools that help them make decisions when they are confronted with complex clinical problems with uncertain outcomes. There are important medical problems for which decision analysis offers such aid.

### 3.10 Appendix A: Derivation of Bayes' Theorem

Bayes' theorem is derived as follows. We denote the conditional probability of disease,  $D$ , given a test result,  $R$ ,  $p[D|R]$ . The prior (pre-test) probability of  $D$  is  $p[D]$ . The definition of conditional probability is:

$$p[D|R] = \frac{p[R,D]}{p[R]} \quad (3.1)$$

The probability of a test result ( $p[R]$ ) is the sum of its probability in diseased patients and its probability in nondiseased patients:

$$p[R] = p[R,D] + p[R,-D].$$

Substituting into Eq. 3.1, we obtain:

$$p[D|R] = \frac{p[R,D]}{p[R,D] + p[R,-D]} \quad (3.2)$$

Again, from the definition of conditional probability,

$$p[R|D] = \frac{p[R,D]}{p[D]} \quad \text{and} \quad p[R|-D] = \frac{p[R,-D]}{p[-D]}$$

These expressions can be rearranged:

$$p[R,D] = p[D] \times p[R|D], \quad (3.3)$$

$$p[R,-D] = p[-D] \times p[R|-D]. \quad (3.4)$$

Substituting Eqs. 3.3 and 3.4 into Eq. 3.2, we obtain Bayes' theorem:

$$p[D|R] = \frac{p[D] \times p[R|D]}{p[D] \times p[R|D] + p[-D] \times p[R|-D]}$$

Model parameter estimation and uncertainty analysis: A report of the ISPOR-SMDM modeling good research practices task force-6. *Medical Decision Making*, 32(5), 722–732. This article describes best practices for estimating model parameters and for performing sensitivity analyses, including probabilistic sensitivity analysis.
- Caro, J., Briggs, A., Siebert, U., & Kuntz, K. (2012). Modeling good research practices – overview: A report of the ISPOR-SMDM modeling good research practices task force-1. *Value in Health*, 15, 796–803. This paper is an introduction to a series of papers that describe best modeling practices.
- Hunink, M., Glasziou, P., Siegel, J., Weeks, J., Pliskin, J., Einstein, A., & Weinstein, M. (2001). *Decision making in health and medicine*. Cambridge: Cambridge University Press. This textbook addresses in detail most of the topics introduced in this chapter.
- Nease, R. F., Jr., & Owens, D. K. (1997b). Use of influence diagrams to structure medical decisions. *Medical Decision Making*, 17(13), 263–275. This article provides a comprehensive introduction to the use of influence diagrams.
- Neumann, P. J., Sanders, G. D., Russell, L. B., Siegel, J. E., & Ganiats, T. G. (Eds.). (2017b). *Cost-effectiveness in health and medicine* (2nd

ed.). New York: Oxford University Press. This book provides authoritative guidelines for the conduct of cost-effectiveness analyses. Chapter 7 discusses approaches for valuing health outcomes.

Owens, D. K., Schacter, R. D., & Nease, R. F., Jr. (1997b). Representation and analysis of medical decision problems with influence diagrams. *Medical Decision Making*, 17(3), 241–262. This article provides a comprehensive introduction to the use of influence diagrams.

Raiffa, H. (1970). *Decision analysis: Introductory lectures on choices under uncertainty*. Reading: Addison-Wesley. This now classic book provides an advanced, nonmedical introduction to decision analysis, utility theory, and decision trees.

Sox, H. C. (1986). Probability theory in the use of diagnostic tests. *Annals of Internal Medicine*, 104(1), 60–66. This article is written for clinicians; it contains a summary of the concepts of probability and test interpretation.

Sox, H. C., Higgins, M. C., & Owens, D. K. (2013). *Medical decision making*. Chichester: Wiley-Blackwell. This introductory textbook covers the subject matter of this chapter in greater detail, as well as discussing many other topics.

Tversky, A., & Kahneman, D. (1974b). Judgment under uncertainty: Heuristics and biases. *Science*, 185, 1124. This now classic article provides a clear and interesting discussion of the experimental evidence for the use and misuse of heuristics in situations of uncertainty.

### ? Questions for Discussion

- Calculate the following probabilities for a patient about to undergo CABG surgery (see ▶ Example 3.2):
  - The only possible, mutually exclusive outcomes of surgery are death, relief of symptoms (angina and dyspnea), and continuation of symptoms. The probability of death is 0.02, and the probability of relief of symptoms is 0.80. What is the probability that the patient will continue to have symptoms?
  - Two known complications of heart surgery are stroke and heart attack, with probabilities of 0.02 and 0.05, respectively. The patient asks what chance he or she has of having both complications. Assume that the complications are conditionally independent, and calculate your answer.
  - The patient wants to know the probability that he or she will have a stroke given that he or she has a heart attack as a complication of the surgery. Assume that 1 in 500 patients has both complications, that the probability of heart attack is 0.05, and that the events are independent. Calculate your answer.
- The results of a hypothetical study to measure test performance of a diagnostic test for HIV are shown in the  $2 \times 2$  table in ■ Table 3.9.
  - Calculate the sensitivity, specificity, disease prevalence, PV+, and PV–.
  - Use the TPR and TNR calculated in part (a) to fill in the  $2 \times 2$  table in ■ Table 3.10. Calculate the disease prevalence, PV+, and PV–.

■ Table 3.9 A  $2 \times 2$  contingency table for the hypothetical study in problem 2

PCR test result	Gold standard test positive	Goldstandard test negative	Total
Positive PCR	48	8	56
Negative PCR	2	47	49
Total	50	55	105

PCR polymerase chain reaction

**Table 3.10** A  $2 \times 2$  contingency table to complete for problem 2b

PCR test result	Gold standard test positive	Gold standard test negative	Total
Positive PCR	x	x	x
Negative PCR	100	99,900	x
Total	x	x	x

PCR polymerase chain reaction  
x quantities that the question ask students to calculate

3. You are asked to interpret the results from a diagnostic test for HIV in an asymptomatic patient whose test was positive when the patient volunteered to donate blood. After taking the patient's history, you learn that the patient has a history of intravenous-drug use. You know that the overall prevalence of HIV infection in your community is 1 in 500 and that the prevalence in people who have injected drugs is 20 times as high as in the community at large.
  - (a) Estimate the pretest probability that this patient is infected with HIV.
  - (b) The patient tells you that two people with whom the patient shared needles subsequently died of AIDS. Which heuristic will be useful in making a subjective adjustment to the pretest probability in part (a)?
  - (c) Use the sensitivity and specificity that you worked out in 2(a) to calculate the post-test probability of the patient having HIV after a positive and negative test. Assume that the pretest probability is 0.10.
  - (d) If you wanted to increase the post-test probability of disease given a

positive test result, would you change the TPR or TNR of the test?

4. You have a patient with cancer who has a choice between surgery or chemotherapy. If the patient chooses surgery, he or she has a 2% chance of dying from the operation (life expectancy = 0), a 50% chance of being cured (life expectancy = 15 years), and a 48% chance of not being cured (life expectancy = 1 year). If the patient chooses chemotherapy, he or she has a 5% chance of death (life expectancy = 0), a 65% chance of cure (life expectancy = 15 years), and a 30% chance that the cancer will be slowed but not cured (life expectancy = 2 years). Create a decision tree. Calculate the expected value of each option in terms of life expectancy.
5. You are concerned that a patient with a sore throat has a bacterial infection that would require antibiotic therapy (as opposed to a viral infection, for which no treatment is available). Your treatment threshold is 0.4, and based on the examination you estimate the probability of bacterial infection as 0.8. A test is available (TPR = 0.75, TNR = 0.85) that indicates the presence or absence of bacterial infection. Should you perform the test? Explain your reasoning. How would your analysis change if the test were extremely costly or involved a significant risk to the patient?
6. What are the three kinds of bias that can influence measurement of test performance? Explain what each one is, and state how you would adjust the post-test probability to compensate for each.
7. How could a computer system ease the task of performing a complex decision analysis?
8. When you search the medical literature to find probabilities for patients similar to one you are treating, what is the most important question to consider? How should you adjust probabilities in light of the answer to this question?

9. Why do you think clinicians sometimes order tests even if the results will not affect their management of the patient? Do you think the reasons that you identify are valid? Are they valid in only certain situations? Explain your answers. See the January 1998 issue of *Medical Decision Making* for articles that discuss this question.
10. Explain the differences in three approaches to assessing patients' preferences for health states: the standard gamble, the time trade-off, and the visual analog scale.

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- How can cognitive science theory meaningfully inform and shape the design, development, and assessment of healthcare information systems?
- How is cognitive science different from behavioral science?
- What are some of the ways in which we can characterize the structure of knowledge?
- What are some of the dimensions of difference between experts and novices?
- Why is it important to consider cognition and human factors in dealing with issues of patient safety?
- How does distributed cognition differ from other theories of human cognition?

## 4.1 Introduction

Enormous advances in health information technologies and more generally, in computing over the past several decades have begun to permeate diverse facets of clinical practice. The rapid pace of technological developments such as the Internet, wireless technologies, and mobile devices, in the last decade, affords significant opportunities for supporting, enhancing and extending user experiences, interactions and communications (Rogers 2004). These advances, coupled with a growing computer literacy among healthcare professionals, afford the potential for great improvements in healthcare. Yet many observers note that the healthcare system is slow to understand information technology and effectively incorporate it into the work environment (Shortliffe and Blois 2001; Karsh et al. 2010; Harrington 2015). Innovative technologies often produce profound cultural, social, and cognitive changes. These transformations necessitate adaptation at many different levels of aggregation from the individual to the larger institution, often causing disruptions of workflow and user dissatisfaction (Bloomrosen et al. 2011).

Similar to other complex domains, biomedical information systems embody ideals in design that often do not readily yield practical solutions in implementation. As computer-based systems infiltrate clinical practice and settings, the consequences often can be felt through all levels of the organization. This impact can have deleterious effects resulting in systemic inefficiencies and suboptimal practice, which can lead to frustrated healthcare practitioners, unnecessary delays in healthcare delivery, and even adverse events (Lin et al. 1998; Weinger and Slagle 2001). How can we manage change? How can we introduce systems that are designed to be more intuitive and also implemented efficiently to be confluent with everyday practice without compromising safety?

### 4.1.1 Introducing Cognitive Science

**Cognitive science** is a multidisciplinary domain of inquiry devoted to the study of cognition and its role in intelligent agency. The primary disciplines include cognitive psychology, artificial intelligence, neuroscience, linguistics, anthropology, and philosophy. From the perspective of informatics, cognitive science can provide a framework for the analysis and modeling of complex human performance in technology-mediated settings. Cognitive science incorporates basic science research focusing on fundamental aspects of cognition (e.g., attention, memory, reasoning, early language acquisition) as well as applied research. Applied cognitive research is focally concerned with the development and evaluation of useful and usable cognitive artifacts. **Cognitive artifacts** are human-made materials, devices, and systems that extend people's abilities in perceiving objects, encoding and retrieving information from memory, and problem-solving (Gillan and Schvaneveldt 1999). In this regard, applied cognitive research is closely aligned with the disciplines of **human-computer interaction** (HCI) and **human factors**. In everyday life, we interact with cognitive artifacts to receive and manipulate information to alter our thinking

processes and offload effort-intensive cognitive activity to the external world, thereby reducing mental workload.

The past three decades have produced a cumulative body of experiential and practical knowledge about system design and implementation that guide future initiatives. This practical knowledge embodies the need for sensible and intuitive user interfaces, an understanding of workflow, and the ways in which systems impact individual and team performance. However, experiential knowledge in the form of anecdotes and case studies is inadequate for producing robust generalizations or sound design and implementation principles. There is a need for a theoretical foundation. Biomedical informatics is more than the thin intersection of biomedicine and computing (Patel and Kaufman 1998). There is a growing role for the social sciences, including the cognitive and behavioral sciences, in biomedical informatics, particularly as they pertain to human-computer interaction and other areas such as **information retrieval** and **decision support** (Patel et al. 2017). In this chapter, we focus on the foundational role of cognitive science in biomedical informatics research and practice. Theories and methods from the cognitive sciences can illuminate different facets of design and implementation of information and knowledge-based systems. They can also play a larger role in characterizing and enhancing human performance on a wide range of tasks involving clinicians, patients, and healthy consumers of biomedical information. These tasks may include developing training programs and devising measures to reduce errors or increase efficiency. In this respect, cognitive science represents one of the basic component sciences of biomedical informatics (Shortliffe and Blois 2001; Patel and Kaufman 1998).

#### 4.1.2 Cognitive Science and Biomedical Informatics

---

How can cognitive science theory meaningfully inform and shape design, development, and assessment of health-care information

systems? Cognitive science provides insight into principles of system usability and *learnability*, the mediating role of technology in clinical performance, the process of medical judgment and decision-making, the training of healthcare professionals, patients, and health consumers, and the design of a safer workplace. The central argument is that it can inform our understanding of human performance in technology-rich healthcare environments (Carayon 2012; Patel et al. 2013b).

Precisely how will cognitive science theory and methods make a significant contribution towards these important objectives? The translation of research findings from one discipline into practical concerns that can be applied to another is rarely a straight-forward process (Rogers 2004). Furthermore, even when scientific knowledge is highly relevant in principle, making that knowledge actionable in a design context can be a significant challenge. In this chapter, we discuss (a) basic cognitive science research and theories that provide a foundation for understanding the underlying mechanisms guiding human performance (e.g., findings pertaining to the structure of human memory), and (b) research in the areas of **medical errors** and **patient safety** as they interact with health information technology).

As illustrated in ■ Table 4.1, there are correspondences between basic cognitive science research, medical cognition and cognitive research in biomedical informatics along several dimensions. For example, theories of human memory and knowledge organization lend themselves to characterizations of expert clinical knowledge that can then be contrasted with the representations of such knowledge in clinical systems. Similarly, research in text comprehension has provided a theoretical framework for research in understanding biomedical texts. Additionally, theories of problem solving can be used to understand the processes and knowledge associated with diagnostic and therapeutic reasoning. This understanding provides a basis for developing medical artificial intelligence and decision support systems.

Cognitive research, theories, and methods can contribute to applications in informatics

**Table 4.1** Correspondences between cognitive science, medical cognition and applied cognitive research in medical informatics

Cognitive Science	Medical Cognition	Biomedical Informatics
Knowledge organization and human memory	Organization of clinical and basic science knowledge	Development and use of medical knowledge bases
Problem solving, Heuristics/reasoning strategies	Medical problem solving and decision making	Medical artificial intelligence/decision support systems/medical errors
Perception/attention	Radiologic and dermatologic diagnosis	Medical imaging systems
Text comprehension	Understanding medical texts Knowledge representation	Information retrieval/digital libraries/health literacy
Conversational analysis	Medical discourse	Medical natural language processing
Distributed cognition	Collaborative practice and research in health care	Computer-based provider order entry systems
Coordination of theory and evidence	Diagnostic and therapeutic reasoning	Evidence-based clinical guidelines
Diagrammatic reasoning	Perceptual processing of patient data displays	Biomedical information visualization

in a number of ways including: (1) seed *basic research findings* that can illuminate dimensions of design (e.g., attention and memory, aspects of the visual system), (2) provide an *explanatory vocabulary* for characterizing how individuals process and communicate health information (e.g., various studies of medical cognition pertaining to doctor-patient interaction), (3) present an *analytic framework* for identifying problems and modeling certain kinds of user interactions, (4) characterize the relationship between health information technology, human factors and patient safety, (5) provide *rich descriptive accounts* of clinicians employing technologies in the context of work, and (6) furnish a generative approach for novel designs and productive applied research programs in informatics (e.g., intervention strategies for supporting low literacy populations in health information seeking).

Based on a review of articles published in the Journal of Biomedical Informatics between January 2001 and March 2014, Patel and Kannampallil (2015) identified 57 articles that focused on topics related to cognitive informatics. The topics ranged from characterizing the limits of clinician problem-solving and reasoning behavior, to describing

coordination and communication patterns of distributed clinical teams, to developing sustainable and cognitively plausible interventions for supporting clinician activities.

The social sciences are constituted by multiple frameworks and approaches. **Behaviorism** constitutes a framework for analyzing and modifying behavior. It is an approach that has had an enormous influence on the social sciences. Cognitive science partially emerged as a response to the limitations of behaviorism. The next section of the chapter contains a brief history of the cognitive and behavioral sciences that emphasizes the points of difference between the two approaches. It also serves to introduce basic concepts in the study of cognition.

## 4.2 Cognitive Science: The Emergence of an Explanatory Framework

In this section, we sketch a brief history of the emergence of cognitive science in view to differentiate it with competing theoretical frameworks in the social sciences. The section also

serves to introduce core concepts that constitute an explanatory framework for cognitive science.

Behaviorism is the conceptual framework underlying a particular science of behavior (Zuriff 1985). It is not to be confused with the term behavioral science which names a large body of work across disciplines, but not a specific theoretical framework. Behaviorism dominated experimental and applied psychology as well as the social sciences for the better part of the twentieth century (Bechtel et al. 1998). Behaviorism represented an attempt to develop an objective, empirically-based science of behavior and more specifically, learning. Empiricism is the view that experience is the only source of knowledge (Hilgard and Bower 1975). Behaviorism endeavored to build a comprehensive framework of scientific inquiry around the experimental analysis of observable behavior. Behaviorists eschewed the study of thinking as an unacceptable psychological method because it was inherently subjective, error-prone, and could not be subjected to empirical validation. Similarly, hypothetical constructs (e.g., mental processes as mechanisms in a theory) were discouraged. All constructs had to be specified in terms of operational definitions, so they could be manipulated, measured, and quantified for empirical investigation (Weinger and Slagle 2001).

For reasons that go beyond the scope of this chapter, classical behavioral theories have been largely discredited as a comprehensive unifying theory of behavior. However, behaviorism continues to provide a theoretical and methodological foundation in a wide range of social science disciplines. For example, behaviorist tenets continue to play a central role in public health research. In particular, health behavior research emphasizes antecedent variables and environmental contingencies that serve to sustain unhealthy behaviors such as smoking (Sussman 2001). Around 1950, there was increasing dissatisfaction with the limitations and methodological constraints (e.g., the disavowal of the unobserved such as mental states) of behaviorism. In addition, developments in logic, information theory, cybernetics, and perhaps most importantly,

the advent of the digital computer, aroused substantial interest in “information processing” (Gardner 1985).

Cognitive scientists placed “thought” and “mental processes” at the center of their explanatory framework. The “computer metaphor” provided a framework for the study of human cognition as the manipulation of “symbolic structures.” It also provided the foundation for a model of memory, which was a prerequisite for an information processing theory (Atkinson and Shiffrin 1968). The implementation of models of human performance as computer programs provided a measure of objectivity and a *sufficiency test* of a theory and also served to increase the objectivity of the study of mental processes (Estes 1975).

Arguably, the landmark publication in the nascent field of cognitive science is Newell and Simon’s “Human Problem Solving” (Newell and Simon 1972). This was the culmination of over 15 years of work on problem solving and research in artificial intelligence. It was a mature thesis that described a theoretical framework, extended a language for the study of cognition, and introduced protocol-analytic methods that have become ubiquitous in the study of high-level cognition. It laid the foundation for the formal investigation of symbolic-information processing (more specifically, problem solving). The development of models of human information processing also provided a foundation for the discipline of human-computer interaction and the first formal methods of analysis (Card et al. 1983).

The early investigations of problem solving focused primarily on investigations of experimentally contrived or toy-world tasks such as elementary deductive logic, the Tower of Hanoi, illustrated in  Fig. 4.1, and mathematical word problems (Greeno and Simon 1988). These tasks required very little background knowledge and were well structured, in the sense that all the variables necessary for solving the problem were present in the problem statement. These tasks allowed for a complete description of the task environment, a step-by-step description of the sequential behavior of the subjects’ performance, and the modeling of subjects’ cognitive and overt

■ Fig. 4.1 Tower of Hanoi task illustrating a start state and a goal state

behavior in the form of a computer simulation. The Tower of Hanoi, in particular, served as an important test bed for the development of an explanatory vocabulary and framework for analyzing problem-solving behavior.

The Tower of Hanoi (TOH) is a relatively straight-forward task that consists of three pegs (A, B, and C) and three or more disks that vary in size. The goal is to move the three disks from peg A to peg C one at a time with the constraint that a larger disk can never rest on a smaller one. Problem solving can be construed as *search* in a **problem space**. A problem space has an *initial state*, a *goal state*, and a *set of operators*. Operators are any moves that transform a given state to a successor state. For example, the first move could be to move the small disk to peg B or peg C. In a three-disk TOH, there are a total of 27 possible states representing the complete problem space. TOH has  $3^n$  states where  $n$  is the number of disks. The minimum number of moves necessary to solve a TOH is  $2^{n-1}$ . Problem solvers will typically maintain only a small set of states at a time.

The search process involves finding a solution strategy that will minimize the number of steps. The metaphor of movement through a problem space provides a means for understanding how an individual can sequentially address the challenges they confront at each stage of a problem and the actions that ensue. We can characterize the problem-solving behavior of the subject at a local level in terms of state transitions or at a more global level in terms of *strategies*. For example, *means-ends analysis* is a commonly used strategy for reducing the difference between the start state and goal state. For instance, moving all but the largest disk from peg A to peg B is an interim goal associated with such a strat-

egy. Although TOH bears little resemblance to the tasks performed by either clinicians or patients, the example illustrates the process of analyzing task demands and task performance in human subjects. The TOH helped lay the groundwork for cognitive task analyses that are performed today.

**Protocol analysis**<sup>1</sup> is among the most commonly used methods (Newell and Simon 1972). Protocol analysis refers to a class of techniques for representing verbal **think-aloud protocols** (Greeno and Simon 1988). Think-aloud protocols are the most common source of data used in studies of problem solving. In these studies, subjects are instructed to verbalize their thoughts as they perform an experimental task. Ericsson and Simon (1993) specify the conditions under which verbal reports are acceptable as legitimate data. For example, retrospective think-aloud protocols are viewed as somewhat suspect because the subject has had the opportunity to reconstruct the information in memory, and the verbal reports are inevitably distorted. Think-aloud protocols recorded in concert with observable behavioral data such as a subject's actions provide a rich source of evidence to characterize cognitive processes.

Cognitive psychologists and linguists have investigated the processes and properties of language and memory in adults and children for many decades. Early research focused on basic laboratory studies of list learning or processing of words and sentences (as in a sentence completion task) (Anderson 1985).

1 The term protocol refers to that which is produced by a subject during testing (e.g., a verbal record). It differs from the more common use of protocol as defining a code or set of procedures governing behavior or a situation.

van Dijk and Kintsch (1983) developed an influential method of analyzing the process of **text comprehension** based on the realization that text can be described at multiple levels from surface codes (e.g., words and syntax) to a deeper level of semantics. Comprehension refers to cognitive processes associated with understanding or deriving meaning from text, conversation, or other informational resources. It involves the processes that people use when trying to make sense of a piece of text, such as a sentence, a book, or a verbal utterance. It also involves the final product of such processes, which is, the mental representation of the text, essentially what people have understood.

Comprehension may often precede problem solving and decision making but is also dependent on perceptual processes that focus attention, the availability of relevant knowledge, and the ability to deploy knowledge in a given context. Some of the more important differences in medical problem solving and decision making arise from differences in knowledge and comprehension. Furthermore, many of the problems associated with decision making are the result of either a lack of knowledge or failure to understand the information appropriately.

The early investigations provided a well-constrained artificial environment for the development of the basic methods and principles of problem solving. They also provide a rich explanatory vocabulary (e.g., problem space), but were not fully adequate in accounting for cognition in knowledge-rich domains of greater complexity and involving uncertainty. In the mid to late 1970s, there was a shift in research to complex “real-life” knowledge-based domains of inquiry (Greeno and Simon 1988). Problem-solving research was studying performance in domains such as physics (Larkin et al. 1980), medical diagnoses (Elstein et al. 1978) and architecture (Akin 1982). Similarly, the study of text comprehension shifted from research on simple stories to technical and scientific texts in a range of domains, including medicine. This paralleled a similar change in artificial intelligence research from “toy programs” to addressing “real-world” problems and the development

of expert systems (Clancey and Shortliffe 1984). The shift to real-world problems in cognitive science was spearheaded by research exploring the nature of expertise. Most of the early investigations on expertise involved laboratory experiments. However, the shift to knowledge-intensive domains provided a theoretical and methodological foundation to conduct both basic and applied research in real-world settings such as the workplace (Vicente 1999) and the classroom (Bruer 1993). These areas of application provided a fertile test bed for assessing and extending the cognitive science framework.

In recent years, the conventional information-processing approach has come under criticism for its narrow focus on the rational/cognitive processes of the solitary individual. One of the most compelling proposals has to do with a shift from viewing cognition as a property of the solitary individual to viewing cognition as distributed across groups, cultures, and artifacts. This claim has significant implications for the study of collaborative endeavors and human-computer interaction. We explore the concepts underlying *distributed cognition* in greater detail in a subsequent section.

### 4.3 Human Information Processing

---

It is well known that product design often fails to consider cognitive and physiological constraints adequately and imposes an unnecessary burden on task performance (Sharp et al. 2019). Fortunately, advances in theory and methods provide us with greater insight into designing systems for the human condition.

Cognitive science serves as a basic science and provides a framework for the analysis and modeling of complex human performance. A computational theory of mind provides the fundamental underpinning for most contemporary theories of cognitive science. The basic premise is that much of human cognition can be characterized as a series of operations or computations on mental representations. **Mental representations** are internal cognitive

states that have a certain correspondence with the external world. For example, they may reflect a clinician's hypothesis about a patient's condition after noticing an abnormal gait as he entered the clinic. These are likely to elicit further inferences about the patient's underlying condition and may direct the physician's information-gathering strategies and contribute to an evolving problem representation.

Two interdependent dimensions by which we can characterize cognitive systems are (1) architectural theories that endeavor to provide a unified theory for all aspects of cognition and (2) the different kinds of knowledge necessary to attain competency in a given domain. Individuals differ substantially in terms of their knowledge, experiences, and endowed capabilities. The architectural approach capitalizes on the fact that we can characterize certain regularities of the human information-processing system. These can be either structural regularities—such as the existence of and the relations between perceptual, attentional, and memory systems and memory capacity limitations—or processing regularities, such as processing speed, selective attention, or problem-solving strategies. Cognitive systems are characterized functionally in terms of the capabilities they enable (e.g., focused attention on selective visual features), the way they constrain human cognitive performance (e.g., limitations on memory), and their development during the lifespan. In regard to the lifespan issue, there is a growing body of literature on cognitive aging and how aspects of the cognitive system such as attention, memory, vision and motor skills change as a function of aging (Fisk et al. 2009). This basic science research is of growing importance to informatics as we seek to develop e-health applications for seniors, many of whom suffer from chronic health conditions such as arthritis and diabetes. A graphical user interface or more generally, a website designed for younger adults may not be suitable for older adults.

Differences in knowledge organization are a central focus of research into the nature of expertise. In medicine, the expert-novice paradigm has contributed to our understanding

of the nature of medical expertise and skilled clinical performance.

#### 4.3.1 Cognitive Architectures and Human Memory Systems

Fundamental research in perception, cognition, and psychomotor skills over the last 50 years has provided a foundation for design principles in human factors and human-computer interaction. Although cognitive guidelines have made significant inroads in the design community, there remains a significant gap in applying basic cognitive research (Gillan and Schvaneveldt 1999). Designers routinely violate basic assumptions about the human cognitive system. There are invariably challenges in applying basic research and theory to applications. More human-centered design and cognitive research can instrumentally contribute to such an endeavor (Zhang et al. 2004).

Over the last 50 years, there have been several attempts to develop a unified theory of cognition. The goal of such a theory is to provide a single set of mechanisms for all cognitive behaviors from motor skills, language, memory, to decision making, problem solving, and comprehension (Newell 1990). Such a theory provides a means to put together a voluminous and seemingly disparate body of human experimental data into a coherent form. Cognitive architecture represents unifying theories of cognition that are embodied in large-scale computer simulation programs. Although there is much plasticity evidenced in human behavior, cognitive processes are bound by biological and physical constraints. Cognitive architectures specify functional rather than biological constraints on human behavior (e.g., limitations on working memory). These constraints reflect the information-processing capacities and limitations of the human cognitive system. Architectural systems embody a relatively fixed permanent structure that is (more or less) characteristic of all humans and doesn't substantially vary over an individual's lifetime. It represents a scientific hypothesis about

those aspects of human cognition that are relatively constant over time and independent of the task (Carroll 2003). Cognitive architectures also play a role in providing blueprints for building future intelligent systems that embody a broad range of capabilities like those of humans (Duch et al. 2008). There are several large-scale cognitive architecture theories that embody computational models of cognition and have informed a substantial body of research in cognitive science and allied disciplines. ACT-R (short for “Adaptive Control of Thought-Rational”) is perhaps, the most widely known cognitive architecture. It was developed by John R. Anderson and is sustained by a large global community of researchers centered at Carnegie Mellon University (Anderson 2013). It is a theory for simulating and understanding human cognition. It started more than 40 years ago as an architecture that could simulate basic tasks related to memory, language and problem solving. It has continued to evolve into a system that can perform an enormous range of human tasks (Ritter et al. 2019).

Cognitive architectures include short-term and long-term memories that store content about an individual’s beliefs, goals, and knowledge, the representation of elements that are contained in these memories as well as their organization into larger-scale structures (Lieto et al. 2018). An extended discussion of architectural theories and systems is beyond the scope of this chapter. However, we employ the architectural frame of reference to introduce some basic distinctions in memory systems. Human memory is typically divided into at least two structures: **long-term memory** and **short-term/working memory**. Working memory is an emergent property of interaction with the environment. Long-term memory (LTM) can be thought of as a repository of all knowledge, whereas working memory (WM) refers to the resources needed to maintain information active during cognitive activity (e.g., text comprehension). The information maintained in working memory includes stimuli from the environment (e.g., words on a display) and knowledge activated from long-term memory. In theory, LTM

is infinite, whereas WM is limited to five to ten “chunks” of information. A chunk is any stimulus or patterns of stimuli that have become familiar from repeated exposure and is subsequently stored in memory as a single unit (Larkin et al. 1980). Problems impose a variable **cognitive load** on working memory. This refers to an excess of information that competes for few cognitive resources, creating a burden on working memory (Chandler and Sweller 1991). For example, maintaining a seven-digit phone number in WM is not very difficult. However, to maintain a phone number while engaging in conversation is nearly impossible for most people. Multi-tasking is one factor that contributes to cognitive load. The structure of the task environment, for example, a crowded computer display is another contributor. High velocity/high workload clinical environments such as intensive care units also impose cognitive loads on clinicians carrying out the task.

#### 4.3.2 The Organization of Knowledge

---

Architectural theories specify the structure and mechanisms of memory systems, whereas theories of knowledge organization focus on the content. There are several ways to characterize the kinds of knowledge that reside in LTM and that support decisions and actions. Cognitive psychology has furnished a range of domain-independent constructs that account for the variability of mental representations needed to engage the external world.

A central tenet of cognitive science is that humans actively construct and interpret information from their environment. Given that environmental stimuli can take a multitude of forms (e.g., written text, speech, music, images, etc.), the cognitive system needs to be attuned to different representational types to capture the essence of these inputs. For example, we process written text differently than we do mathematical equations. The power of cognition is reflected in the ability to form abstractions - to represent perceptions, experiences, and thoughts in some medium

### 1. 43-year-old white female who developed diarrhea after a brief period of 2 days of GI upset

1.1	female	ATT: Age (old); DEG: 43 year; ATT: white
1.2	develop	PAT: [she]; THM: diarrhea; TNS: past
1.3	period	ATT: brief; DUR: 2 days; THM: 1.4
1.4	upset	LOC: GI
1.5	TEM:ORD	[1.3], [1.2]

■ Fig. 4.2 Propositional analysis of a think-aloud protocol of a primary care physician

other than that in which they have occurred without extraneous or irrelevant information (Norman 1993). Representations enable us to remember, reconstruct, and transform events, objects, images, and conversations absent in space and time from our initial experience of the phenomena. Representations reflect states of knowledge.

**Propositions** are a form of natural language representation that captures the essence of an idea (i.e., semantics) or concept without explicit reference to linguistic content. For example, “hello”, “hey”, and “what’s happening” can typically be interpreted as a greeting containing identical propositional content even though the literal semantics of the phrases may differ. These ideas are expressed as language and translated into speech or text when we talk or write. Similarly, we recover the propositional structure when we read or listen to verbal information. Numerous psychological experiments have demonstrated that people recover the gist of a text or spoken communication (i.e., propositional structure) not the specific words (Anderson 1985; van Dijk and Kintsch 1983). Studies have also shown the individuals at different levels of expertise will differentially represent a text (Patel and Kaufman 1998). For example, experts are more likely to selectively encode relevant propositional information that will inform a decision. On the other hand, non-experts will often remember more information, but much of the recalled information may not be relevant to the decision (Patel and Groen 1991a, b).

Propositional representations constitute an important construct in theories of comprehension. Propositional knowledge can be expressed using a predicate calculus formalism or as a semantic network. The predicate

calculus representation is illustrated below. A subject’s response, as given on ■ Fig. 4.2, is divided into sentences or segments and sequentially analyzed. The formalism includes a head element of a segment and a series of arguments. For example, in proposition 1.1, the focus is on a female who has the attributes of being 43 years of age and white. The TEM:ORD or temporal order relation indicates that the events of 1.3 (GI upset) precede the event of 1.2 (diarrhea). The formalism is informed by an elaborate propositional language (Frederiksen 1975) and was first applied to the medical domain by Patel and her colleagues (Patel and Groen 1986). The method provides us with a detailed way to characterize the information subjects understood from reading a text, based on their summary or explanations.

Kintsch (1998) theorized that comprehension involves an interaction between what the text conveys and knowledge in long-term memory. Comprehension occurs when the reader uses prior knowledge to process the incoming information presented in the text. The text information is called the *textbase* (the propositional content of the text). For instance, in medicine, the textbase could consist of the representation of a patient problem as written in a patient chart. The situation model is constituted by the textbase representation plus the domain-specific and everyday knowledge that the reader uses to derive a broader meaning from the text. In medicine, the situation model would enable a physician to draw inferences from a patient’s history leading to a diagnosis, therapeutic plan or prognosis (Patel and Groen 1991a, b). This situation model is typically derived from the general knowledge and specific knowledge acquired through medical teaching, readings

(e.g., theories and findings from biomedical research), clinical practice (e.g., knowledge of associations between clinical findings and specific diseases, knowledge of medications or treatment procedures that have worked in the past) and the textbase representation. Like other forms of knowledge representation, the situation model is used to “fit in” the incoming information (e.g., text, perception of the patient). Since the knowledge in LTM differs among physicians, the resulting situation model generated by any two physicians is likely to differ as well. Theories and methods of text comprehension have been widely used in the study of medical cognition and have been instrumental in characterizing the process of guideline development and interpretation (Peleg et al. 2006; Patel et al. 2014).

**Schemata** represent higher-level knowledge structures. They can be construed as data structures for representing categories of concepts stored in memory (e.g., fruits, chairs, geometric shapes, and thyroid conditions). There are schemata for concepts underlying situations, events, sequences of actions and so forth. To process information with the use of a schema is to determine which model best fits the incoming information. Schemata have constants (all birds have wings) and variables (chairs can have between one and four legs). The variables may have associated default values (e.g., birds fly) that represent the prototypical circumstance.

When a person interprets information, the schema serves as a “filter” for distinguishing relevant and irrelevant information. Schemata can be considered as generic knowledge structures that contain slots for particular kinds of propositions. For instance, a schema for myocardial infarction may contain the findings of “chest pain,” “sweating,” “shortness of breath,” but not the finding of “goiter,” which is part of the schema for thyroid disease.

The schematic and propositional representations reflect abstractions and don’t necessarily preserve literal information about the external world. Imagine that you are having a conversation at the office about how to rearrange the furniture in your living room. To engage in such a conversation, one needs to be able to construct images of the objects and

their spatial arrangement in the room. **Mental images** are a form of internal representation that captures perceptual information recovered from the environment. There is compelling psychological and neuropsychological evidence to suggest that mental images constitute a distinct form of mental representation (Bartolomeo 2008). Images play a particularly important role in domains of visual diagnosis such as dermatology and radiology.

**Mental models** are an analog-based construct for describing how individuals form internal models of systems. Mental models are designed to answer questions such as “how does it work?” or “what will happen if I take the following action?” “Analogy” suggests that the representation explicitly shares the structure of the world it represents (e.g., a set of connected visual images of a partial road map from your home to your work destination). This contrasts with an abstraction-based form such as propositions or schemas in which the mental structure consists of either the gist, an abstraction, or summary representation. However, like other forms of mental representation, mental models are always incomplete, imperfect, and subject to the processing limitations of the cognitive system. Mental models can be derived from perception, language, or one’s imagination (Payne 2003). *Running* of a model corresponds to a process of mental simulation to generate possible future states of a system from observed or hypothetical state. For example, when one initiates a Google Search, one may reasonably anticipate that the system will return a list of relevant (and less than relevant) websites that correspond to the query. Mental models are a particularly useful construct in understanding human-computer interaction.

An individual’s mental models provide predictive and explanatory capabilities of the function of a physical system. More often the construct has been used to characterize models that have a spatial and temporal context, as is the case in reasoning about the behavior of electrical circuits (White and Frederiksen 1990). The model can be used to simulate a process (e.g., predict the effects of network interruptions on getting cash from an ATM machine). Kaufman, Patel and Magder (1996)

characterized clinicians' mental models of the cardiovascular system (specifically, cardiac output). The study characterized the development of an understanding of the system as a function of expertise. The research also documented various conceptual flaws in subjects' models and how these flaws impacted subjects' predictions and explanations of physiological manifestations. ■ Figure 4.3 illustrates the four chambers of the heart and blood flow in the pulmonary and cardiovascular systems. The claim is that clinicians and medical students have variably robust representations of the structure and function of the system. This model enables prediction and explanation of the effects of perturbations in the system on

blood flow and on various clinical measures such as left ventricular ejection fraction.

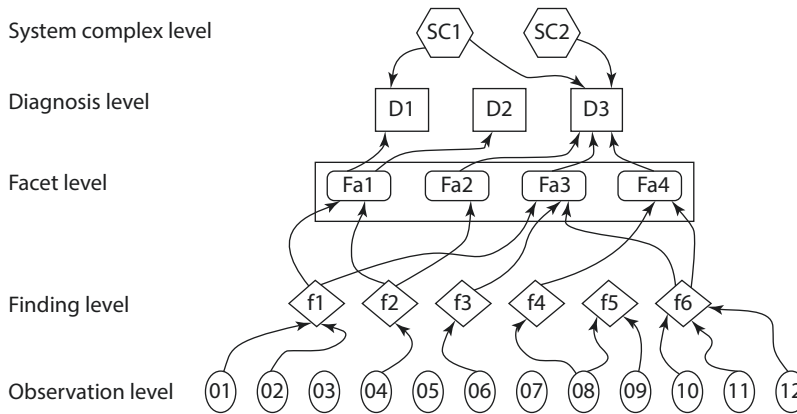

Thus far, we have only considered domain-general ways of characterizing the organization of knowledge. In view to understanding the nature of medical cognition, it is necessary to characterize the domain-specific nature of knowledge organization in medicine. Given the vastness and complexity of the domain of medicine, this can be a rather daunting task. There is no single way to represent all biomedical (or even clinical) knowledge, but it is an issue of considerable importance for research in biomedical informatics. Much research has been conducted in biomedical artificial intelligence to develop biomedical ontologies for use in knowledge-based systems (Ramoni et al. 1992). Patel et al. (1997) address this issue in the context of using empirical evidence from psychological experiments on medical expertise to test the validity of the AI systems. **Developers of biomedical taxonomies, nomenclatures, and vocabulary** systems such as UMLS or SNOMED are engaged in a similar pursuit (see ► Chap. 7).

We have employed an epistemological framework developed by Evans and Gadd (1989). They proposed a framework that serves to characterize the knowledge used for medical understanding and problem solving, and for differentiating the levels at which biomedical knowledge may be organized. This framework represents a formalization of biomedical knowledge as realized in textbooks and journals and can be used to provide us with insight into the organization of clinical practitioners' knowledge (see ■ Fig. 4.4).

The framework consists of a hierarchical structure of concepts formed by *clinical observations* at the lowest level, followed by *findings*, *facets*, and *diagnoses*. Clinical observations are units of information that are recognized as potentially relevant in the problem-solving context. However, they do not constitute clinically useful facts. Findings are composed of observations that have potential clinical significance. Establishing a finding reflects a decision made by a physician that an array of data contains a significant cue or cues that need to be considered. Facets consist of clusters of findings that indicate an underlying

■ Fig. 4.3 Schematic model of circulatory and cardiovascular physiology. The diagram illustrates various structures of the pulmonary and systemic circulation system and the process of blood flow. The illustration is used to exemplify the concept of mental model and how it could be applied to explaining and predicting physiologic behavior

■ Fig. 4.4 Epistemological frameworks representing the structure of medical knowledge for problem solving

medical problem or class of problems. They reflect general pathological descriptions such as left-ventricular failure or thyroid condition. Facets resemble the kinds of constructs used by researchers in medical artificial intelligence to describe the partitioning of a problem space. They are interim hypotheses that serve to divide the information in the problem into sets of manageable sub-problems and to suggest possible solutions. Facets also vary in terms of their levels of abstraction. Diagnosis is the level of classification that subsumes and explains all levels beneath it. Finally, the systems level consists of information that serves to contextualize a problem, such as the ethnic background of a patient.

#### 4.4 Medical Cognition

The study of expertise is one of the principal paradigms in problem-solving research, which has been documented in a number of volumes in literature (Sternberg and Ericsson 1996; Ericsson 2009; Ericsson et al. 2018). Comparing experts to novices provides us with the opportunity to explore the aspects of performance that undergo change and result in increased problem-solving skill (Glaser 2000). It also permits investigators to develop domain-specific models of competence that can be used for assessment and training purposes.

A goal of this approach has been to characterize expert performance in terms of the knowledge and cognitive processes used in comprehension, problem solving, and decision making, using carefully developed laboratory tasks (Chi and Glaser 1981), where deGroot's (1965) pioneering research in chess represents one of the earliest characterizations of expert-novice differences. In one of his experiments, subjects were allowed to view a chess board for 5–10 seconds and were then required to reproduce the position of the chess pieces from memory. The grandmaster chess players were able to reconstruct the mid-game positions with better than 90% accuracy, while novice chess players could only reproduce approximately 20% of the correct positions. When the chess pieces were placed on the board in a random configuration, not encountered in the course of a normal chess match, expert chess masters' recognition ability fell to that of novices. This result suggests that superior recognition ability is not a function of superior memory, but is a result of an enhanced ability to recognize typical situations (Chase and Simon 1973). This phenomenon is accounted for by a process known as "**chunking**." Patel and Groen (1991b) showed a similar phenomenon in medicine. The expert physicians were able to reconstruct patient summaries in an accurate manner when patient information was collected out of order (e.g., history, physical exam, lab results), as long as the pattern of information, even out of sequence was famil-

iar. When the sentences were placed out of order in a way that the pattern was unfamiliar, the expert physicians' recognition ability was no better than the novices.

It is well known that knowledge-based differences impact the problem representation and determine the strategies a subject uses to solve a problem. Simon and Simon (1978) compared a novice subject with an expert subject in solving textbook physics problems. The results indicated that the expert solved the problems in one-quarter of the time required by the novice with fewer errors. The novice solved most of the problems by working *backward* from the unknown problem solution to the givens of the problem statement. The expert worked *forward* from the givens to solve the necessary equations and determine the quantities they are asked to solve for. Differences in the directionality of reasoning by levels of expertise has been demonstrated in diverse domains from computer programming (Perkins et al. 1990) to medical diagnosis (Patel and Groen 1986).

The expertise paradigm spans the range of content domains including physics (Larkin et al. 1980), sports (Allard and Starkes 1991), music (Sloboda 1991), and medicine (Patel et al. 1994). Edited volumes (Ericsson 2006; Chi et al. 1988; Ericsson et al. 2018; Ericsson and Smith 1991; Hoffman 1992) provide an informative general overview of the area. This research has focused on differences between subjects varying in levels of expertise in terms of memory, reasoning strategies, and in particular the role of domain-specific knowledge. Among the expert's characteristics uncovered by this research are the following: (1) experts are capable of perceiving large patterns of meaningful information in their domain, which novices cannot perceive; (2) they are fast at processing and at deployment of different skills required for problem solving; (3) they have superior short-term and long-term memories for materials (e.g., clinical findings in medicine) within their domain of expertise, but not outside of it; (4) they typically represent problems in their domain at deeper, more principled levels whereas novices show a superficial level of representation; (5) they spend more time assessing the problem prior

to solving it, while novices tend to spend more time working on the solution itself and little time in problem assessment; (6) individual experts may differ substantially in terms of exhibiting these kinds of performance characteristics (e.g., superior memory for domain materials).

Usually, someone is designated as an expert based on a certain level of performance, as exemplified by Elo ratings in chess; by virtue of being certified by a professional licensing body, as in medicine, law, or engineering; on the basis of academic criteria, such as graduate degrees; or simply based on years of experience or peer evaluation (Hoffman et al. 1995). The concept of an expert, however, refers to an individual who surpasses competency in a domain (Sternberg and Horvath 1999). Although competent performers, for instance, may be able to encode relevant information and generate effective plans of action in a specific domain, they often lack the speed and the flexibility that we see in an expert. A domain expert (e.g., a medical practitioner) possesses an extensive, accessible knowledge base that is organized for use in practice and is tuned to the particular problems at hand. In the study of medical expertise, it has been useful to distinguish different types of expertise.

Patel and Groen (1991a, b) distinguished between general and specific expertise, a distinction supported by research indicating differences between subexperts (i.e., expert physicians who solve a case outside their field of specialization) and experts (i.e., domain specialist) with respect to reasoning strategies and organization of knowledge. General expertise corresponds to expertise that cuts across medical subdisciplines (e.g., general medicine). Specific expertise results from having extensive experience within a medical subdomain, such as cardiology or endocrinology. An individual may possess both or only generic expertise.

The development of expertise can follow a somewhat unusual trajectory. It is often assumed that the path from novice to expert goes through a steady process of gradual accumulation of knowledge and fine-tuning of skills. That is, as a person becomes more familiar with a domain, his or her level of per-

formance (e.g., accuracy, quality) gradually increases. However, research has shown that this assumption is often incorrect (Lesgold et al. 1988; Patel et al. 1994). Cross-sectional studies of experts, intermediates, and novices have shown that people at intermediate levels of expertise may perform more poorly than those at a lower level of expertise on some tasks.

Furthermore, there is a longstanding body of research on learning that has suggested that the learning process involves phases of error-filled performance followed by periods of stable, comparatively error-free performance. In other words, human learning does not consist of the gradually increasing accumulation of knowledge and fine-tuning of skills. Rather, it requires the arduous process of continually learning, re-learning, and exercising new knowledge, punctuated by periods of an apparent decrease in mastery and declines in performance, which may be necessary for learning to take place. ■ Figure 4.5 presents an illustration of this learning and development phenomenon known as the **intermediate effect**.

The intermediate effect has been found in a variety of tasks and with a great number of performance indicators. The tasks used include comprehension and explanation of clinical problems, doctor-patient communica-

■ **Fig. 4.5** Schematic representation of intermediate effect. The straight line gives a commonly assumed representation of performance development by level of expertise. The curved line represents the actual development from novice to expert. The Y-axis may represent any of a number of performance variables such as the number of errors made, number of concepts recalled, number of conceptual elaborations, or number of hypotheses generated in a variety of tasks

tion, recall and explanation of laboratory data, generation of diagnostic hypotheses, and problem solving (Patel and Groen 1991a, b). The performance indicators used have included recall and inference of medical-text information, recall, and inference of diagnostic hypotheses, generation of clinical findings from a patient in doctor-patient interaction, and requests for laboratory data, among others. The research has also identified developmental levels at which the intermediate phenomenon occurs, including senior medical students and residents. It is important to note, however, that in some tasks, the development is **monotonic**. For instance, in diagnostic accuracy, there is a gradual increase, with an intermediate exhibiting a greater degree of accuracy than the novice and the expert demonstrating a still greater degree than the intermediate. Furthermore, when the relevancy of the stimuli to a problem is considered, an appreciable monotonic phenomenon appears. For instance, in recall studies, novices, intermediates, and experts are assessed in terms of the total number of propositions recalled showing the typical non-monotonic effect. However, when propositions are divided in terms of their relevance to the problem (e.g., a clinical case), experts recall more relevant propositions than intermediates and novices, suggesting that intermediates have difficulty separating what is relevant from what is not.

During the periods when the intermediate effect occurs, a reorganization of knowledge and skills takes place, characterized by shifts in perspectives or a realignment or creation of goals. The intermediate effect is also partly due to the unintended changes that take place as the person reorganizes for intended changes. People at intermediate levels typically generate a great deal of irrelevant information and seem incapable of discriminating what is relevant from what is not. As compared to a novice student (■ Fig. 4.6), the reasoning pattern of an intermediate student shows the generation of long chains of discussion evaluating multiple hypotheses and reasoning in haphazard direction (■ Fig. 4.7). A well-structured knowledge structure of a senior level student leads him more directly to a

Fig. 4.6 Problem interpretations by a novice medical student. The given information from patient problem is represented on the right side of the figure and the new generated information is given on the left side, information in the box represents diagnostic hypothesis. Intermediate hypotheses are represented as solid dark

circles (filled). Forward driven or data driven inference arrows are shown from left to right (solid dark line). Backward or hypothesis driven inference arrows are shown from right to left (solid light line). Thick solid dark line represents rule out strategy

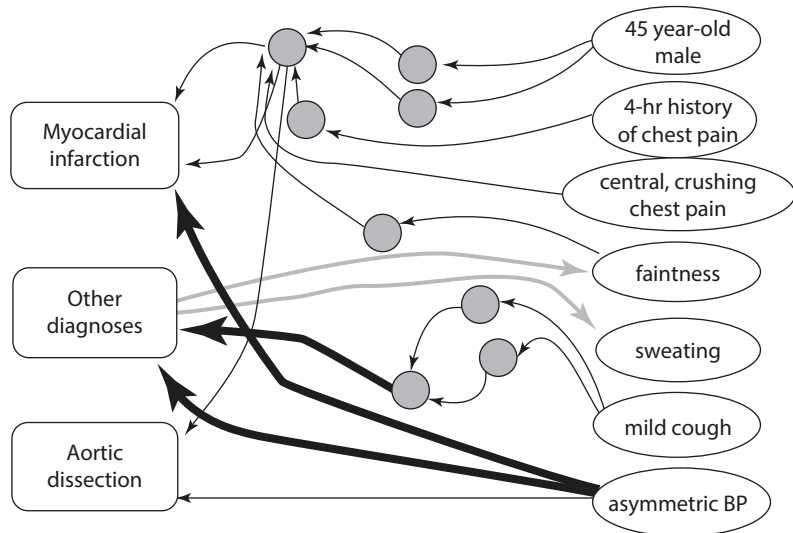

Fig. 4.7 Problem interpretations by an intermediate medical student

solution (Fig. 4.8). Thus, the intermediate effect can be explained as a function of the learning process, maybe as a necessary phase of learning. Identifying the factors involved in the intermediate effect may help in improving performance during learning (e.g., by designing decision-support systems or intelligent tutoring systems that help the user in focusing on relevant information).

The intermediate effect is not a one-time phenomenon. Rather, it repeatedly occurs at strategic points in a student or physician's training and follows periods in which large bodies of new knowledge or complex skills are acquired. These periods are followed by intervals in which there is a decrement in performance until a new level of mastery is achieved.

**Fig. 4.8** Problem interpretations by a senior medical student

#### 4.4.1 Expertise in Medicine

The systematic investigation of medical expertise began more than 60 years ago with research by Ledley and Lusted (1959) into the nature of clinical inquiry. They proposed a two-stage model of clinical reasoning involving a hypothesis-generation stage, followed by a hypothesis-evaluation stage. This latter stage is most amenable to formal decision analytic techniques. The earliest empirical studies of medical expertise can be traced to the works of Rimoldi (1961) and Kleinmuntz and McLean (1968) who conducted experimental studies of diagnostic reasoning by contrasting students with medical experts in simulated problem-solving tasks. The results emphasized the greater ability of expert physicians to attend to relevant information selectively and narrow the set of diagnostic possibilities (i.e., consider fewer hypotheses).

The origin of contemporary research on medical thinking is associated with the seminal work of Elstein, Shulman, and Sprafka (1978) who studied the problem-solving processes of physicians by drawing on then-contemporary methods and theories of cognition. This model of problem-solving has had a substantial influence both on studies of medical cognition and medical education. They were the first to use experimental methods and theories of cognitive science to investigate clinical competency.

Their research findings led to the development of an elaborated model of **hypothetico-deductive reasoning**, which proposed that physicians reasoned by first generating and then testing a set of hypotheses to account for clinical data (i.e., reasoning from hypothesis to data). First, physicians generated a small set of hypotheses very early in the case, as soon as the first pieces of data became available. Second, physicians were selective in the data they collected, focusing only on the relevant data. Third, physicians made use of a hypothetico-deductive method of diagnostic reasoning (Elstein et al. 1978).

The previous research was largely modeled after early problem-solving studies in knowledge-lean tasks. Medicine is a knowledge-rich domain, and a different approach was needed. Feltovich, Johnson, Moller, and Swanson (1984), drawing on models of knowledge representation from medical artificial intelligence, characterized fine-grained differences in knowledge organization between subjects of different levels of expertise in the domain of pediatric cardiology. Patel and colleagues studied the knowledge-based solution strategies of expert cardiologists as evidenced by their pathophysiological explanations of a complex clinical problem (Patel and Groen 1986). The results indicated that subjects who accurately diagnosed the problem, employed a **forward-directed (data-driven) reasoning** strategy—

using patient data to lead toward a complete diagnosis (i.e., reasoning from data to hypothesis). This is in contrast to subjects who misdiagnosed or partially diagnosed the patient problem. They tended to use a **backward or hypothesis-driven reasoning** strategy.

Patel and Groen (1991a, b) investigated the nature and directionality of clinical reasoning in a range of contexts of varying complexity. The objectives of this research program were both to advance our understanding of medical expertise and to devise more effective ways of teaching clinical problem solving. It has been established that the patterns of data-driven and hypothesis-driven reasoning are used differentially by novices and experts. Experts tend to use data-driven reasoning, which depends on the physician possessing a highly organized knowledge base about the patient's disease (including sets of signs and symptoms). Because of their lack of substantive knowledge or their inability to distinguish relevant from irrelevant knowledge, novices and intermediates use more hypothesis-driven reasoning, often resulting in very complex reasoning patterns. The fact that experts and novices reason differently suggests that they might reach different conclusions (e.g., decisions or understandings) when solving medical problems. Similar patterns of reasoning have been found in other domains (Larkin

et al. 1980). Due to their extensive knowledge base and the high-level inferences they make, experts typically skip steps in their reasoning.

Although experts typically use data-driven reasoning during clinical performance, this type of reasoning sometimes breaks down, and the expert must resort to hypothesis-driven reasoning. Although data-driven reasoning is highly efficient, it is often error-prone in the absence of adequate domain knowledge, since there are no built-in checks on the legitimacy of the inferences that a person makes. Pure data-driven reasoning is only successful in constrained situations, where one's knowledge of a problem can result in a complete chain of inferences from the initial problem statement to the problem solution, as illustrated in Fig. 4.9. In contrast, hypothesis-driven reasoning is slower and may make heavy demands on working memory, because one must keep track of goals and hypotheses. It is, therefore, most likely to be used when domain knowledge is inadequate, or the problem is complex. Hypothesis-driven reasoning is usually exemplary of a *weak method* of problem solving in the sense that is used in the absence of relevant prior knowledge and when there is uncertainty about problem solution. In problem-solving terms, strong methods engage knowledge, whereas weak methods refer to general strategies. Weak does not necessar-

**Fig. 4.9** Diagrammatic representation of data-driven (top down) and hypothesis-driven (bottom-up) reasoning. From the presence of vitiligo, a prior history of progressive thyroid disease, and examination of the thyroid (clinical findings on the left side of figure), the physician reasons forward to conclude the diagnosis of Myxedema (right of figure). However, the anomalous

finding of respiratory failure, which is inconsistent with the main diagnosis, is accounted for as a result of a hypometabolic state of the patient, in a backward-directed fashion. COND: refers to a conditional relation; CAU: indicates a causal relation; and RSLT: identifies a resultive relation

ily imply ineffectual in this context. However, hypothesis-driven reasoning may be more conducive to the novice learning experience in that it can guide the organization of knowledge (Patel et al. 1990).

In the more recent literature, described in a chapter by Patel and colleagues (2013a), two forms of human reasoning that are more widely accepted are deductive and inductive reasoning. **Deductive reasoning** is a process of reaching specific conclusions (e.g., a diagnosis) from a hypothesis or a set of hypotheses, whereas **inductive reasoning** is the process of generating possible conclusions based on available data, such as data from a patient. However, when reasoning in real-world clinical situations, it is too simplistic to think of reasoning with only these two strategies. A third form of reasoning, abductive, which combines deductive and inductive reasoning, was proposed (Peirce 1955). A physician developing and testing explanatory hypotheses based on a set of heuristics, may be considered abductive reasoning (Magnani 2001). Thus, an **abductive reasoning** process where a set of hypotheses are identified and then each of these hypotheses is evaluated on the basis of its potential consequences (Elstein et al. 1978; Ramoni et al. 1992). This makes abductive reasoning a data-driven process that relies heavily on the domain expertise of the person.

During the testing phase, hypotheses are evaluated by their ability to account for the current problem. Deduction helps in building up the consequences of each hypothesis, and this kind of reasoning is customarily regarded as a common way of evaluating diagnostic hypotheses (Joseph and Patel 1990; Kassirer 1989; Patel et al. 1994; Patel, Evans, and Kaufman 1989). All these types of inferences play different roles in the hypothesis generation and testing phases (Patel and Ramoni 1997; Peirce 1955). Our inherent ability to adapt to different kinds of knowledge domains, situations, and problems requires the use of a variety of reasoning modes, and this process describes the notion of abductive medical reasoning (Patel and Ramoni 1997). In contrast, novices and intermediate subjects (e.g., medical trainees) are more likely to employ more deliberative, effortful, and

cognitively taxing forms of reasoning that can resemble hypothetico-deductive methods. As problems increase in complexity and uncertainty, expert clinicians' resort to hybrid forms of reasoning that may include substantial backward-directed reasoning.

The study of medical cognition has been summarized in a series of articles (Patel et al. 1994, 2018) and edited volumes (e.g., Evans and Patel 1989). In more recent times, medical cognition is discussed in the context of informatics and in the new field of investigation, **cognitive informatics** (Patel and Kannampallil 2015; Patel et al. 2014, 2015b, 2017). Furthermore, foundations of cognition also play a significant role in investigations of HCI, including human factors and patient safety. Details of HCI in biomedicine are covered in ► Chap. 5.

## 4.5 Human Factors Research and Patient Safety

- » Human error in medicine and the adverse events which may follow are problems of psychology and engineering not of medicine (“Senders 1993”) (cited in (Woods et al. 2008).

**Human factors** research is a discipline devoted to the study of technology systems and how people work with them or are impacted by these technologies (Henriksen 2010). Human factors research discovers and applies information about human behavior, abilities, limitations, and other characteristics to the design of tools, machines, systems, tasks, and jobs, and environments for productive, safe, comfortable, and effective human use (Chapanis 1996). In the context of healthcare, human factors are concerned with the full complement of technologies and systems used by a diverse range of individuals including clinicians, hospital administrators, health consumers and patients (Flin and Patey 2009). Human factors work approaches the study of health practices from several perspectives or levels of analysis. A full exposition of human factors in medicine is beyond the scope of this chapter. For a detailed treatment of these

issues, the reader is referred to the Handbook of Human Factors and Ergonomics in Health Care and Patient Safety (Carayon et al. 2011). The focus in this chapter is on cognitive work in human factors and healthcare, particularly in relation to patient safety. We recognize that patient safety is a systemic challenge at multiple levels of aggregation beyond the individual. It is clear that understanding, predicting, and transforming human performance in any complex setting requires a detailed understanding of both the setting and the factors that influence performance (Woods et al. 2008).

Our objective in this section is to introduce a theoretical foundation, establish important concepts, and discuss illustrative research in **patient safety**. The field of human factors is guided by principles of engineering and applied cognitive psychology (Chapanis 1996). Human factors analysis applies knowledge about the strengths and limitations of humans to the design of interactive systems and their environment. The objective is to ensure their effectiveness, safety, and ease of use. Mental models and issues of decision making are central to human-factors analysis. Any system will be easier and less burdensome to use to the extent that it is co-extensive with users' mental models. The different dimensions of cognitive capacity, including memory, attention, and workload are central to human-factor analyses. Our perceptual system inundates us with more stimuli than our cognitive systems can process. Attentional mechanisms enable us to selectively prioritize and attend to certain stimuli and attenuate other ones. They also have the property of being sharable, which enables us to multitask by dividing our attention between two activities. For example, if we are driving on a highway, we can easily have a conversation with a passenger at the same time. However, as the skies get dark or the weather changes or suddenly you find yourself driving through winding mountainous roads, you will have to allocate more of your attentional resources to driving and less to the conversation.

Human factors research leverages theories and methods from cognitive engineering to characterize human performance in complex

settings and challenging situations in aviation, industrial process control, military command control and space operations (Woods et al. 2008). The research has elucidated empirical regularities and provides explanatory concepts and models of human performance. This allows us to derive common underlying patterns in somewhat disparate settings.

#### 4.5.1 Patient Safety

Patient safety refers to the prevention of healthcare errors, and the elimination or mitigation of patient injury caused by healthcare errors (Patel and Zhang 2007). It has been an issue of considerable concern for the past quarter-century, but the greater community was galvanized by the National Academy of Medicine report "To Err is Human," (Kohn et al. 2000) and by a follow-up report, "Improving Diagnosis in Health Care" (Balogh et al. 2015). The 2000 report communicated the surprising fact that up to 98,000 preventable deaths every single year in the United States are attributable to human error, which makes it the 8th leading cause of death in this country. Although one may argue over the specific numbers, there is no disputing that too many patients are harmed or die every year as a result of human actions or absence of action.

We can only analyze errors after they happened, and they often seem to be glaring blunders after the fact. This leads to the assignment of blame or searches for a single cause of the error. However, in hindsight, it is exceedingly difficult to recreate the situational context, stress, shifting attention demands, and competing goals that characterized a situation prior to the occurrence of an error. This sort of retrospective analysis is subject to hindsight bias. **Hindsight bias** masks the dilemmas, uncertainties, demands, and other latent conditions that were operative before the mishap. Too often the term 'human error' connotes blame and a search for the guilty culprits, suggesting some sort of human deficiency or irresponsible behavior. Human factors researchers recognized that this approach error is inherently incomplete and poten-

tially misleading. They argue for the need for a more comprehensive systems-centered approach that recognizes that error could be attributed to a multitude of factors as well as the interaction of these factors. Error is the failure of a planned sequence of mental or physical activities to achieve its intended outcome when these failures cannot be attributed to chance (Patel and Zhang 2007; Reason 1990). Reason (1990) introduced an important distinction between **latent** and **active failures**. Active failure represents the face of error. The effects of active failure are immediately felt. In healthcare, active errors are committed by providers such as nurses, physicians, or pharmacists who are actively responding to patient needs at the “sharp end”. The latent conditions are less visible but equally important. Latent conditions are enduring systemic problems that may not be evident for some time, combine with other system problems to weaken the system’s defenses and make errors possible. There is a lengthy list of potential latent conditions including poor interface design of important technologies, communication breakdown between key actors, gaps in supervision, inadequate training, and absence of a safety culture in the workplace—a culture that emphasizes safe practices and the reporting of any conditions that are potentially dangerous.

Zhang, Patel, Johnson, and Shortliffe (2004) developed a taxonomy of errors partially based on the distinctions proposed by Reason (1990). They further classified errors in terms of **slips** and **mistakes** (Reason 1990). A slip occurs when the actor selected the appropriate course of action, but it was executed inappropriately. A mistake involves an inappropriate course of action reflecting an erroneous judgment or inference (e.g., a wrong diagnosis or misreading of an x-ray). Mistakes may either be knowledge-based owing to factors such as incorrect knowledge, or they may be rule-based, in which case the correct knowledge was available, but there was a problem in applying the rules or guidelines. They further characterize medical errors as a progression of events. There is a period when everything is operating smoothly. Then an unsafe practice unfolds resulting in

a kind of error, but not necessarily leading to an adverse event. For example, if there is a system of checks and balances that is part of routine practice or if there is a systematic supervisory process in place, the vast majority of errors will be trapped and defused in this middle zone. If these measures or practices are not in place, an error can propagate and cross the boundary to become an adverse event. At this point, the patient has been harmed. In addition, if an individual is subject to a heavy workload or intense time pressure, then that will increase the potential for an error, resulting in an adverse event.

The notion that human error should not be tolerated is prevalent in both the public and personal perception of the performance of most clinicians. However, researchers in other safety-critical domains have long since abandoned the quest for zero defect, citing it as an impractical goal, and choosing to focus instead on the development of strategies to enhance the ability to recover from error (Morel et al. 2008). Patel and her colleagues conducted empirical investigations into error detection and recovery by experts (attending physicians) and non-experts (resident trainees) in the critical care domain, using both laboratory-based and naturalistic approaches (Patel et al. 2011). These studies show that expertise is more closely tied to the ability to detect and recover from errors and not so much to the ability not to make errors. The study results show that both the experts and non-experts are prone to commit and recover from errors, but experts’ ability to detect and recover from knowledge-based errors is better than that of trainees. Error detection and correction in complex real-time critical care situations appears to induce certain urgency for quick action in a high alert condition, resulting in rapid detection and correction. Studies on expertise and understanding of the limits and failures of human decision-making are important if we are to build robust decision-support systems to manage the boundaries of risk of error in decision making (Patel et al. 2015a; Patel and Cohen 2008). Research on situational complexity and medical errors is documented in a recent book by Patel, Kaufman, and Cohen (2014).

## 4.5.2 Unintended Consequences

It is widely believed that health information technologies have the potential to transform healthcare in a multitude of ways, including the reduction of errors. However, it is increasingly apparent that technology-induced errors are deeply consequential and have had deleterious consequences for patient safety.

There is evidence to suggest that a poorly designed user interface can present substantial challenges even for the well-trained and highly skilled user (Zhang et al. 2003). Lin et al. (1998) conducted a series of studies on a patient-controlled analgesic or PCA device, a method of pain relief that uses disposable or electronic infusion devices and allows patients to self-administer analgesic drugs as required. Lin and colleagues investigated the effects of two interfaces to a commonly used PCA device, including the original interface. Based on **cognitive task analysis**, they redesigned the original interface so that it was more in line with sound human factors principles. Based on the cognitive task analysis, they found the existing PCA interface to be problematic in several different ways. For example, the structure of many subtasks in the programming sequence was unnecessarily complex. There was a lack of information available on the screen to provide meaningful feedback and to structure the user experience (e.g., negotiating the next steps). For example, a nurse would not know that he or she was on the third of five screens or when they were half way through the task. Based on the CTA analysis, Lin et al. (1998) also redesigned the interface according to sound human factors principles and demonstrated significant improvements in efficiency, error rate, and reported workload.

Zhang and colleagues employed a modified heuristic evaluation method (see ► Sect. 4.5, above) to test the safety of two infusion pumps (Zhang et al. 2003). Based on an analysis by four evaluators, a total of 192 violations with the user interface design were documented. Consistency and visibility (the ease in which a user can discern the system state) were the most widely documented violations. Several of the violations were classified as

problems of substantial severity. Their results suggested that one of the two pumps were likely to induce more medical errors than the other ones.

It is clear that usability problems are consequential and have the potential to impact patient safety. Kushniruk et al. (2005) examined the relationship between particular kinds of usability problems and errors in a handheld prescription writing application. They found that particular usability problems were associated with the occurrence of an error in entering the medication. For example, the problem of inappropriate default values automatically populating the screen was found to be correlated with errors in entering the wrong dosages of medications. In addition, certain types of errors were associated with mistakes (not detected by users) while others were associated with slips about unintentional errors. Horsky et al. (2005) analyzed a problematic medication order placed using a CPOE system that resulted in an overdose of potassium chloride being administered to an actual patient. The authors used a range of investigative methods including inspection of system logs, semi-structured interviews, the examination of the electronic health record, and cognitive evaluation of the order entry system involved. They found that the error was due to a confluence of factors including problems associated with the display, the labeling of functions, and ambiguous dating of the dates in which medication was administered. The poor interface design did not assist with the decision-making process, and in fact, its design served as a hindrance, where the interface was a poor fit for the *conceptual operators* utilized by clinicians when calculating medication dosage (i.e., based on volume, not duration).

Koppel et al. (2005) published an influential study examining how computer-provider order-entry systems (CPOE) facilitated medical errors. The study, which was published in JAMA (Journal of the American Medical Association), used a series of methods including interviews with clinicians, observations, and a survey to document the range of errors. According to the authors, the system facilitated 22 types of medication errors, and many

of them occurred with some frequency. The errors were classified into two broad categories: (1) information errors generated by fragmentation of data and failure to integrate the hospital's information systems and (2) human-machine interface flaws reflecting machine rules that do not correspond to work organization or usual behaviors.

The growing body of research on unintended consequences spurred the American Medical Informatics Association to devote a policy meeting to consider ways to understand and diminish their impact (Bloomrosen et al. 2011). The matter is especially pressing given the increased implementation of health information technologies nationwide, including ambulatory care practices that have little experience with health information technologies. The authors outline a series of recommendations, including a need for more cognitively-oriented research to guide the study of the causes and mitigation of unintended consequences resulting from health information technology implementations. These changes could facilitate improved management of those consequences, resulting in enhanced performance, patient safety, as well as greater user acceptance.

#### 4.5.3 Distributed Cognition and Electronic Health Records

---

In this chapter, we have considered a classical model of information-processing cognition in which mental representations mediate all activity and constitute the central units of analysis. The analysis emphasizes how an individual formulates internal representations of the external world. To illustrate the point, imagine an expert user of a word processor who can effortlessly negotiate tasks through a combination of key commands and menu selections. The traditional cognitive analysis might account for this skill by suggesting that the user has formed an image or schema of the layout structure of each of eight menus, and retrieves this information from memory each time an action is to be performed. For example, if the goal is to “insert a clip art icon,”

the user would recall that this is subsumed under pictures that are the ninth item on the “Insert” menu and then execute the action, thereby achieving the goal. However, there are some problems with this model. Mayes, Draper, McGregor, and Koatley (1988) demonstrated that even highly skilled users could not recall the names of menu headers, yet they could routinely make fast and accurate menu selections. The results indicate that many or even most users relied on cues in the display to trigger the right menu selections. This suggests that the display can have a central role in controlling interaction in graphical user interfaces.

As discussed, the conventional information-processing approach has come under criticism for its narrow focus on the rational/cognitive processes of the solitary individual. In the previous section, we considered the relevance of external representations to cognitive activity. The emerging perspective of **distributed cognition** offers a more far-reaching alternative. The distributed view of cognition represents a shift in the study of cognition from being the sole property of the individual to being “stretched” across groups, material artifacts, and cultures (Hutchins 1995; Suchman 1987). This viewpoint is increasingly gaining acceptance in cognitive science and human-computer interaction research. In the distributed approach to HCI research, cognition is viewed as a process of coordinating distributed internal (i.e., knowledge) and external representations (e.g., visual displays, manuals). Distributed cognition has two central points of inquiry, one that emphasizes the inherently social and collaborative nature of cognition (e.g., doctors, nurses and technical support staff in neonatal care unit jointly contributing to a decision process), and one that characterizes the mediating effects of technology or other artifacts on cognition.

The mediating role of technology can be evaluated at several levels of analysis from the individual to the organization. Technologies, whether they be computer-based or an artifact in another medium, transform the ways individuals and groups think. They do not merely augment, enhance, or expedite perfor-

mance, although a given technology may do all of these things. The difference is not merely one of quantitative change, but one that is qualitative in nature.

In a distributed world, what becomes of the individual? We believe it is important to understand how technologies promote enduring changes in individuals. Salomon, Perkins and Globerson (1991) introduced an important distinction in considering the mediating role of technology on individual performance, the effects with technology and the effects of technology. The former is concerned with the changes in performance displayed by users while equipped with the technology. For example, when using an effective medical information system, physicians should be able to gather information more systematically and efficiently. In this capacity, medical information technologies may alleviate some of the cognitive load associated with a given task and permit physicians to focus on higher-order

thinking skills, such as diagnostic hypothesis generation and evaluation. The effects of technology refer to enduring changes in general cognitive capacities (knowledge and skills) as a consequence of interaction with a technology. This effect is illustrated subsequently in the context of the enduring effects of an EHR (see ► Chap. 10).

We employed a pen-based EHR system, DCI (Dossier of Clinical Information), in several of our studies (see Kushniruk et al. 1996). Using the pen or computer keyboard, physicians can directly enter information into the EHR, such as the patient's chief complaint, past history, history of present illness, laboratory tests, and differential diagnoses. Physicians were encouraged to use the system while collecting data from patients (e.g., during the interview). The system allows the physician to record information about the patient's differential diagnosis, the ordering of tests, and the prescription of medication.

■ Fig. 4.10 Display of a structured electronic medical record with graphical capabilities

The graphical interface provides a highly structured set of resources for representing a clinical problem, as illustrated in ■ Fig. 4.10.

We have studied the use of this EHR in both laboratory-based research (Kushniruk et al. 1996) and actual clinical settings using cognitive methods (Patel et al. 2000). The laboratory research included a simulated doctor-patient interview. We have observed two distinct patterns of EHR usage in the interactive condition, one in which the subject pursues information from the patient predicated on a hypothesis; the second strategy involves the use of the EHR display to guide asking the patient questions. In the screen-driven strategy, the clinician is using the structured list of findings in the order in which they appear on the display to elicit information from the patient. All experienced users of this system appear to have both strategies in their repertoire.

In general, a screen-driven strategy can enhance performance by reducing the cognitive load imposed by information-gathering goals and allow the physician to allocate more cognitive resources toward testing hypotheses and rendering decisions. On the other hand, this strategy can encourage a certain sense of complacency. We observed both effective as well as counter-productive uses of this screen-driven strategy. A more experienced user consciously used the strategy to structure the information-gathering process, whereas a novice user used it less discriminately. In employing this screen-driven strategy, the novice elicited almost all of the relevant findings in a simulated patient encounter. However, she also elicited numerous irrelevant findings and pursued incorrect hypotheses. In this particular case, the subject became too reliant on the technology and had difficulty imposing her own set of working hypotheses to guide the information-gathering and diagnostic-reasoning processes.

The use of a screen-driven strategy is evidence of how technology transforms clinical cognition, as manifested in clinicians' patterns of reasoning. Patel et al. (2000) extended this line of research to study the cognitive consequences of using the same EHR system in a

diabetes clinic. The study considered the following questions (1) How do physicians manage information flow when using an EHR system? (2) What are the differences in the way physicians organize and represent this information using paper-based and EHR systems, and (3) Are there long-term, enduring effects of the use of EHR systems on knowledge representations and clinical reasoning? One study focused on an in-depth characterization of changes in knowledge organization in a single subject as a function of using the system. The study first compared the contents and structure of patient records produced by the physician using the EHR system and paper-based patient records, using ten pairs of records matched for variables such as patient age and problem type. After having used the system for six months, the physician was asked to conduct his/her next five patient interviews using only hand-written paper records.

The results indicated that the EHRs contained more information relevant to the diagnostic hypotheses. In addition, the structure and content of information were found to correspond to the structured representation of the particular medium. For example, EHRs were found to contain more information about the patient's past medical history, reflecting the query structure of the interface. The paper-based records appear to better preserve the integrity of the time course of the evolution of the patient problem, whereas, this is notably absent from the EHR. Perhaps, the most striking finding is that, after having used the system for six months, the structure and content of the physician's paper-based records bore a closer resemblance to the organization of information in the EHR than the paper-based records produced by the physician prior to exposure to the system. This finding is consistent with the enduring *effects of technology* even in the absence of the particular system (Salomon et al. 1991). The authors conclude that given these potentially enduring effects, the use of a particular EHR will almost certainly have a direct effect on medical decision making.

The previously discussed research demonstrates how information technologies can

mediate cognition and even produce enduring changes in how one performs a task. What dimensions of an interface contribute to such changes? What aspects of a display are more likely to facilitate efficient task performance, and what aspects are more likely to impede it? Norman (1986) argued that well-designed artifacts could reduce the need for users to remember large amounts of information, whereas poorly designed artifacts increased the knowledge demands on the user and the burden of working memory. In the distributed approach to HCI research, cognition is viewed as a process of coordinating distributed internal and external representations, and this, in effect, constitutes an indivisible information-processing system.

One of the appealing features of the distributed cognition paradigm is that it can be used to understand how properties of objects on the screen (e.g., links, buttons) can serve as external representations and reduce cognitive load. The distributed resource model proposed by Wright, Fields, and Harrison (2000) addresses the question of “what information is required to carry out some task and where should it be located: as an interface object or as something that is mentally represented to the user.” The relative difference in the distribution of representations (internal and external) is central to determining the efficacy of a system designed to support a complex task. Wright, Fields, and Harrison (2000) were among the first to develop an explicit model for coding the kinds of resources available in the environment and how they are embodied on an interface.

Horsky, Kaufman, and Patel (2003a, b) applied the distributed resource model and analysis to a provider order entry system. The goal was to analyze specific order-entry tasks such as those involved in admitting a patient to a hospital and then to identify areas of complexity that may impede optimal recorded entries. The research consisted of two-component analyses: a cognitive walk-through evaluation that was modified based on the distributed resource model and a simulated clinical ordering task performed by

seven physicians. The CW analysis revealed that the configuration of resources (e.g., very long menus, complexly configured displays) placed unnecessarily heavy cognitive demands on users, especially those who were new to the system. The resources model was also used to account for patterns of errors produced by clinicians. The authors concluded that the redistribution and reconfiguration of resources might yield guiding principles and design solutions in the development of complex interactive systems.

The distributed cognition framework has proved to be particularly useful in understanding the performance of teams or groups of individuals in a particular work setting (Hutchins 1995). Hazlehurst and colleagues (Hazlehurst et al. 2003, 2007) have drawn on this framework to illuminate how work in healthcare settings is constituted using shared resources and representations. The *activity system* is the primary explanatory construct. It is comprised of actors and tools, together with shared understandings among actors that structure interactions in a work setting. The “propagation of representational states through activity systems” is used to explain cognitive behavior and investigate the organization of the system and human performance. Following Hazlehurst et al. (2007, p. 540), “a **representational state** is a particular configuration of an information-bearing structure, such as a monitor display, a verbal utterance, or a printed label, that plays some functional role in a process within the system.” The author has used the concept to explain the process of medication ordering in an intensive care unit and the coordinated communications of a surgical team in a heart room.

The framework for distributed cognition is still an emerging one in human-computer interaction. It offers a novel and potentially powerful approach for illuminating the kinds of difficulties users encounter and finding ways to better structure the interaction by redistributing the resources. Distributed cognition analyses may also provide a window into why technologies sometimes fail to reduce errors or even contribute to them.

## 4.6 Conclusion

Theories and methods from cognitive science can shed light on a range of issues about the design and implementation of health information technologies. They can also serve an instrumental role in understanding and enhancing the performance of clinicians and patients as they engage in a range of cognitive tasks related to health. We believe that fundamental studies in psychology and cognitive science in general, can provide general guiding principles to study these issues, and can be combined with field studies which serve to illuminate different facets and contextualize the phenomena observed in laboratory studies. The potential scope of applied cognitive research in biomedical informatics is very broad. Significant inroads have been made in areas such as EHRs and patient safety. However, there are promising areas of future cognitive research that remain largely uncharted. These include understanding how to capitalize on health information technology without compromising patient safety (particularly in providing adequate decision support), understanding how various visual representations/graphical forms mediate reasoning in biomedical informatics and how these representations can be used by patients and health consumers with varying degrees of literacy. These are only a few of the cognitive challenges related to harnessing the potential of cutting-edge technologies to improve patient safety.

### Questions for Discussion

1. How can cognitive science theory meaningfully inform and shape design, development, and assessment of health-care information systems?
2. Describe two or three kinds of mental representations and briefly characterize their significance in understanding human performance.
3. What is the purpose and value of cognitive architectures?
4. Identify three ways in which novices differ from experts in medicine.
5. What are the limitations of interpreting retroactive data on medical errors?
6. Explain the difference between latent and active failures and their implications for patient safety?
7. How does the field of Cognitive Informatics capture the interaction of cognition and informatics in biomedicine and healthcare?

8. Explain the role inductive, deductive and abductive reasoning play in medical diagnostic reasoning?
9. Explain some ways in which technology-mediated errors can compromise patient safety.
10. What are some of the assumptions of the distributed cognition framework? What implications does this approach have for the evaluation of electronic health records?
11. Explain the difference between the *effects of technology* and the *effects with technology*? How can each of these effects contribute to improving patient safety and reducing medical error?
12. The use of electronic health records (EHR) has been shown to differentially affect clinical reasoning relative to paper charts. Briefly characterize the effects they have on reasoning, including those that persist after the clinician ceases to use the system.

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What are the major attributes of system usability?
- What are the methods that can be used to evaluate usability of a health information system?
- How does a poorly designed HIT implementation contribute to disruptions to clinical workflow?

5

## 5.1 Introduction to Human-Computer Interaction

---

Human-computer interaction (HCI) is a multifaceted discipline devoted to the *study and practice* of design and usability (Carroll 2003). The history of computing and more generally, that of artifact design, are rife with stories of dazzlingly powerful devices with remarkable capabilities that are thoroughly unusable by anyone except for the team of designers and their immediate families. In the often-cited book, *Psychology of Everyday Things*, Donald Norman (1988) describes a litany of poorly designed artifacts ranging from programmable VCRs to answering machines and water faucets that are inherently non-intuitive and difficult to use. Similarly, there have been numerous innovative and promising clinical information technologies that have yielded decidedly suboptimal results and resulted in deep user dissatisfaction. At a minimum, difficult interfaces result in steep learning curves and structural inefficiencies in task performance. At worst, problematic interfaces can have serious consequences for patient safety (Koppel et al. 2005; Lin et al. 1998; Zhang et al. 2004).

Myers and Rosson (1992) reported that nearly 50% of software code was devoted to the user interface, and a survey of developers indicated that, on average, 6% of their project budgets were spent on usability evaluation. Given the complexities of the modern graphical user interfaces (GUI), it is likely that more than 50% of the code is now

devoted to the GUI. On the other hand, usability evaluations have greatly increased over the last 20 years (Jaspers 2009). There have been numerous books and articles devoted to promoting effective user interface design (Preece et al. 2015; Shneiderman et al. 2016), and the importance of enhancing the user experience has been widely acknowledged by both consumers and producers of information technology. Part of the impetus is that usability has been demonstrated to be highly cost effective. Karat (1994) reported that for every dollar a company invests in the usability of a product, it receives between \$10 and \$100 in benefits. Although much has changed in the world of computing since Karat's estimate (e.g., the flourishing of the World Wide Web and mobile apps), it is clear that investments in usability still yield substantial rates of return (Nielsen 2008). It remains far costlier to fix a problem after product release than in an early design phase. The concept of usability as well as the methods and tools to measure and promote it are now “touchstones in the culture of computing” (Carroll 2003).

HCI has spawned a professional orientation that focuses on practical matters concerning the integration and evaluation of applications of technology to support human activities. There are also active academic HCI communities that have contributed significant advances to the science of computing. HCI researchers have been devoted to the development of innovative design concepts such as **virtual reality, ubiquitous computing, multimodal interfaces, collaborative workspaces, mobile technologies, and immersive and virtual environments**. HCI research has been instrumental in transforming the software engineering process towards a more user-centered iterative system development (e.g., rapid prototyping). HCI research has also been focally concerned with the cognitive, social, and cultural dimensions of the computing experience. In this regard, it is concerned with developing analytic frameworks for characterizing how technology can be used more productively across a range of tasks, settings, and user populations.

In this chapter, we describe the foundations of the role of HCI in biomedical informatics with a specific focus on methods for usability evaluation and clinical workflow. We also discuss the implications of HCI and clinical workflow methods for future biomedical informatics research. This chapter is a companion to chapter 4 in this volume on cognitive informatics (Chap. 4)

## 5.2 Role of HCI in Biomedical Informatics

HCI research in healthcare emerged at a time when health information technology and electronic health records (EHRs) were becoming more central to the practice of medicine (Patel et al. 2015). Much HCI work has been devoted to creating or enhancing design in healthcare systems. However, the focus of most of our work has been on the cognitive mediation of technology in healthcare practice (Patel et al. 2015). Most of the early HCI research focused on the solitary user of technology. Although such research is still commonplace, the focus has extended to distributed health information systems (Hazelhurst et al. 2007; Horsky et al. 2003) and analysis of unintended sociotechnical consequences with a particular focus on computerized provider order entry systems (Koppel et al. 2005). HCI studies in biomedicine extend across clinical and consumer health informatics, addressing a range of user populations including providers, biomedical scientists, and patients. While the implications of HCI principles for the design of HIT are acknowledged, the adoption of the tools and techniques among clinicians, informatics researchers and developers of HIT are limited. There is a consensus that HIT has not realized its potential as a tool that facilitates clinical decision-making, coordination of care, and improvement of patient safety (Middleton et al. 2013).

The field of human computer interaction intersects behavioral, and computer and information science. Thus, this field involves the study of interaction between people and computers. Computing systems includes both software and hardware. In addition, devices from

smartphones to glucose meters are devices that present usability challenges. In this chapter, the focus is on the software and the interface components. Thus the major focus of HCI is with the evaluation of interactive computer systems for human use. In the healthcare environment, it is important to understand HCI to ensure the users and the computers interact successfully. Therefore, the goals of HCI are to deploy usable, useful and safe systems.

## 5.3 Theoretical Foundations

In recent years, there has been a significant growth in research and application regarding HCI and healthcare systems. They have produced a collective body of experiential and practical knowledge about user experience, adoption and implementation to guide future design work. Some of the work is not specifically guided by a theoretical foundation and these efforts have proven to be useful in elucidating problems and contributing to user-centered design efforts. Human-computer interaction work is at least partly an empirical science in which local knowledge derived from a small body of studies will suffice in solving a problem. However, it is also necessary that we extrapolate knowledge from one context to another. Concentrated efforts in HCI are time-consuming, tend to employ small numbers of subjects and are conducted in a limited number of settings. For example, it is simply not possible to conduct an HCI research project in many different hospitals or to thoroughly test every facet of an electronic health record system. Knowledge solely based on practical experience or empirical studies are not adequate to account for the immense variety of health information technologies and the rich array of contexts that constitute the practice of medicine (Kaufman et al. 2015).

There are many facets to technology use and a range of theories that address them. For example, the technology acceptance model that focuses on user's perceived usefulness and usage intentions has been widely used in healthcare research (Venkatesh 2000). **Sociotechnical systems theory** is very broad in scope. It views all organizations as having the

following elements that comprise its organizational design: technological (including the actual IT system, usability, and unintended consequences), social (doctors, staff, patients, etc.), and external environment (e.g., political, economic, cultural, and legal influences) (Hendrick and Kleiner 1999). These subsystems are intricately connected, such that changes to any one affects others, sometimes in unanticipated or dysfunctional ways (Aarts et al. 2007; Ash et al. 2004). One of the most influential theories in clinical informatics was offered by Sittig and Singh (2010). They proposed an 8-dimensional model of interrelated concepts that can be used to explain performance in complex adaptive systems in the healthcare arena. The model has been applied in a range of settings model to understand and improve HIT applications at various stages of development and implementation.

**Cognitive engineering** (CE) is an interdisciplinary approach to the development of principles, methods, and tools to assess and guide the design of systems to support human performance (Hettinger et al. 2017). The approach is rooted in both cognitive science and engineering and has been used to support design of displays, decision support and training in numerous high-risk domains (Kushniruk et al. 2004). A computational theory of mind provides the fundamental underpinning for most contemporary cognitive theories. The basic premise is that much of human cognition can be characterized as a series of operations, computations on mental representations. At a higher level of cognitive analysis, CE also focuses on the discrepancy between user's goals and the physical controls embodied in a system (Norman 1986). Interface design choices differentially mediates task performance and various methods of analysis including those described below endeavor to measure this impact.

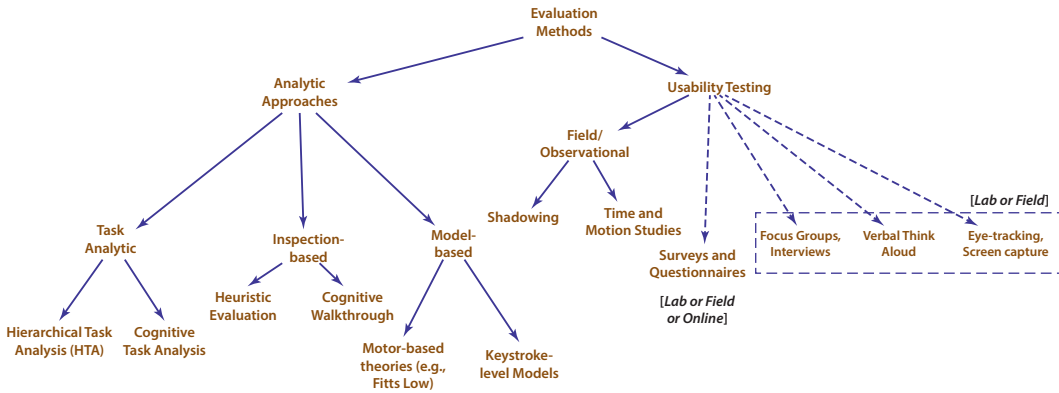

**Distributed cognition** (DCog) represents a shift in the study of cognition from an exclusive focus on the mind of the individual to being “stretched” across groups, material artifacts and cultures (Hutchins 1995). This paradigm has gained substantial currency in HCI research. In the distributed approach, cognition is viewed as a process of coordinating distributed internal (i.e., what's in the mind) and

external representations (e.g., visual displays, post-it notes). DCog has two lines of analysis, one that emphasizes the social and collaborative nature of cognition (e.g., surgeons, nurses and respiratory therapists in cardiothoracic surgical setting jointly contributing to a decision process), and one that characterizes the mediating effects of technology (e.g., EHRs, paper charts, mobile devices, apps) or other artifacts on cognition. DCog constitutes a family of interrelated theories rather than a single approach (Cohen et al. 2006). The approaches collectively offer a penetrating view of the complexities embodied in human-computer interaction. However, there is no “off-the-shelf” methodology for using it in research or as a practitioner (Furniss et al. 2015). The application of DCog theory and methods are complicated by the fact that there are no set of features to attend to and no checklist or prescribed method to follow (Rogers 2012). In addition, the analysis and abstraction requires a high level of skill and training. More in-depth reviews of DCog can be found in (Rogers 2004) and as applied to healthcare in (Hazlehurst et al. 2008; Kaufman et al. 2015). DCog approaches have been particularly useful in the analysis of teamwork and EHR-mediated workflow in complex environments (Blandford and Furniss 2006; Hazlehurst et al. 2007; Kaufman et al. 2009). It is not unusual for HCI researchers to engage multiple theories depending on the area of focus.

## 5.4 Usability of Health Information Technology<sup>1</sup>

Theories of cognitive science meaningfully inform and shape design, development and assessment of health-care information systems by providing insight into principles of

<sup>1</sup> Parts of the section, have been adapted, *with permission*, from Kannampallil, T. G., & Abraham, J. (2015). Evaluation of health information technology: Methods, frameworks and challenges. In V. L. Patel, T. G. Kannampallil, & D. Kaufman (Eds.), *Cognitive informatics in health and biomedicine: Human computer interaction*. London: Springer.

■ Fig. 5.1 Classification of evaluation methods

system *usability* and *learnability*, as well as the design of a safer workplace.

Usability methods, most often drawn from cognitive science, have been used to evaluate a wide range of medical information technologies including infusion pumps (Karat 1994), ventilator management systems, physician order entry (Ash et al. 2003; Horsky et al. 2003; Koppel et al. 2005), pulmonary graph displays (Wachter et al. 2003), information retrieval systems, and research web environments for clinicians (Elkin et al. 2002). In addition, usability techniques are increasingly used to assess patient-centered environments (Chan and Kaufman 2011; Cimino et al. 2000; Kaufman et al. 2003a, b). The methods include observations, focus groups, surveys and experiments. Collectively, these studies make a compelling case for the instrumental value of such research to improve efficiency, user acceptance and relatively seamless integration with current workflow and practices.

What do we mean by usability? Nielsen suggests that usability includes the following five attributes: (1) *learnability*: system should be relatively easy to learn, (2) *efficiency*: an experienced user can attain a high level of productivity, (3) *memorability*: features supported by the system should be easy to retain once learned, (4) *errors*: system should be designed to minimize errors and support error detection and recovery, and (5) *satisfaction*: the user experience should be subjectively satisfying.

The question then becomes how we evaluate and study the various attributes of usability. We classified usability evaluation methods into two categories: analytic evaluation approaches and usability testing. Analytic evaluation studies use experts as participants—usability experts, domain experts, software designers—or in some cases, are conducted without participants using task-analytic, inspection-based or model-based approaches and are conducted in laboratory-based settings.

We categorized usability testing into field-based studies that capture situated and contextual aspects of HIT use, and a general category of methods (e.g., interviews, focus groups, surveys) that solicit user opinions and can be administered in different modes (e.g., face-to-face or online). A brief categorization of the evaluation approaches can be found in ■ Fig. 5.1. In the following sections, we provide a detailed description of each of the evaluation approaches along with research examples of its use.

### 5.4.1 Analytical Approaches

Analytical approaches rely on analysts' judgments and analytic techniques to perform evaluations on user interfaces, and often do not directly involve the participation of end users. These approaches employ experts—general usability, human factors, or soft-

ware—for conducting the studies. In general, analytical evaluation techniques involve task-analytic approaches, inspection-based methods, and predictive *model-based* methods (e.g., keystroke models, Fitts Law).

#### 5.4.1.1 Task Analysis<sup>2</sup>

Task analysis is one of most commonly used techniques to evaluate “existing practices” in order to understand the rationale behind people’s goals of performing a task, the motivations behind their goals, and how they perform these tasks (Preece et al. 1994). As described by Vicente (1999), task analysis is an evaluation of the “trajectories of behavior.” There are several variants of task analysis—**hierarchical task analysis** (HTA) and **cognitive task analysis** (CTA) being the most commonly used in biomedical informatics research.

HTA is the simplest task analytic approach and involves the breaking down of a task into sub-tasks and smaller constituted parts (e.g., sub-sub-tasks). The tasks are organized according to specific goals. This method, originally designed to identify specific training needs, has been used extensively in the design and evaluation of interactive interfaces (Annett and Duncan 1967). The application of HTA can be explained with an example: consider the goal of printing a Microsoft Word document that is on your desktop. The sub-tasks for this goal would involve finding (or identifying) the document on your desktop, and then print it by selecting the appropriate printer. The HTA for this task can be organized as follows:

0. Print document on the desktop
  1. Go to the desktop
  2. Find the document
    - 2.1. Use “Search” function
    - 2.2. Enter the name of the document
    - 2.3. Identify the document
  3. Open the document
  4. Select the “File” menu and then “Print”

4.1. Select relevant printer

4.2. Click “Print” button

*Plan 0:* do 1–3–4; if file cannot be located by a visual search, do 2–3–4

*Plan 2:* do 2.1–2.2–2.3

In this task analysis, the task can be decomposed as follows: moving to your desktop, searching for the document (either visually or by using the search function and typing in the search criteria), selecting the document, opening and printing it using the appropriate printer. The order in which these tasks are performed may change based on specific situations. For example, if the document is not immediately visible on the desktop (or if the desktop has several documents making it impossible to identify the document visually), then a search function is necessary. Similarly, if there are multiple printer choices, then a relevant printer must be selected. The plans include a set of tasks that a user must undertake to achieve the goal (i.e., print the document). In this case, there are two plans: plan 0 and plan 2 (all plans are conditional on tasks having pertinent sub-tasks associated with it). For example, if the user cannot find a document on the desktop, plan 2 is instantiated, where a search function is used to identify the document (steps 2.1, 2.2 and 2.3). ■ Figure 5.2 depicts the visual form of the HTA for this particular example.

HTA has been used in evaluating interfaces and medical devices. For example, Chung et al. (2003) used HTA to compare the differences between six infusion pumps. Using HTA, they identified potential sources for the generation of human errors during various tasks. While exploratory, their use of HTA provided insights into how the HTA can be used for evaluating human performance and for predicting potential sources of errors. Alternatively, HTA has been used to model information and clinical workflow in ambulatory clinics (Unertl et al. 2009). Unertl et al. (2009) used direct observations and semi-structured interviews to create a HTA of the workflows. The HTA was then used to identify the gaps in existing HIT functionality for supporting clinical workflows, and the needs of chronic disease care providers.

2 While GOMS (See ► Sect. 5.4.1.3) is considered a task-analytic approach, we have categorized it as a model-based approach for predictions of task completion times. It is based on a task analytic decomposition of tasks.

■ Fig. 5.2 Graphical representation of task analysis of printing a document: the tasks are represented in the boxes; the line underneath certain boxes represents the fact that there are no sub-tasks for these tasks

CTA is an extension of the general task analysis technique to develop a comprehensive understanding regarding the knowledge, cognitive/thought processes and goals that underlie observable task activities (Chipman et al. 2000). Although the focus is on knowledge and cognitive components of the task activities and performance, CTA relies on observable human activities to draw insights on the knowledge-based constraints and challenges that impair effective task performance.

CTA techniques are broadly classified into three groups based: (a) interviews and observations, (b) process tracing and (c) conceptual techniques (Cooke 1994). CTA using interviews and observations involve developing a comprehensive understanding of tasks through discussions with, and task observations of experts. For example, a researcher observes an expert physician performing the task of medication order entry into a CPOE (Computerized Physician Order Entry) system and asks to follow up questions regarding the specific aspects of the task. In a study on understanding providers' management of abnormal test results, Hysong et al. (2010) conducted CTA-based interviews with 28 primary care physicians on how and when they manage alerts, and how they use the various features on the EHR system to filter and sort their alerts.

CTA supported by process-tracing approaches relies on capturing task activities

through direct (e.g., verbal think aloud) or indirect (e.g., unobtrusive screen recording) data capture methods. Whereas the process-tracing approach is generally used to capture expert behaviors, it has also been used to evaluate general users. In a study on experts' information seeking behavior in critical care, Kannampallil et al. (2013a) used the process-tracing approach to identify the nature of these activities including the information sources, cognitive strategies, and shortcuts used by critical care physicians in decision-making tasks. The CTA approach relied on the verbalizations of physicians, their access to various sources, and the time spent on accessing these sources to identify the strategies of information seeking.

Finally, CTA supported by conceptual techniques rely on the development of representations of a domain (and their related concepts) and the potential relationships between them. This approach is often used with experts and different methods are used for knowledge elicitation including concept elicitation, structured interviews, ranking approaches, card sorting, structural approaches such as multi-dimensional scaling, and graphical associations (Cooke 1994).

#### 5.4.1.2 Inspection-Based Evaluation

**Inspection methods** involve experts appraising a system, playing the role of a user to identify potential usability and interaction issues with

a system. Inspection methods are often conducted on fully developed systems or interfaces but may also be used for prototypes. Inspection methods rely on a usability expert, i.e., a person with significant training and experience in evaluating interfaces, to go through a system and identify whether the user interface elements conform to a pre-determined set of usability guidelines and design requirements (or principles). The most commonly used inspection methods are **heuristic evaluations (HE)** and walkthroughs.

HE techniques utilize a small set of experts to evaluate a user interface (or a set of interfaces in a system) based on their understanding of a set of heuristic principles regarding interface design (Johnson et al. 2005). This technique was developed by Jakob Nielsen and colleagues (Nielsen and Molich 1990), and has been used extensively in the evaluation of user interfaces. The original set of heuristics was developed by Nielsen based on an abstraction of 249 usability problems. In general, the following ten heuristic principles (or a subset of these) are most often considered for HE studies: system status visibility; match between system and real world; user control and freedom; consistency and standards; error prevention; recognition rather than recall; flexibility and efficiency of use; aesthetic and minimalist design; help users recognize, diagnose and recover from errors; and help and documentation (retrieved from: <http://www.nngroup.com/articles/ten-usability-heuristics/>). Conducting an HE involves a usability expert going through an interface to identify potential violations to a set of usability principles (referred to as “heuristics”). These perceived violations could involve a variety of interface elements such as windows, menu items, links, navigation, and interaction.

Evaluators typically select a relevant subset of heuristics for evaluation (or add more based on the specific needs and context). The selection of heuristics is based on the type of system and interface being evaluated. For example, the relevant heuristics for evaluating an EHR interface would be different from that of an app on a mobile device. After selecting a set of applicable heuristics, one or more

usability experts evaluate the user interface against the identified heuristics. After evaluating the heuristics, the potential violations are rated according to a severity score (1–5, where 1 indicates a cosmetic problem and 5 indicates a catastrophic problem). This process is iterative and continues until the expert feels that a majority (if not all) of the violations are identified. It is also generally recommended that a set of 4–5 usability experts are required to identify 95% of the perceived violations or problems with a user interface. However, it is not uncommon to employ fewer experts (e.g., 3). It should be acknowledged that the HE approach may not lead to the identification of all problems and the identified problems may be localized (i.e., specific to a particular interface in a system). An example of an HE evaluation form is shown in  Fig. 5.3.

In the healthcare domain, HE has been used in the evaluation of medical devices and HIT interfaces. For example, Zhang et al. (2003) used a modified set of 14 heuristics to compare the patient safety characteristics of two 1-channel volumetric infusion pumps. Four independent usability experts evaluated both infusion pumps using the list of heuristics and identified 89 usability problems categorized as 192 heuristic violations for pump 1, and 52 usability problems categorized as 121 heuristic violations for pump 2. The heuristic violations were also classified based on their severity. In another study, Allen et al. (2006) developed a simplified list of heuristics to evaluate web-based healthcare interfaces (printouts of each interface). Multiple usability experts assigned severity ratings for each of the identified violations and the severity ratings were used to re-design the interface.

Walkthroughs are another inspection-based approach that relies on experts to evaluate the cognitive processes of users performing a task. It involves employing a set of potential stakeholders (designers, usability experts) to characterize a sequence of actions and goals for completing a task. Most commonly used walkthrough, referred to as **cognitive walkthrough (CW)**, involves observing, recording and analyzing the actions and behaviors of users as they complete a scenario of use. CW is focused on identifying the usability and

### 1. Visibility of System Status

The system should always keep user informed about what is going on, through appropriate feedback within reasonable time.

I. Please check your response for the individual items related to this usability factor:

#	Usability Factor	Response	Comments
1.1	Does every screen have a title or header that describes its contents?	<input type="checkbox"/> Yes <input checked="" type="checkbox"/> No <input type="checkbox"/> NA	<i>There is only one data entry screen and the more important issue is whether the navigation at the top of the screen provides a guide for what follows and it doesn't do that adequately. The title of should be</i>
1.2	Is there visual feedback in menus or dialog boxes about which choices are selectable?	<input checked="" type="checkbox"/> Yes <input type="checkbox"/> No <input type="checkbox"/> NA	<i>Radio buttons work fine for that purpose.</i>
1.3	Is there a clear indication of the current location?	<input type="checkbox"/> Yes <input checked="" type="checkbox"/> No <input type="checkbox"/> NA	<i>It is only a single page, but the modules should be more clearly segregated</i>
1.4	Is the menu-naming terminology consistent with the user's task domain?	<input type="checkbox"/> Yes <input type="checkbox"/> No <input checked="" type="checkbox"/> NA	
1.5	Does the system provide visibility; that is, by looking, can the user tell the state of the system and the alternatives for action?	<input checked="" type="checkbox"/> Yes <input type="checkbox"/> No <input type="checkbox"/> NA	<i>The only state changes are hiding/revealing and noting that something has been completed. "View Details" would be clearer than details.</i>
1.6	Is there a consistent icon design scheme across the site?	<input type="checkbox"/> Yes <input type="checkbox"/> No <input checked="" type="checkbox"/> NA	
1.7	Do GUI menus make obvious which item has been selected?	<input checked="" type="checkbox"/> Yes <input type="checkbox"/> No <input type="checkbox"/> NA

Specific considerations for the "visibility heuristic"

Expert evaluation and comments (in italics)

Rating of severity of violations

II. Please circle the overall severity rating for this usability factor:

No Usability Problem	Cosmetic Problem Only	Minor Usability Problem	Major Usability Problem	Usability Catastrophe
0	1	2	3	4

III. If you have other comments, please specify.

*System visibility isn't a big issue in this application because there aren't many state changes. My comments refer to the main data entry page and the plan which I assume is for the caregiver. Does the following message ever go away?*

Fig. 5.3 Example of an HE form (for visibility)

comprehensibility of a system (Polson et al. 1992). The aim of CW is to investigate and determine whether the user's knowledge and skills and the interface cues are sufficient to produce an appropriate goal-action sequence that is required to perform a given task (Kaufman et al. 2003a, b). CW is derived from the cognitive theory of how users work on computer-based tasks, using the exploratory learning approach, where system users continually appraise their goals and evaluate their progress against these goals (Kahn and Prail 1994).

While performing CW, the focus is on simulating the human-system interaction, and evaluating the fit between the system features and the user's goals. Conducting CW studies involves multiple steps. Potential participants (e.g., users, designers, usability experts) are provided a set of task sequences or scenarios

for working with an interface or system. For example, for an interface for entering demographic and patient history details, participants (e.g., physicians) are asked to enter the age, gender, race and clinical history information. As the participants perform their assigned task, their task sequences, errors and other behavioral aspects are recorded. Often, follow up interviews or think aloud (described in a later section) are used to identify participants' interpretation of the tasks, how they make progress, and potential points of mismatches in the system. Detailed observations and recordings of these mismatches are documented for further analysis. While in most situations CWs are performed by individuals, sometimes groups of stakeholders perform the walkthrough together. For example, usability experts, designers and potential users could go through systems together to identify

the potential issues and drawbacks. Such group walkthroughs are often referred to as pluralistic walkthroughs.

In biomedical informatics domain, it must be noted that CW has been used extensively in evaluating situations other than human-computer interaction. For example, the CW method (and its variants) has been used to evaluate diagnostic reasoning, decision-making processes and clinical activities. For example, Kushniruk et al. (1996) used the CW method to perform an early evaluation of the mediating role of HIT in clinical practice. The CW was not only used to identify usability problems but was instrumental in the development of a coding scheme for subsequent usability testing. Hewing et al. (2013) used CW to evaluate an expert ophthalmologist's reasoning regarding retinal disease in infants. Using images, clinical experts were independently asked to rate the presence and severity of retinal disease and provide an explanation of how they arrived at their diagnostic decisions. Similar approaches were used by Kaufman et al. (2003a, b) to evaluate the usability of a home-based, telehealth system.

#### 5.4.1.3 Model-Based Evaluation

Model-based evaluation approaches use predictive modeling approaches to characterize the efficiency of user interfaces. Model-based approaches are often used for evaluating routine, expert task performance. For example, how can the keys of a medical device interface be optimally organized such that the users can complete their tasks quickly and accurately? Similarly, predictive modeling can be used to compare the data entry efficiency between interfaces with different layouts and organization. We describe two commonly used predictive modeling techniques in the evaluation of interfaces.

Card et al. (1980) proposed the GOMS (Goals, Operators, Methods and Selection Rules) analytical framework for predicting human performance with interactive systems. Specifically, GOMS models predict the time taken to complete a task by a skilled/expert user based on “the composite of actions of retrieving plans from long-term memory,

choosing among alternative available methods depending on features of the task at hand, keeping track of what has been done and what needs to be done, and executing the motor movements necessary for the keyboard and mouse” (Olson and Olson 2003). In other words, GOMS assumes that the execution of tasks can be represented as a serial sequence of cognitive operations and motor actions.

GOMS is used to describe an aggregate of the task and the user's knowledge regarding how to perform the task. This is expressed regarding the *Goals*, *Operators*, *Methods* and *Selection* rules. *Goals* are the expected outcomes that a user wants to achieve. For example, a goal for a physician could be documenting the details of a patient interaction on an EHR interface. *Operators* are the specific actions that can be performed on the user interface. For example, clicking on a text box or selecting a patient from a list in a dropdown menu. *Methods* are sequential combinations of operators and sub-goals that need to be achieved. For example, in the case of selecting a patient from a dropdown list, the user has to move the mouse over to the dropdown menu, click on the arrow using the appropriate mouse key to retrieve the list of patients. Finally, *selection* rules are used to ascertain which methods to choose when several choices are available. For example, using the arrow keys on the keyboard to scroll down a list versus using the mouse to select.

One of the simplest and most commonly used GOMS approaches is the Keystroke-Level Model (KLM), which was first described in Card et al. (1983). As opposed to the general GOMS model, the KLM makes several assumptions regarding the task. In KLM, methods are limited to keystroke level operations and task duration is predicted based on these estimates. For the KLM, there are six types of operators: *K* for pressing a key; *P* for pointing the mouse to a target; *H* for moving hands to the keyboard or pointing device; *D* for drawing a line segment; *M* for mental preparation for an action; and *R* for system response. Based on experimental data or other predictive models (e.g., Fitts Law), each of these operators is assigned a value or a param-

eterized estimate of execution time. We describe an example from Saitwal et al. (2010) on the use of the KLM approach.

In a study investigating the usability of EHR interfaces, Saitwal et al. (2010) used the KLM approach to evaluate the time is taken, and the number of steps required to complete a set of 14 EHR-based tasks. The purpose of the study was to characterize the issues with the user interface and also to identify potential areas for improvement. The evaluation was performed on the AHLTA (Armed Forces Health Longitudinal Technology Application) user interface. A set of 14 prototypical tasks was first identified. Sample tasks included entering the patient's current illness, history of present illness, social history and family history. KLM analysis was performed on each of the tasks: this involved breaking each of the tasks into its component goals, operators, methods and selection rules. The operators were also categorized as physical (e.g., move the mouse to a button) or mental (e.g., locate an item from a dropdown menu). For example, the selection of a patient name involved eight steps ( $M$  – mental operation;  $P$  – physical operation): (1) think of location on the menu [ $M$ , 1.2s], (2) move hand to the mouse [ $P$ , 0.4s], (3) move the mouse to “Go” in the menu [ $P$ , 0.4s], (4) extend the mouse to “Patient” [ $P$ , 0.4s], (5) retrieve the name of the patient [ $M$ , 1.2s], (6) locate patient name on the list [ $M$ , 1.2s], (7) move mouse to the identified patient [ $P$ , 0.4s] and (8) click on the identified patient [ $P$ , 0.4s]. In this case, there were a total of 8 steps that would take 5.2s to complete. Similarly, the number of steps and the time taken for each of the 14 considered AHLTA tasks were computed.

In addition, GOMS and its family of methods can be productively used to make comparisons regarding the efficiency of performing tasks interfaces. However, such approaches are approximations and have several disadvantages. Although GOMS provides a flexible and often reliable mechanism for predicting human performance in a variety of computer-based tasks, there are several potential limitations. A brief summary is provided here, and interested readers can find further

details in Card et al. (1980). GOMS models can be applied only to the *error-free, routine* tasks of *skilled* users. Hence, it is not possible to make time predictions for non-skilled users, who are likely to take considerable time to learn to use a new system. For example, the use of the GOMS approach to predict the potential time spent by physicians in using a new EHR would be inaccurate owing to relative lack of knowledge of the physicians regarding the use of the various interfaces, and the learning curve required to be up-to-speed with the new system. The complexity of clinical work processes and tasks, and the variability of the user population create significant challenges for the effective use of GOMS in measuring the effectiveness of clinical tasks.

Fitts Law is used to predict human motor behavior; it is used to predict the time taken to acquire a target (Fitts 1954). On computer-based interfaces, it has been used to develop a predictive model of time it takes to acquire a target using a mouse (or another pointing device). The time taken to acquire a target depends on the distance between the pointer and target (referred to as amplitude,  $A$ ) and the width of the target ( $W$ ). The movement time (MT) is mathematically represented as follows:

$$MT = k \cdot \log_2 \left( \frac{A}{W} + 1 \right)$$

where  $k$  is a constant,  $A$  – amplitude,  $W$  – width of the target.

In summary, based on Fitts law, one can say that the larger objects are easier to acquire while smaller, closely aligned objects are much more difficult to acquire with a pointing device. While the direct application of Fitts law is not often found in the evaluation studies of HIT or health interfaces in general, it has a profound influence in the design of interfaces. For example, the placement of menu items and buttons, such that a user can easily click on them for selection, are based on Fitts law parameters. Similarly, in the design of number keypads for medical devices, the size of the buttons and their location can be effectively predicted by Fitts law parameters.

In addition to the above-mentioned predictive models, there are several other less common models. While a detailed description of each of them or their use is beyond the scope of this chapter, we provide a brief introduction to another predictive approach: Hick-Hyman choice reaction time (Hick 1951; Hyman 1953). Choice reaction time, RT, can be predicted based on the number of available stimuli (or choices),  $n$ :

$$RT = a + b \cdot \log_2(n)$$

where  $a$  and  $b$  are constants.

Hick-Hyman law is particularly useful in predicting text entry rates for different keyboards (MacKenzie et al. 1999), and time required to select from different menus (e.g., a linear vs. a hierarchical menu). In particular, the method is useful to make decisions regarding the design and evaluation of menus. For example, consider two menu design choices: 9 items deep/3 items wide and 3 items deep/9 items wide. The RT for each of these can be calculated as follows:  $(3 \times (a + b \cdot \log_2(n))) < 9 \times (a + b \cdot \log_2(n))$ . This shows that the access to menus is more efficient when it is designed breadth-wise rather than depth-wise.

## 5.5 Usability Testing and User-Based Evaluation

In this section, we have grouped a range of approaches that are generally used for evaluating the usability of HIT systems. In general, we have classified them into field/observational studies and general approaches for usability evaluation that can be utilized in both field and laboratory settings. While formal usability testing is often conducted in laboratory settings where user performance (and other selected variables) are evaluated based on pre-selected tasks, we have loosely classified the evaluation techniques that utilize users in the evaluation process into general approaches (those that can be used in both field and laboratory-based studies) and field studies.

### 5.5.1 Interviews and Focus Groups

Interviews and focus groups are commonly used to elicit information about opinions and perspectives of participants and their work practices (Mason 2002). Interviews are viewed as an approach to elicit additional information and are often used in concert with other field study methods (e.g., observation or shadowing).

Individual interviews can be classified into three major categories based on the format and level of standardization of the interview questions – structured, semi-structured and narrative (or unstructured). During *structured interviews*, all interviewees are asked the same questions in the same order. This allows for comparisons between responses across interviewees, which can be analyzed using qualitative and quantitative methods. *Semi-structured interviews* are flexible and allow for probing of participants (i.e., with follow up questions) to discuss relevant issues (Denton et al. 2018).

Focus group is a type of interactive interviewing method that involves an in-depth discussion of a particular topic of interest with a small group of participants. Focus group method has been described as “a carefully planned discussion designed to obtain perceptions on a defined area of interest in a permissive, non-threatening environment” (Krueger 2009). The central elements of focus groups as highlighted by Vaughn et al. (1996) include: (a) the group is an informal assembly of target participants to discuss a topic; (b) the group is small, between 6 to 12 members and is relatively homogeneous; (c) the group conversation is facilitated by a trained moderator with prepared questions and probes; and (d) given that the primary goal of a focus group is to elicit the perceptions, feelings, attitudes, and ideas of participants about a selected topic, it can be used to generate hypotheses for further research (Krueger 2009).

Unlike individual interviews, focus group discussions allow the researcher to probe responses to a particular research topic while capturing the underlying group dynamics of the participants. According to Kitzinger

(1995), interaction is the crucial feature of focus groups because the interaction between participants views the group as a single unit and also captures their view of the world, the language they use about an issue and their values and beliefs about a situation (Gibbs 1997). For instance, a focus group involving usability experts, system designers and care providers can allow participants to share their varying perspectives on system design based on their work role. This will enable them to voice the key issues on the fit or (lack thereof) between the functionalities of the system and the clinical workflow.

Another important factor that plays a vital role in focus group sessions is the presence of a skilled moderator (or facilitator) (Burrows and Kendall 1997) who manages the conversations and interactions between participants. Moreover, scheduling a convenient time and location for administering focus group interviews can be very difficult, given the number of participants that are involved.

### 5.5.2 Verbal Think Aloud

Verbal think aloud (or simply “think aloud”) is used to capture rich verbal data on the thought processes that underlie human actions. Analysis of these verbal reports can be used to characterize the underlying information and knowledge structures. Think aloud evaluations are generally characterized into two types: (1) concurrent and (2) retrospective (Ericsson and Simon 1980). A concurrent think aloud requires uninterrupted and direct verbalizations of participants as they perform a task, and is considered to be complete and consistent with their thought sequence. In contrast, a retrospective think aloud requires the researcher to ask and prompt subjects to recall their thought sequence while performing a task (or after completing a task). Ericsson and Simon (1984), the original proponents of the verbal think aloud method, suggested the value of think aloud data is based on the following assumptions: (1) the verbalizations capture

only a subset of the cognitive processes underlying behavior; (2) human mind is an information processor; and (3) the verbalizations capture contents of working memory (i.e., information recently acquired is accessed).

Think aloud studies are typically conducted to identify and characterize cognitive processes such as reasoning, problem solving, and decision-making processes. For example, Patel and colleagues (Patel et al. 1994, 2001; Patel and Groen 1991a, b) have conducted several studies using verbal think aloud that investigated the nature of reasoning using electronic tools, its effects of expertise and decision-making. Most of these studies relied on verbalizations by a participant (e.g., a physician), and in-depth linguistic analysis of the verbalizations to identify inherent strategies in their reasoning and decision-making. Similarly, Fonteyn and Grobe (1994) utilized a think aloud study to understand the reasoning and decision-making behaviors of critical care nurses regarding unstable patients. Insights on the reasoning process of expert nurses informed the design of an expert system. Other examples of similar key studies can be found here (Fisher and Fonteyn 1995; Fowler 1997; Funkesson et al. 2007; Grobe et al. 1991; Simmons et al. 2003).

One of the concerns that have been raised in evaluation studies using verbal think aloud method is the issue of sample size. While many researchers have used a small sample size of five participants to focus on in-depth analysis of the cognitive processes, others have critiqued the sample size (e.g., Lewis 1994). Lundgrén-Laine and Salanterä (2010) have suggested that the characteristics of the study participants in terms of their verbalization skills and the appropriate application of the think aloud is more important than the sample size (Caulton 2001; Fonteyn et al. 1993; Hall et al. 2004). Measures of information and participant saturation are often used to determine study completion. A detailed description of the think aloud method and approaches for its analysis can be found here (Ericsson and Simon 1984).

### 5.5.3 Usability Surveys and Questionnaires

Surveys and questionnaires are widely used in usability evaluation studies. Their widespread use is related to ease of administration (through multiple modes: online, face-to-face) and limited time required to complete (especially those that use Likert scale measures). In terms of usability evaluation, there are several surveys that are commonly used. A list of the commonly used usability surveys are provided below:

- (a) *QUIS* (Questionnaire for User Interface Satisfaction): ► <http://lap.umd.edu/quis/>: measure user interface interaction and subjective satisfaction;
- (b) *SUMI* (Software Usability Measurement Inventory): ► <http://sumi.ucc.ie/>: assess usability of software;
- (c) *PSSUQ* (Post-Study System Usability Questionnaire), and *ASQ* (After Scenario Questionnaire): ► <http://hcibib.org/perlman/question.cgi?form=ASQ> (Lewis 1991): address global usability of a system along with specific scenarios of use;
- (d) *SUS* (System Usability Scale – ► <http://www.usability.gov/how-to-and-tools/methods/system-usability-scale.html>) (Brooke 1996): a general survey of system usability;
- (e) *Subjective workload assessment* (NASA-TLX Workload Instrument): ► <http://humansystems.arc.nasa.gov/groups/tlx/paperpencil.html>) (Hart and Staveland 1988): a multi-item scale to determine the physical, temporal, mental, effort, frustration and performance while working with interfaces.

Although most of the above-mentioned surveys are validated for their reliability, researchers often use a variety of self-created surveys and questionnaires. Questionnaires, as opposed to the surveys that use a specific scale (e.g., a scale of 1–7), often use open-ended questions to elicit responses from participants regarding system use (e.g., “Describe some of the challenges that you faced while using the system?”).

Surveys are often used along with other data collection methods and are considered a

complementary data collection method in HIT evaluation. For example, Karahoca and colleagues (Karahoca et al. 2010) used a generic survey along with system usage logs to characterize the usability of two mobile device prototypes. Similar open-ended questionnaires along with additional observational data was used by Holzinger and colleagues (Holzinger et al. 2011) to characterize patient interactions with a mobile interface. Dalai and colleagues (Dalai et al. 2014) used the SUS scale and the NASA-TLX scales for comparing the effectiveness of two interfaces for comprehending psychiatric clinical narratives. These survey scales were used in concert with an analysis of verbal reports to evaluate the effectiveness of presented interfaces.

### 5.5.4 Field/Observational Approaches

In contrast to the analytic evaluation techniques that often yield objective data, there are several qualitative approaches that focus on the subjective and contextual assessments of system design and user interactions within the *context* of a real work environment (Assila et al. 2014). These qualitative approaches are generally categorized as ethnographic-based methods and require an “immersion” in the field in order to understand the experiences and practices of the informants (Schatzberg 2008). Although field and observational methods are more central to human factors, they have also played an instrumental role in understanding how health information technologies mediate a range of decision-making, coordination and associated patient care activities. The next section provides examples of observational research in clinical settings within the context of clinical workflow and usability.

## 5.6 Clinical Workflow

Workflow is a “set of tasks grouped into chronologically ordered processes, plus the people and resources required to complete the

tasks and accomplish a desired goal” (Unertl et al. 2010). It is widely believed that workflow analysis is essential for ensuring successful design and implementation of health IT (Harrington 2015; Schumacher and Lowry 2010; Xie and Carayon 2015). **Electronic health record** workflow is a subset of workflow activities that are mediated by EHRs and related technologies (Harrington 2015). These activities are not viewed as discrete, but rather are embedded in a situational context and broader workflow. Clinical workflow, especially in high velocity clinical settings, is characterized by perpetual change, multiple providers with varying levels of communication, and a high volume of workload, multitasking, and interruptions (Harrington 2015). Workflow is further complicated by the need to negotiate complex and nonintuitive systems. When EHRs are well integrated into clinical workflow, it increased the likelihood of positive healthcare outcomes and diminished error rates (Carayon et al. 2010; Lau et al. 2012). In contrast, when health IT was not well integrated into clinical workflow in a way that supports clinicians’ cognitive work, it can compromise patient safety (Carayon et al. 2010).

Clinical workflow has been extensively studied over the course of the last 20 years. A cursory search of the term “clinical workflow” in Google Scholar yields more than 16,000 articles and more than 8000 since 2014. The scope of workflow research is rather expansive incorporating analysis of individuals, work environments, human-system interfaces and organizational factors. There has also been a focus on workflow as a mediator of patient safety (Carayon et al. 2014; Middleton et al. 2013). The emphasis of this section is on EHR workflow, which names the subset of workflow mediated by EHRs and other health IT (Zheng et al. 2010). EHRs are known to lack flexibility and resist easy modification and are relatively independent of context. However, clinical workflow is variable and context dependent, and tends to resist “one-size-fits-all” solutions. Studies on EHR-mediated workflow tend to focus on task-performance of the individual clinician, for example, (1) the impact of usability on

workflow (ref), (2) time and motion studies that endeavor to quantify how clinicians allocate their time, or (3) the role of the EHR in the coordination of care, for example, examining the ways the systems serve as either a facilitator or impediment to the delivery of care (Weir et al. 2011).

Although EHR has conferred significant advantages such as decision support (Ben-Assuli et al. 2015) and improved clinical note quality (Burke et al. 2014), it has also contributed to an onerous documentation burden which impacts workflow. According to AMIA’s EHR 2020 Task Force’s report, AMIA’s report on the EHR 2020 Task Force’s, clinician’s time investment in patient care documentation has doubled in the last 20 years (Payne et al. 2015). A large scale survey of clinicians affiliated with the American College of Physicians found that clinicians reported a loss of time (relative to paper-based records) of 4 hours per week (McDonald et al. 2014). The authors concluded that this could decrease access and increase the cost of care. However, findings varied significantly across studies. Researchers have employed a range of methods to document burden including log files and time on task studies. Hripesak et al. used audit logs to perform a detailed analysis of time spent reviewing and documenting clinical notes (Hripesak et al. 2011). They found significant variation among clinicians with a range of 20–100 minutes documenting and 7 minutes to 56 reviewing notes. They also noted that a significant percent of notes (e.g., 38% of nursing notes) were never read by anyone. This impacted communication, for example, the transfer of information from nurses to physicians. In a recent study, Collins and colleague used log files to study flowsheet documentation at a highly granular level (Collins et al. 2018). They found that clinicians (mostly nurses) manually entered between 600–900 data points. The authors argue for the need for better automated device integration.

In summary, there is heterogeneity in findings in relation to documentation. Some can be attributable to differences specific to settings, for example, as reflected in the use of scribes and in relation to the execution of Meaningful Use mandates. Other differences

are reflected in the study methods. However, it is quite clear that EHRs typically add significantly to the documentation burden and that has resulted in frustration among users.

EHR usability problems and their impact on workflow are well documented. For example, the Healthcare Information and Management Systems Society (HIMSS) survey found that workflow was clinicians' number one EHR usability "pain point" (Ribitzky et al. 2010). Respondents also reported frustration due to numerous alerts and difficulties with navigation resulting from the need to negotiate too many displays in the EHR to access information (Carayon et al. 2010). As referred to previously, Saitwal and colleagues (Saitwal et al. 2010) employed a cognitive task analytic approach to evaluate an EHR interface and quantified interactive behavior (e.g., task duration, number of steps). Challenges of employing the user interface were: (a) large number of average total steps to complete routine tasks, (b) slow execution time, and (c) overall mental workload. Similarly, Carayon et al. (6) summarized a range of usability issues in their systematic review of the workflow literature, including the large number of mouse clicks to complete a task, difficulties in navigating between many screens to input and retrieve information and cluttered screens. These usability problems serve to increase cognitive load. Information overload, a form of cognitive load, is a problem that occurs when attentional, perceptual and cognitive capacity is exceeded by the quantity of data presented via an interface to the extent that errors occur in users' information processing (Zahabi et al. 2015).

Cognitive overload can be partially attributed to poor user design. Small interface differences can be consequential and have a significant impact on task efficiency. According to Gray and colleagues, interactive behavior is constrained by the design and configuration of displays "as well as by the ways in which elementary cognitive, perceptual, and motor operations can be combined" (Gray and Boehm-Davis 2000). Poorly configured interfaces can increase navigational complexity. Navigation in this context refers to

route taken to complete a task including the action steps and the trajectory through space (e.g., sequence of tabs or display screens). In a systematic review, Roman et al. found that navigation actions (e.g., scrolling through a patient list) were often linked to specific usability heuristic violations, including flexibility and efficiency of use, and lack of an emphasis on recognition rather than recall (Roman et al. 2017).

Medication reconciliation (MedRec) tools are an essential part of a strategy to reduce medication errors and prevent adverse events (Agrawal 2009). MedRec tools enable clinicians to compare lists of medications in patients history and revise the lists so that they are up-to-date and accurate. There have been several recent studies that have applied cognitive methods of analysis to MedRec (Boockvar et al. 2011; Lesselroth et al. 2013). Horsky and colleagues et al. investigate the accuracy of two different medication reconciliation tools integrated into EHRs in a simulated study (Horsky et al. 2017). They found that the reconciled records were significantly more accurate when clinicians used the second tool. Specifically, the comparison showed clinicians made three times as many errors in EHRs with single column medication lists, as compared to using side-by-side lists. The authors concluded that the better outcome using the second tool was strongly facilitated by a design that was more effective in supporting a cognitively demanding task. The system made less demands on working memory than the first. Plaisant and colleagues similarly contrasted a conventional interface design (control) with a novel prototype (Twinlist) (Plaisant et al. 2015). The Twinlist interface divided information into five columns, while the control used two side-by-side lists. Evaluation showed that in Twinlist participants completed MedRec significantly faster and more accurately than the control. Both studies demonstrated the comparative advantage of having access to needed information on a single screen as opposed to having to toggle between two screens or tabs.

The studies described above employed simulated methods. Duncan compared

MedRec interfaces in three Mayo Clinic campuses in which different EHR systems were used (Duncan et al. 2018b). Although they support the same set of functions, the interfaces differed in important respects. Specifically, the steps to access the medication list and perform the addition of a last dose differ. System 2 necessitated a three-step process as opposed to a single step needed to execute the same reconciliation goal (system 1). The systems were compared using a predictive model (KLM) and with live observations captured to video. As described earlier in this chapter, the keystroke-level model (KLM) is a widely used analysis where execution time of routine tasks (performed without errors) are estimated. Duncan found that the KLM estimates for the MedRec task closely approximated the observations. Both methods found that the time required to reconcile a single medication was more than 2 seconds greater for system 2, which also required more mouse clicks and screen transitions. The two systems differ in terms of interactive complexity and demands on working memory. The difference highlights the importance of emphasizing recognition rather than recall to minimize the memory load on clinicians.

Duncan and colleagues employed a similar approach with the same EHR systems in relation to a vital signs documentation and medication administration record tasks (Duncan et al. 2018a; Duncan et al., 2020). Vital signs are used to gauge a patient's hemodynamic stability and, in this case, provide a point of reference prior to surgery. The objectives were to: (1) analyze aspects of vital signs charting interfaces and determine how these aspects differentially mediate task performance and (2) investigate variations in vital signs documentation across clinical sites. Analyses revealed that accessing displays and the organization of interface elements are often unintuitive and inefficient, creating unnecessary complexities when interacting with the system. The study documented the ways in which the systems differed in their modes of interaction, organization of patient information and cognitive support. The authors noted that identifying barriers to interface usability and

bottlenecks in EHR-mediated workflow can lead to system redesigns that minimize cognitive load and may also improve patient safety and efficiency.

## 5.7 Future Directions

---

The role of HCI, and more specifically, usability, is likely to be more embedded within the biomedical informatics research paradigm over the next decade. This is primarily because of the role health information technologies play in transforming the practice of medicine. Such a transformation has led to the widespread use of technology in patient care (e.g., the use of EHRs) and the development of patient-facing applications for self-management of care (e.g., mobile devices). As a result, the role of usability is likely to have an increased focus in potentially two areas: development of new approaches for unobtrusive evaluation of user interactions, and in the evaluation of consumer-facing applications for health.

As previously described, usability and user interaction studies are expensive, in terms of time, and effort that are involved. Recent efforts on usability evaluation have focused on utilizing logs of user interactions—including audit trails, and other unobtrusively collected interaction data (e.g., key stroke or eye-tracker). One classic example of such data is the EHR-based audit logs. In a recent study on EHR use in an emergency department, Kannampallil and colleagues used user log files to track the physician interactions during patient care activities (Kannampallil et al. 2018b). Similar efforts on tracing and modeling interaction and navigation behaviors are ongoing. The availability of more powerful tools for data capture and analysis will create new opportunities for computer scientists, psychologists and clinicians to collaborate on HCI-related investigations of technology-mediated clinical practice. In a recent study of such a collaboration, Vankipuram and colleagues showed that the process of data-driven iterative workflow redesign using visualization of overlaid data from quantitative and qualitative sources could be used to identify

inefficiencies and bottlenecks in clinical workflow and potentially contribute to process improvement (Vankipuram et al., 2019).

The growth of wearable devices and mobile sensing technologies have led to the development and use of a large number of consumer-facing applications and tools. Although much of these are on mobile devices, other patient-facing applications such as portals and social networking tools have gained prominence in recent years. These applications are rapidly evolving and, in many cases, still require significant improvements for translation into a usable and sufficiently robust product.

## 5.8 Conclusion

The implementation and broad use of health information technologies have grown rapidly over the course of the last decade. Clinical applications and increasingly patient-facing systems are beginning to transform healthcare practices. They offer significant potential for transforming the quality of patient care as well as enabling patient to become agents of change in managing their own health. Usability challenges continue to provide significant impediments to productive use of technology and efficient workflow. The focus of this chapter has been on methods of usability evaluation. There is a wealth of different methods available for researchers and professional usability analysts to deploy in view to optimize the user experience. The methods have contributed to a growing body of knowledge to inform user-centered design and best practices across the range of health technologies.

Norman, D. A. (1993). Things that make us smart: Defending human attributes in the age of the machine. Reading: Addison-Wesley

Pub. Co. This book addresses significant issues in human-computer interaction in a very readable and entertaining fashion.

Patel, V. L., Kannampallil, T., & Kaufman, D. (Eds.). (2015). Cognitive informatics in health and biomedicine: Human computer interaction. London: Springer. This edited book addresses the key gaps on the applicability of theories, models and evaluation frameworks of HCI and human factors for research in biomedical Informatics.

Preece, J., Rogers, Y., & Sharp, H. (2015). Interaction design: Beyond human-computer interaction (4th ed.). West Sussex: Wiley. A very readable and relatively comprehensive introduction to human-computer interaction. A new edition will be available in April, 2019.

Zheng, K., Westbrook, J., Kannampallil, T., & Patel, V. L. (Eds.). (2018). Cognitive informatics: Reengineering clinical workflow for more efficient and safer care. London: Springer. This edited book offers a comprehensive aspect of clinical workflow, supported by the theoretical, methodological, empirical, and pragmatic perspectives from experts in the field.

### Questions for Discussion

1. What role do the theories of HCI and cognitive science play in providing insight into principles of system *usability*, as well as the design of a safer workplace?
2. A large urban hospital is planning to implement a provider order entry system. You have been asked to advise them on system usability and to study the cognitive effects of the system on performance. Discuss the issues involved and suggests some of the steps you would take to study system usability.
3. What are the primary differences between analytic usability evaluation methods and usability testing?
4. What are some of the considerations for choosing analytic approaches for usability evaluation?
5. How does usability impact clinical workflow? How can we provide better cognitive support for workflow?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What key functions do software applications perform in health care?
- How are the components of the software development lifecycle applied to health care?
- What are the trade-offs between purchasing commercial, off-the-shelf systems and developing custom applications?
- What are important considerations in comparing commercial software products?
- Why do systems in health care, both internally-developed and commercial purchased, require continued software development?

## 6.1 How Can a Computer System Help in Health Care?

---

In this chapter, we focus on the software applications and components of health care information systems, and describe how they are used and applied to support health care delivery. We give examples of some basic functions that may be performed by health information systems, and discuss important considerations in how the software may be acquired, implemented and used. This understanding of how a system gets put to use in health care settings will help as you read about the various specific applications in the chapters that follow.

Health care is an information-intensive field. Clinicians are constantly gathering, reviewing, analyzing and communicating information from many sources to make decisions. Humans are complex, and individuals have many different characteristics that are relevant to health care and that need to be considered in decision-making. Health care is also complex, with a huge body of existing knowledge that is expanding at an ever-increasing rate. Software for managing health information is intended to facilitate the use of this information at various points in the

care delivery process. Software can determine the ways by which data are obtained, organized and processed to yield information. Software, in terms of design, development, acquisition, configuration and maintenance, is therefore a major component of the field of biomedical informatics. This chapter provides an introduction to some of the practical considerations regarding health information software, including both general software engineering principles, as well as the application of these principles to health care settings.

To this aim, we first describe the major software functions within a health care environment or health information system. While not all functions can be covered in detail, some specific examples are given to indicate the breadth of software applications as well as to provide an understanding of their relevance. We also describe the software development life cycle, with specific applications to health care. We then describe important considerations and strategies for acquiring and implementing software in health care settings. Finally, we discuss emerging trends influencing software engineering related to health information systems. Each system can be considered in regard to what it would take to make it functional in a health care system, and what advantages and disadvantages the software may have, based on how it was created and implemented. Understanding these principles will help you identify the risks and benefits of various applications, so that you can identify how to optimize the positive impact of health information systems.

## 6.2 Software Functions in Health Care

---

### 6.2.1 Case Study of Health Care Software

---

The following case study illustrates many important functions of health care software.

*John Miller is a 42-year old man living in a medium-sized U.S. city. He is married and has*

two children. He has type 2 diabetes, but it is currently well controlled and he has no other health concerns. There is some history of cardiovascular disease in his family. John has a primary care physician, Linda Stark, who practices at a clinic that is part of a larger health delivery network, Generation Healthcare System (GHS). GHS includes a physician group, primary and specialty care clinics, a tertiary care hospital and an affiliated health insurance plan.

John needs to make an appointment with Dr. Stark. He logs into the GHS **patient portal** and uses an online scheduling application to request an appointment. While in the patient portal, John also reviews results from his most recent visit and prints a copy of his current medication list in order to discuss the addition of an over-the-counter supplement he recently started taking.

Before John arrives for his visit, the clinic's scheduling system has already alerted the staff of John's appointment and the need to collect information related to his diabetes. Upon his arrival, Dr. Stark's nurse gathers the requested diabetes information and other vital signs data and enters these into the **electronic health record** (EHR). In the exam room, Dr. Stark reviews John's history, the new information gathered during this visit, and recommendations and reminders provided by the EHR on a report tailored to her patient's medical history. They both go over John's medication list and Dr. Stark notes that, according to the EHR's drug-drug interaction tool, the supplement he is taking may have an interaction with one of his diabetes medications. One of the reminders suggests that John is due for a hemoglobin A1c (HbA1c) test, and Dr. Stark orders this in the EHR. Dr. Stark's nurse, who has been notified of the lab test order, draws a blood sample from John. Before the appointment ends, Dr. Stark completes and signs the clinic note and forwards a visit summary for John to review on the patient portal.

A few days after his appointment, John receives an email from GHS that notifies him of an important piece of new information in his patient record. Logging into the patient portal application, John sees that his HbA1c test is back. The test indicates that the result is elevated. Dr. Stark has added a note to the result

saying that she has reviewed the lab and would like to refer John to the GHS Diabetes Specialty Clinic for additional follow-up. John uses the messaging feature in the patient portal to respond to Dr. Stark and arrange for an appointment. John also clicks on an **info button** next to the lab result to obtain more information about the abnormal value. He is linked to patient-focused material about HbA1c testing, common causes for elevated results, and ways this might be addressed. Lastly, John reviews the visit summary note from his appointment with Dr. Stark to remind him about suggestions she had for replacing his supplement.

At his appointment with the Diabetes Specialty Clinic, John notes that they have access to all the information in his record. A diabetes care manager, Maria, reviews the important aspects of John's medical history. She suggests more frequent monitoring of his laboratory test results and evaluating whether he is able to control his diabetes without changes to his medications. Maria highlights diet and exercise suggestions in his patient portal record that have been shown to help similar patients. When the visit is complete, Maria sends an electronic summary of the visit to Dr. Stark.

A year later, John is experiencing greater difficulty controlling his diabetes. Dr. Stark and Maria have continued to actively monitor his HbA1c and other laboratory test results, and occasionally make changes to his treatment regimen. They use the EHR to visualize laboratory test results and correlate them with changes in medications. Due to a variety of personal and financial challenges, John struggles with adherence to his medication regimen, and he is not maintaining a healthy diet. As a result, his blood sugar has become seriously unstable, and the population health management module of the EHR flags John for urgent evaluation due to a dangerously high home blood glucose reading. Maria confirms the reading with John, collects additional information about his health status, and escalates the issue to Dr. Stark. Dr. Stark then recommends John go to the GHS hospital emergency department (ED) for urgent evaluation. Doctors in the ED access John's electronic record including his medication and lab history, as well as notes from Dr. Stark and Maria, which help them quickly assess his condition

and develop a treatment plan. John is admitted to the hospital, and physicians, nurses, and others caring for him access his longitudinal medical records and document new observations and treatments. They are also able to electronically reconcile his outpatient prescriptions with his inpatient medications to ensure continuity. After a brief hospital stay, John is stabilized and ready to be discharged, with an updated list of medications.

Because Dr. Stark is listed as John's primary care physician, she is notified electronically of both the hospital admission and discharge. She reviews his discharge summary in the EHR and instructs her staff to send a message through the patient portal to John, to let him know she reviewed his inpatient record and to schedule a follow-up appointment.

The GMS EHR is also part of a statewide **health information exchange (HIE)**, which allows medical records to be easily shared with health care providers outside the GMS system. This means that if John should need to visit a hospital, emergency department or specialty care clinic outside the GMS network, his record would be available for review and any information entered by these outside providers would be similarly available to Dr. Stark and others within the GMS network. The local and state health departments where John lives are also linked to the HIE. This allows clinics, hospitals and labs to electronically submit information to the health departments for disease surveillance and case reporting purposes.

Back at home, John's wife, Gina, is able to view his medical records on the GHS patient portal because he has granted her proxy access to his account. This allows her to see notes from Dr. Stark and schedule appointments. Gina also views the hospital discharge instructions that were electronically sent to John's patient record. As she reviews the information about diabetes that GHS had automatically linked to John's record, Gina sees a notification about a clinical research study involving genetic links with diabetes. Concerned about their two children, Gina discusses the study with John, and they review more online materials about the study. Interested in the possible benefits of the research, John electronically volunteers to participate in the study, and he is later contacted

by a study coordinator. Because GHS investigators are conducting the study, relevant parts of John's EHR are easily shared with the clinical trials management system.

This fictional case study highlights many of the current opportunities for improving health care delivery, including improved access to care, increased patient engagement, shared patient-provider decision-making, better care management, medication reconciliation, improved transitions of care, population health management, and research recruitment. In the case study, each of these goals required software to make health information accessible to the correct individuals at the proper time.

In today's health care system, few individuals enjoy the interaction with software depicted in the *John Miller* case study. Although the functions described in the scenario exist at varying levels of maturity, most health care delivery institutions have not connected all the functions together as described. The current role of software engineering in health care is therefore two-fold: to design and implement software applications that provide required functions, and to connect these functions in a seamless experience for both the clinicians and the patients.

The case study highlights the usefulness of several functions provided by health care software applications for clinicians, patients, and administrators. Some of these functions include:

1. Acquiring and storing data
2. Summarizing and displaying data
3. Facilitating communication and information exchange
4. Generating alerts, reminders, and other forms of decision support
5. Supporting educational, research, and public health initiatives

## 6.2.2 Acquiring and Storing Data

---

The amount of data needed to describe the health and health care of even a single person is huge. Health professionals require assistance with data acquisition to deal with the data that must be collected and processed. One of the first uses of computers in a medi-

cal setting was the automatic analysis of blood specimens and other body fluids by instruments that measure chemical concentrations or that count cells and organisms. These systems generated printed or electronic results to health care workers and identified values that were outside normal limits. Computer-based patient monitoring that collected physiological data directly from patients were another early application of computing technology (see ► Chap. 19). These systems provided frequent, consistent collection of vital signs, electrocardiograms (ECGs), and other indicators of patient status. More recently, researchers have developed medical imaging applications as described in ► Chaps. 9 and 20, including computed tomography (CT), magnetic resonance imaging (MRI), and digital subtraction angiography. The calculations for these computationally intensive applications cannot be performed manually; computers are required to collect and manipulate millions of individual observations.

Early computer-based medical instruments and measurement devices provided results only to human beings. Today, most instruments can transmit data directly into the EHR, although the interfaces can still be awkward and poorly standardized (see ► Chaps. 5 and 8). Computer-based systems that acquire information directly from patients are also data-acquisition systems; they free health professionals from the need to collect and enter demographic and health history information.

Various departments within a hospital use computer systems to store clinical data. For instance, clinical laboratories use information systems to keep track of orders and specimens and to report test results; most pharmacy and radiology departments use computers to perform analogous functions. Their systems may connect to outside services (e.g., pharmacy systems are typically connected to one or more drug distributors so that ordering and delivery are rapid and local inventories can be kept small). By automating processing in areas such as these, health care facilities are able to provide efficient service, reduce labor costs, and minimize errors.

### 6.2.3 Summarizing and Displaying Data

---

Computers are well suited to performing tedious and repetitive data-processing tasks, such as collecting and tabulating data, combining related data, and formatting and producing reports. They are particularly useful for processing large volumes of data.

Data acquired by computer systems can be detailed and voluminous. Data analysis systems must aid decision makers by reducing and presenting the intrinsic information in a clear and understandable form. Software can be used to create useful visualizations that facilitate trend analysis and compute secondary parameters (e.g., means, standard deviations, rates of change) to help identify abnormalities. Clinical research systems have modules for performing powerful statistical analyses over large sets of patient data. When employing such tools, research investigators should have insight into the methods being used. For clinicians, graphical displays are useful for interpreting data and identifying trends.

Fast retrieval of information is essential for any computer system. Data must be well organized and indexed so that information recorded in an EHR system can be easily retrieved. Here the variety of users must be considered. Obtaining recent information about a patient entering the office differs from the needs that a research investigator will have in accessing the same data. The query interfaces provided by EHRs and clinical research systems assist researchers in retrieving pertinent records from the huge volume of patient information. Recently, there has been increasing industry adoption of the **Health Level 7 International (HL7)** Fast Healthcare Interoperability Resources (FHIR) standard for sharing data on a patient-by-patient basis. The FHIR standard is being adapted for population-level data sharing through the FHIR Bulk Data initiative. As discussed in ► Chap. 21, bibliographic retrieval systems are also an essential component of health information services.

### 6.2.4 Facilitating Communication and Information Exchange

In hospitals and other large-scale health care institutions, myriad data are collected by multiple health professionals who work in a variety of settings; each patient receives care from a host of providers—nurses, physicians, technicians, pharmacists, and so on. Communication among the members of the team is essential for effective health care delivery. Data must be available to decision makers when and where they are needed, independent of when and where they were obtained. Computers help by storing, transmitting, sharing, and displaying those data. As described in ► Chaps. 2 and 12, the patient record is the primary vehicle for communication of clinical information. The limitation of the traditional paper-based patient record is the concentration of information in a single location, which prohibits simultaneous entry and access by multiple people. Hospital information systems (HISs; see ► Chap. 13) and EHR systems (► Chap. 12) allow distribution of many activities, such as admission, appointment, and resource scheduling; review of laboratory test results; and inspection of patient records to the appropriate sites.

Information necessary for specific decision-making tasks is rarely available within a single computer system. Clinical systems are installed and updated when needed, available, and affordable. Furthermore, in many institutions, inpatient, outpatient, and financial activities are supported by separate organizational units. Patient treatment decisions require inpatient and outpatient information. Hospital administrators must integrate clinical and financial information to analyze costs and to evaluate the efficiency of health care delivery. Similarly, clinicians may need to review data collected at other health care institutions, or they may wish to consult published biomedical information. Communication networks that permit sharing of information among independent computers and geographically distributed sites are now widely available. Actual integration of the information they contain requires additional software,

adherence to standards, and operational staff to keep it all working as technology and systems evolve.

### 6.2.5 Generating Alerts, Reminders, and Other Forms of Decision Support

In the end, all the functions of storing, displaying and transmitting data support decision-making by health professionals, patients, and their caregivers. The distinction between decision-support systems and systems that monitor events and issue alerts is not clear-cut; the two differ primarily in the degree to which they interpret data and recommend patient-specific action. Perhaps the best-known examples of decision-support systems are the clinical consultation systems or event-monitoring systems that use population statistics or encode expert knowledge to assist physicians in diagnosis and treatment planning (see ► Chap. 22). Similarly, some nursing information systems help nurses to evaluate the needs of individual patients and thus assist their users in allocating nursing resources. ► Chapter 22 discusses systems that use algorithmic, statistical, or artificial-intelligence (AI) techniques to provide advice about patient care.

Timely reactions to data are crucial for quality in health care, especially when a patient has unexpected problems. Data overload, created by the ubiquity of information technology, is as detrimental to good decision making as is data insufficiency. Data indicating a need for action may be available but are easily overlooked by overloaded health professionals. Surveillance and monitoring systems can help people cope with all the data relevant to patient management by calling attention to significant events or situations, for example, by reminding doctors of the need to order screening tests and other preventive measures (see ► Chaps. 12 and 22) or by warning them when a dangerous event or constellation of events has occurred.

Laboratory systems routinely identify and flag abnormal test results. Similarly, when

patient-monitoring systems in intensive care units detect abnormalities in patient status, they sound alarms to alert nurses and physicians to potentially dangerous changes. A pharmacy system that maintains computer-based drug-profile records for patients can screen incoming drug orders and warn physicians who order a drug that interacts with another drug that the patient is receiving or a drug to which the patient has a known allergy or sensitivity. By correlating data from multiple sources, an integrated clinical information system can monitor for complex events, such as interactions among patient diagnosis, drug regimen, and physiological status (indicated by laboratory test results). For instance, a change in cholesterol level can be due to prednisone given to an arthritic patient and may not indicate a dietary problem.

### 6.2.6 Supporting Educational, Research, and Population and Public Health Initiatives

---

Rapid growth in biomedical knowledge and in the complexity of therapy management has produced an environment in which students cannot learn all they need to know during training—they must learn how to learn and must make a lifelong educational commitment. Today, physicians and nurses have available a broad selection of computer programs designed to help them to acquire and maintain the knowledge and skills they need to care for their patients. The simplest programs are of the drill-and-practice variety; more sophisticated programs can help students to learn complex problem-solving skills, such as diagnosis and therapy management (see ► Chap. 21). Computer-aided instruction provides a valuable means by which health professionals can gain experience and learn from mistakes without endangering actual patients. Clinical decision-support systems and other systems that can explain their recommendations also perform an educational function. In the context of real patient cases, they can suggest actions and explain the reasons for those actions.

As health care increasingly shifts to a mode of care based on population health rather than episodic health care transactions, there is increasing need for information systems to monitor and manage individuals' health outside the context of clinical visits. Surveillance also extends beyond the health care setting. Appearances of new infectious diseases, unexpected reactions to new medications, and environmental effects should be monitored. Thus the issue of data integration has a national or global scope (see the discussion of the National Health Information Infrastructure in ► Chaps. 1 and 16 that deals with public health informatics).

## 6.3 Software Development and Engineering

---

Clearly, software can be used in many different ways to manage and manipulate health information to facilitate health care delivery. However, just using a computer or a software program does not improve care. If critical information is unavailable, or if processes are not organized to operate smoothly, a computer program will only expose challenges and waste time of clinical staff that could be better applied in delivering care. To be useful, software must be developed with an understanding of its role in the care setting, geared to the specific functions that are required, and developed correctly. To be used, software must be integrated to support the users' workflow. We will discuss both aspects of software engineering – development and integration.

### 6.3.1 Software Development

---

Software development can be a complex, resource-intensive undertaking, particularly in environments like health care where safety and security provide added risk. The **software development life cycle** (SDLC) is a framework imposed over software development in order to better ensure a repeatable, predictable process that controls cost and improves quality of

the software product (usually an application). SDLC is a subset of the systems development life cycle, focusing on the software component of a larger system. In practice, and particularly in health care, software development encompasses more than just the software, often stretching into areas such as process re-engineering in order to maximize the benefits of the software product. Although SDLC most literally applies to an in-house development project, all or most of the life cycle framework is also relevant to shared development and even purchase of commercial off-the-shelf (COTS) software. The following is an overview of the phases of the SDLC.

### 6.3.1.1 Planning/Analysis

The software development life cycle begins with the formation of a project goal during the planning phase. This goal typically derives from an organization's or department's mission/vision, focusing on a particularly need or outcome. This is sometimes called project conceptualization. Planning includes some initial scoping of the project as well as resource identification (including funding). It is important to address what is not included in the project in order to create appropriate expectations for the final product. A detailed analysis of current processes and needs of the target users is often done. As part of the analysis, specific user requirements are gathered. Depending on the development process, this might include either detailed instructions on specific functions and operating parameters or more general user stories that explain in simple narrative the needs, expected workflow and outcomes for the software. It is important that users of the system are consulted, as well as those in the organization who will implement and maintain the software. The decision of whether to develop the software in-house, partner with a developer, or purchase a vendor system will likely determine the level of detail needed in the requirements. Vendors will want very specific requirements that allow them to properly scope and price their work. The requirements document will usually become part of a contract with a vendor and will be used to determine if the final product meets the agreed specification for the soft-

ware. In-house development can have less detailed requirements, as the contract to build the software is with the organization itself, and can allow some evolution of the requirements as the project progresses. However, the more flexibility that is allowed and the longer changes or enhancements are permitted, the higher the likelihood of "scope creep" causing schedule and cost overruns.

Other tasks performed during analysis include an examination of existing products and potential alternative solutions, and, particularly for large projects, a cost/benefit analysis. A significant, and frequently overlooked, aspect of the planning and analysis phase is to determine outcome measures that can be used during the life cycle to demonstrate progress and evaluate success or failure of the project. These measures can be refined and details added as the project progresses. The planning and analysis phase typically ends when a decision to proceed is made, along with at least a rough plan of how to implement the next steps in the SDLC. If the organization decides to purchase a solution, a request for proposals (RFP) that contains the requirements document is released to the vendor community.

The planning and analysis stage of software development is perhaps both the most difficult and the most important stage in the development lifecycle as it is applied to health care. Requirements for software in health care are inherently difficult to define for many reasons. Health care practice is constantly changing, and as new therapies or approaches are discovered and validated, these new advancements can change the way care is delivered. In addition, the end-users of health care software are comparatively advanced relative to other industries. Unlike industries where front-line workers may be directed by supervisors with more advanced training and greater flexibility in decision making, in health care the front-line workers are often physicians, who are often the most highly-trained workers in the system (although not necessarily the most advanced with respect to computer literacy) and require the greatest flexibility for decisions. This flexibility makes it difficult to define workflows or even get indications of the workflows being followed,

since physicians will not always make explicit what actions or plans are being pursued. This flexibility is important for patient care, because it allows front-line clinicians to adapt appropriately to different settings, staffing levels, and specialties. The need for flexibility is such that defining requirements for software that could reduce flexibility is criticized as “cookbook” medicine, constituting a common reason for resistance to software adoption. However, this resistance is not just characteristic of software – clinical guidelines and other approaches to structured or formalized care processes can also be criticized, and the challenge of applying discovered-knowledge to clinical care processes remains difficult.

Over time, however, there have been some successful efforts that have defined standard requirements for health information software. Among the most notable efforts have been in EHRs, where organizations have created lists of requirements and certified systems that match those requirements. The Certification Commission for Health Information Technology (CCHIT) began in 2004 and defined criteria for electronic health records’ functionality, interoperability and security (Leavitt and Gallagher 2006). Later, the certification approach was adopted by the Office of the National Coordinator of Health Information Technology (ONC) in 2010, when a list of EHR functions that were most related to “meaningful use” of EHRs was established (Blumenthal and Tavenner 2010). Such “meaningful use” of EHRs came with significant financial incentives administered by the Centers for Medicare and Medicaid Services (CMS), leading to a rapid increase in the adoption of EHRs meeting these requirements (Washington et al. 2017).

### 6.3.1.2 Design

During the Design phase, potential software solutions are explored. System architectures are examined for their abilities to meet the needs stated in the requirements. Data storage and interface technologies are assessed for appropriate fit. User front-end solutions are investigated to assess capabilities for required user input and data display functions. Other

details, such as security, performance, and internationalization are also addressed during design. Analysts with domain knowledge in the target environment are often employed during this phase in order to translate user requirements into suitable proposals. Simple mock-ups of the proposed system may be developed, particularly for user-facing components, in order to validate the design and identify potential problems and missing information. Closely related to this, an integrated, automated testing architecture, with appropriate testing scripts/procedures, may be designed in this phase in order to ensure the software being developed meets quality standards and is responsive to the requirements. The depth and completeness of the design is contingent on the software development process, as well as other factors. In some cases, the entire design is completed before moving on to software coding. In other development strategies, a high-level system architecture is designed but the details of the software components are delayed until each component or component feature is being created. The pros and cons of these approaches are discussed later in this chapter. For vendor-developed systems, the purchasing organization will often hold design reviews and demonstrations of mock-ups or prototypes with the vendor to assess the solutions. In the case of COTS software, the purchasing organization relies on the vendor’s system description and reviews from third parties, supplemented by system demonstrations, to determine the appropriateness of the design. As with the Analysis phase, it is important to include the target users and IT operations personnel in the design reviews.

Ideally, the software could be designed solely around the care requirements and the use of information. However, rarely are the clinical requirements of the use case the only consideration. In the design phase, other requirements are considered, such as the software cost and how it integrates with an existing health IT strategy of an organization. Resources applied to a development project are not available for other potential projects, so costs are always influential. The design phase must consider various alternatives to

meet the most important requirements, recognizing trade-offs and contingency approaches. Additional considerations are how the software will support long-term needs, not just the immediate requirements that have been identified. Clinicians and clinical workflow analysts are often the primary participants in the requirements analysis stage, whereas informaticians are more prominent in the design phase. This is because during this latter phase the clinical goals and strategies are considered together with what can be vastly different design approaches, and the ability to consider the various strengths and weaknesses of these different approaches is critical. Often, design considerations are between custom development, purchasing niche applications, or purchasing components of a monolithic EHR. The considerations of development versus COTS software is discussed in more detail in the Acquisition Strategy section (► 6.3.3.1) below.

### 6.3.1.3 Development

Coding of the software is done during the Development phase of the SDLC. The software engineers use the requirements and system designs as they program the code. Analysts help resolve questions about requirements and designs for the programmers when it is unclear how software might address a particular feature. The software process defines the pace and granularity of the development. In some cases, an entire software component or system is developed at once by the team. In other cases, the software is broken down into logical pieces and the programmers only work on the features that are relevant to the piece they are currently working on. As software components are completed, unit tests are run to confirm the component is free of known bugs and produces expected outputs or results.

In health care, development includes coding of custom software as well as configuration of COTS software. Health care practices across institutions (and even within larger organizations) are so variable that all software requires some – often substantial – configuration. Configuration can range from assigning local values to generic variables within the

software, to complete development of documentation templates, order sets, clinical decision support rule, reports, and so on. In fact, configuration can be so considerable that institutions may use an internal brand name for the software and configuration project that is different from the name of the COTS software, which represents their local configuration. This configuration is often done using tools built specifically for the commercial software, which facilitate the integration of the configuration products into the software infrastructure. The tools can be complex, requiring significant training for developers. Typically, tools work well for basic configuration and may also have advanced functionality that can be used to configure more complicated functionality. The most intensive time investment for configuration is typically when the tools do not directly support certain configurations, and developers must find approaches to creatively adapt the development “around the tools.”

### 6.3.1.4 Integration and Test

For complex software projects consisting of several components and/or interfaces with outside systems, an Integration phase in the SDLC is employed to tie together the various pieces. Some aspects of the software integration are likely done during the Development phase by simulating or mocking the outputs to, and inputs from, other systems. During Integration, these connections are finalized. Simulations are run to demonstrate functional integration of the various system components. Once the various components are integrated, a thorough testing regimen is conducted in order to prove the end-to-end operation of the entire software system. Specific test scenarios are run with known inputs and expected outputs. This is typically done in a safe, non-operational environment in order to avoid conflicts and unnecessary risk to production environments, although some inbound information from live systems may be used to verify scenarios that are difficult to simulate.

Testing and integration in health care are similar to other complex environments, in that it can be difficult to create a testing environment that matches the dynamics of the

real-world setting. Generally, testing is done around multiple use cases or case studies, using data to support the cases. In a production environment, however, there may be data and information that do not match the case studies, since both people and health care are complex. As a result, internally-developed applications are often provisionally used in a “pilot” phase as part of testing. For COTS software, companies may use simulation laboratories that try to mimic the clinical environment, or work with specific health care organizations as development and testing partners. Later, however, this can lead to challenges if data representing the dynamics of one organization are not easily transferable, and software must be further tested with new environments. Software transferability between institutions has been demonstrated in studies, even for specific applications (Hripcsak et al. 1998). Another challenge is that with current privacy laws, organizations are more reluctant to release data to vendors for testing.

### 6.3.1.5 Implementation

Once the software passes integration testing it moves to the implementation phase. In this phase, the software is installed in the live environment. In preparation for installation, server hardware, user devices, network infrastructure, changes specific to individual facilities, etc., may need to be implemented and tested as well. In addition, user training will be performed in the weeks before the software goes live. Any changes to policies and procedures required by the software will also be implemented in the build-up to installation.

Health care presents interesting considerations in each phase of the software development cycle, but the challenges have been more visible in implementation than any other phase. This may be because health IT, while intended to facilitate more efficient workflows with information, is still disruptive. Disruption happens most during implementation, when clinicians actually begin using the software, and studies have shown that during this time clinical productivity does decline (Shekelle et al. 2006). If users do not perceive that the benefits are sufficient to justify this disrupt-

tion, or if the efficiency does not improve quickly enough after the initial implementation, they may choose to disregard the software or even revolt against its implementation. There have been prominent examples in biomedical informatics of software implementations failing during implementation (Bates 2006; Smelcer et al. 2009; Sullivan 2017), and even studies demonstrating harm (Han et al. 2005). Because of these risks, health IT professionals need to be flexible in implementation, and adapt the implementation strategies to how the system is adopted. Users have been shown to use health IT software in different ways for different benefits, and may need incentives or prodding to advance to different levels of use.

### 6.3.1.6 Verification and Validation

To ensure that the software satisfies the original requirements for the system and meets the need of the organization, a formal verification and validation of the software is performed. The implementing organization *verifies* that the software has the features and performs all the functions specified in the requirements document. The software is also *validated* to show that it performs according to specified operational requirements, that it produces valid outputs, and that it can be operated in a safe manner. For purchased software, the verification and validation phase is used by the purchasing organization in order to officially accept the software.

Since clinicians often use software at different levels or in different ways, tracking patterns of use can be an important approach for verification and validation of software in health care. Additionally, because they have experience working in complicated environments, users can be good at identifying inconsistencies in data or software functions. Two approaches that have been used and can be successful for validation are monitoring use, and facilitating user feedback.

### 6.3.1.7 Operations and Maintenance

Software eventually enters an operations and maintenance (O&M) phase where it is being regularly used to support the operational needs of the organization. During this phase,

an O&M team will ensure that the software is operating as desired and will be fielding the support needs of the users. Updates may need to be installed as new versions of the software are released. This may require new integration and testing, implementation, and verification and validation steps. Ongoing training will be required for new users and system updates. The O&M team may conduct regular security reviews of the system and its use. Data repositories and software interfaces will be monitored for proper operation and continued information validity. Software bugs and feature enhancement requests will be collected. These may drive an entire new development life cycle as new requirements persuade an organization to explore significant upgrades to its current software or even an entirely new system.

Maintenance is a demanding task in health information software. It involves correcting errors; adapting configurations and software to growth, new standards, and new regulations; and linking to other information sources. Maintenance tasks can exceed by more than double the initial acquisition costs, making it a substantial consideration that should affect software design. COTS suppliers often provide maintenance services for 15–30% of the purchase price annually, but custom development or configuration maintenance must be supported by the purchasing organization. If the software is not maintained, it can quickly become unusable in a health care setting. Indeed, optimization of COTS EHRs is a central and ongoing focus of applied clinical informatics, and this is likely to continue for the foreseeable future.

### 6.3.1.8 Evaluation

An important enhancement to the SDLC suggested by Thompson et al. (1999) is the inclusion of an evaluation process during each of the phases of the life cycle. The evaluation is influenced by risk factors that may affect a particular SDLC segment. An organization might perform formative evaluations during each phase, depending on specific needs, in order to assess the inputs, processes and resources employed during development. During

Verification and Validation or O&M, a summative evaluation may be performed to assess the outcome effects, organizational impact, and cost-benefit of the software solution.

Health IT is considered an intervention into the health care delivery system, so evaluations have been done and published as comparative studies in the clinical literature (Bates et al. 1998; Campanella et al. 2016; Evans et al. 1998; Hunt et al. 1998; Jones et al. 2014). These evaluations, and syntheses of multiple studies, have identified areas of impact and areas where the effect of health IT software is inconsistent. Researchers have also noted that most of these studies have occurred in institutions where software was developed internally, with disproportionate under-representation of COTS software systems in evaluations, especially considering that most health care institutions use COTS rather than internal development (Chaudhry et al. 2006). It is hoped that the existing evaluations can be a model for software evaluations of COTS, to clarify their impact on care.

## 6.3.2 Software Development Models

Different software development processes or methods can be used in an SDLC. The **software development process** describes the day-to-day methodology followed by the development team, while the life cycle describes a higher-level view that encompasses aspects that take place well before code is ever written and after an application is in use. The following are two of the most common examples of different development processes in clinical information systems development.

### 6.3.2.1 Waterfall Model

The Waterfall model of software development suggests that each step in the process happens sequentially, as shown in  Fig. 6.1. The term “Waterfall” refers to the analogy of water cascading downward in stages. A central concept of the Waterfall methodology is to solidify all of the requirements, establish complete functional specifications, and create the final soft-

■ Fig. 6.1 The Waterfall model of software development

ware design prior to performing programming tasks. This concept is referred to as “Big Design Up Front,” and reflects the thinking that time spent early-on making sure requirements and design are correct saves considerable time and effort later. Steve McConnell, an expert in software development, estimated that “...a requirements defect that is left undetected until construction or maintenance will cost 50–200 times as much to fix as it would have cost to fix at requirements time” (McConnell 1996).

The waterfall model provides a structured, linear approach that is easy to understand. Application of the model is best suited to software projects with stable requirements that can be completely designed in advance. In practice, it may not be possible to create a complete design for software a priori. Requirements and design specifications can change even late in the development process. Clients may not know exactly what requirements they need before reviewing a working prototype. In other cases, software developers may identify problems during the implementation that necessitate reworking the design or modifying the requirements.

### 6.3.2.2 Agile Models

In contrast to the Waterfall model, modern software development approaches have attempted to provide more flexibility, particularly in terms of involving the customer

throughout the process. In 2001, a group of software developers published the Manifesto for Agile Software Development, which emphasizes iterative, incremental development and welcomes changes to software requirements even late in the development process (Beck et al. 2001).

Agile development eschews long-term planning in favor of short iterations that usually last from 1 to 4 weeks. During each iteration, a small collaborative team (typically 5–10 people) conducts planning, requirements analysis, design, coding, unit testing, and acceptance testing activities with direct involvement of a customer representative. Multiple iterations are required to release a product, and larger development efforts involve several small teams working toward a common goal. The agile method is value-driven, meaning that customers set priorities at the beginning of each iteration based on perceived business value.

Agile methods emphasize face-to-face communication over written documents. Frequent communication exposes problems as they arise during the development process. Typically, a formal meeting is held each morning during which team members report to each other what they did the previous day, what they intend to do today, and what their roadblocks are. The brief meeting, sometimes called a “stand-up,” “scrum,” or “huddle,” usually lasts 5–15 minutes, and includes the

development team, customer representatives and other stakeholders. A common implementation of agile development is Extreme Programming.

### 6.3.3 Software Engineering

The software development life cycle can be used to actually create the software, and understanding it is critical for those developing software in biomedical informatics. However, as the field has expanded, software has matured to the point that it is developed by and available from commercial companies, so that software development has become less of a concern for most of the field. A more important consideration in biomedical informatics has been the strategy of whether to develop and how to develop. Software vendors can spread development costs over multiple organizations, rather than one organization having to fund the full development, which can make purchasing software economically advantageous. On the other hand, the core requirements for software continue to change, and sometimes organizations need specific capabilities that are not met by existing vendor software options. In addition to software development, informaticians often participate in software acquisition, as well as in subsequent enhancements to acquired software.

#### 6.3.3.1 Software Acquisition

In health care information technology applications, a significant question is whether to develop the software internally or purchase an existing system from a vendor. Whether to “build vs. buy” is a core decision in planning and implementation.

Considerations for purchasing software begin with how the software will be selected. Software can be a component of a monolithic vendor system, be a secondary application sold by the same vendor as the EHR, or be “best-of-breed,” meaning the software that meets the requirements best, independent of its architecture or source. Another consideration is whether the software needs to integrate with other applications. Some specialty

applications require minimal data sharing with other software, while other applications must be tightly integrated with existing systems to achieve a benefit. Two examples are a picture archiving and communications system (PACS) and a medication reconciliation tool. Perhaps the most important requirement for a PACS is to provide access to images for a radiologist, who can then “read” the image and document a report which can be transferred into the EHR as a static document. On the other hand, a medication reconciliation tool may need substantial integration with medication ordering and administration modules in an EHR to support workflows of the care team. Another consideration, related to integration, is the storage mechanism. A stand-alone system will likely have a separate database, while an integrated system may be able to store and retrieve data using a common data repository. User interface deployment is also important, and possibilities include Web-based clients, **thin clients** (e.g., Citrix), and locally-installed **thick-client** applications. Greater functionality may exist with a thick-client application, but Web-based and thin-client tools are easier to update and distribute to users. Finally, security and privacy considerations are critical in health care, and can influence both the requirements and design of software. Security considerations can include whether **user authentication** is shared with other applications, or what data access events are audited for identifying potential security threats.

Most healthcare delivery organizations today use commercial – as opposed to locally developed – EHRs. But in reality, there is still a mix between building and buying health information technology. As mentioned, organizations using commercial systems require substantial local configuration that ranges from application-specific parameter configuration to coordinating multiple software applications to link together. Even when there is a commitment to limit local configuration, there may still be separate systems, local configuration or even development with data warehousing and analytics solutions for the EHR data. There is no single solution, commercial or internally-developed, that meets all

the health information needs of most health care organizations, and many implementations involve a mixture of software from multiple vendors. While there can be advantages to allowing best-of-breed, a current trend among organizations is to consolidate as much functionality as possible with one vendor. Another observed trend is for organizations that build systems to consider purchasing COTS, due to the substantial maintenance costs associated with in-house development and the increased functionality often available with vendor solutions. At present, virtually all health care organizations that utilize an EHR in the United States use a COTS solution or are in the process of migrating to such a solution.

Usually, if vendor software exists, it is more cost-efficient to purchase the software than build comparable capabilities internally for use at a single organization. This is because the vendor can spread development costs over multiple organizations, rather than one organization having to fund the full development. In fact, few organizations have the existing infrastructure and personnel to consider internal development for anything other than small applications. However, those few institutions with developed health information systems are notable for the success of their software. So while the costs may be higher for internal development, the benefits may also be higher. Furthermore, such solutions may be potentially licensed to other organizations, thereby spreading the cost of development across multiple organizations. Still, these institutions have invested many years to build an infrastructure that makes these benefits possible, and it is unlikely that many organizations can afford the time and resource investment to follow the same model. Even within historically internally-developing organizations, buying systems that can integrate with the existing system is oftentimes more efficient than development. An appropriate general guide is therefore, “Buy where you can, build where you can’t.”

Once an organization decides to acquire a health information system, there are many other decisions beyond whether to build or buy. In fact, since the costs in time and money

are oftentimes prohibitive for internal development, the decision to build is typically the easiest decision to make for a large health information system such as the EHR. Coupled with the Meaningful Use EHR Incentive Program, adoption of at least basic EHRs in the United States is very high, exceeding 90% (see ■ Figs. 6.2, 6.3 and 6.4).<sup>1</sup>

Once a decision to purchase a commercial system is made, the next decision is what system to purchase. There is a wide variation in the functionalities between different EHR systems, even though certification efforts have defined basic functions that each system should have (see ■ Fig. 6.3). Even systems with the same certified functions may approach the functions so differently that some implementations will be incongruent to an organization.<sup>2</sup> Key factors an organization should consider when choosing a system include (a) the core functionality of the software, including integration with other systems, (b) total system cost, (c) the service experience of other customers, and (d) the system’s certification status. Some organizations have performed systematic reviews of different commercial software offerings that can be a helpful start to identify possible vendors and understand variations between systems. For example, KLAS Research publishes periodic assessments of both software functions and vendor performance that can be used to identify potential software products. However, since systems are complex, it is important to meet with and discuss experiences with actual organizations that have used the software. This is typically done through site visits to existing customer organizations. It is also common for organizations to make a broad request of vendors for proposals to address a specific software need, especially

Fig. 6.4 Health IT developers product use by hospitals participating in the Medicare EHR, from ONC (2017a)

when the needs are not standard components of EHR software.

After a commercial product is selected, an organization must then choose how extensive the software will be. EHR companies typically have a core EHR system, with additional modules that have either been developed or acquired and integrated into their system. The set of modules used by each institution varies. One organization may use the core EHR system and accompanying modules for certain specialties, such as internal medicine and family practice, while choosing to purchase separate best-of-breed software for other specialties, like obstetrics/gynecology and emergency medicine, even when the core EHR vendor has functional modules for those areas. Another organization may choose to purchase and implement all specialty systems offered from the core EHR vendor, and only purchase other software if a similar module is not available from the vendor. These decisions also must be made for all ancillary systems, including laboratory, pharmacy, radiology, etc. This is both a pre-implementation decision and a long-term strategy. Once the EHR is implemented, many specialties that were not included in the initial implementation plan may request software and data integration, depending on the success of the EHR implementation.

For organizations that choose components of multiple vendor offerings to any degree, they will need to address how to integrate the components together to minimize disruption to the users' workflow. There are various strategies that can be pursued to integrate modules, either at the level of user context (user authentication credentials are maintained), the level of the application view (one application is viewable as a component within another application), or at the level of data sharing (data are exchanged between the applications). If components are not integrated, a user must access each application separately, by opening the software application, logging in to each separately, and selecting the patient within each. When data are integrated at the user context, a user moves between both applications, but the user and patient context are shared. This “single sign-

on” approach alleviates one of the main barriers to the user, by facilitating the login and patient selection, while retaining all the functionality of each system.

A deeper level of integration is at the application view. In this case, a primary application provides a portal that views another application; the second application shares user and patient context and is accessible through the user's main workflow system. The second application may use data from the primary application and/or other data sources. Rapidly expanding in adoption for this type of integration is the HL7 Substitutable Medical Applications and Reusable Technologies (SMART) framework, in particular in combination with HL7 Fast Healthcare Interoperability Resources (FHIR) for data interchange. This approach, known as SMART on FHIR, is enabling an ecosystem wherein applications developed by health care organizations or third-party vendors can be seamlessly integrated within the EHR (Kawamoto et al. 2019; Mandel et al. 2016).

The deepest level of integration is where 1 data elements from one system are also stored in the other system. With this approach, one system is determined to be the main repository, and data from the other systems are automatically stored into the repository. This approach has the advantage of the most complete use of data, e.g., decision support logic can use data from multiple systems, which can be more accurate. The disadvantage is that the integration can be expensive, requiring new interfaces for each integrated system.

Another and often overlooked consideration of EHR software modules is data analytics capabilities, usually discussed in conjunction with a data warehouse. EHR systems generally include reporting functionality, where specific reports can be configured to summarize and display data stored in the system. However, these systems often do not facilitate ad hoc data extracts that are commonly needed for more complicated data analysis. Additionally, if modules from multiple software vendors are used, the data reporting functions will be limited according to how well data are integrated. One typical approach

is to use a separate data warehouse and analysis system, with functions to create ad hoc reports, that can combine data from multiple systems. Data integration with warehouses is less expensive than with repositories, because the data do not need to be synchronized. Instead, data can be extracted in batches from source systems, transformed to the warehouse data model, and then loaded into the warehouse at periodic intervals. The greatest cost of integration is the data transformation, but this transformation is similar to what is required when receiving data through a real-time interface.

The **Meaningful Use** program, which has evolved to become the **Promoting Interoperability** program, has greatly influenced the systems that are installed by an institution. Initially, the ONC created a list of important EHR functions. They also created a requirement that hospitals and physician practices use a “certified” system – i.e., one that has demonstrated it provides those functions – to receive the incentives, and other criteria that the functions must be used in clinical care (Washington et al. 2017). As a result, health care organizations rapidly implemented EHRs that were certified and best fulfilled regulatory requirements.

### 6.3.3.2 Case Studies of EHR Adoption

Consider the following case studies of institutions adopting EHR systems. All examples are fictional, but reflect the complexity of the issues with EHR software.

*Best-Care Medical Center had been using information systems for many years, dating back to when some researchers in the cardiology department built a small system to integrate data from the purchased laboratory and pharmacy information systems. Eventually, the infection control group for the hospital began using the system, and contributed efforts to expand its functionality. Other departments began developing decision support rules, and the system continued to grow. Eventually, the institution made a commitment to redevelop the infrastructure to support a much larger group of users and functions, and named it A-Chart. Satisfaction with the system was high where it had been initially developed, and with other*

*related specialties. However, over time there was disproportionate development in these areas, and clinicians in other specialties complained about the rudimentary functionality, especially when compared to existing vendor systems for their specialty. As a result, the organization decided to purchase a new vendor system. This made the other specialties happy, but was a big concern to the groups that had been using A-Chart for years. These clinicians feared that they would have to reconfigure their complicated decision support rules with a new system, or worse, that functionality would no longer be supported. To alleviate concerns, representatives from each department were asked to participate in both drafting a Request for Proposals and then reviewing the proposals from four different vendors. Many clinicians liked System X, but in the end the hospital chose System Y, which seemed to have most of the same capabilities but was perceived to be more affordable than System X. However, System Y did not include a laboratory system, so the medical center purchased a separate laboratory system and built interfaces to connect it with the core EHR.*

*Patients’ Choice is an integrated delivery system with a long history of EHR use. Years ago, it existed as two separate systems of hospitals and clinics. Shortly before the merger of these systems, the hospitals and clinics purchased separate EHRs, InPatSys and CliniCare. At the time of the merger, the institution felt that each would be best served by a best-of-breed system, to support the different workflows, and there was no single system that both sides of the organization could agree to use. Years later, as Patients’ Choice began to integrate care between the hospitals and clinics, the clinicians and administrators became increasingly frustrated at how different the InPatSys and CliniCare systems were, and that they had to use two separate systems to care for the same patients. A team was formed to evaluate the options, and the CliniCare system was eventually replaced by OutPatSys, the outpatient version of InPatSys. To prevent losing data as they moved from one system to the other, the Patients’ Choice IT department prepared the OutPatSys system by loading existing laboratory results and vital sign measurements from*

*CliniCare. A SMART on FHIR application provided an integrated view of historical CliniCare data inside the OutPatSys system.*

*Hometown Community Hospital historically used various niche information systems, but no EHR. With the availability of Meaningful Use incentives, the hospital decided to acquire a commercial EHR. A leadership team visited six hospitals to investigate how various EHRs were used. Ultimately, the hospital made the decision to purchase eCompuChart, because it was highly rated and seemed best adapted to their needs. Hometown hired a new Chief Information Officer who had recently implemented eCompuChart at a community hospital in a neighboring state. They also promoted Dr. Jones, who had recently moved from another hospital that had also used eCompuChart, to Chief Medical Information Officer (CMIO). The CIO and CMIO negotiated a contract with DigiHealth, a consulting company with experience in implementing EHRs, to plan and coordinate the implementation. Among other recommendations from DigiHealth, most existing systems were replaced with modules from eCompuChart to simplify maintenance.*

In practice, organizations may not adopt a complete “build” or a complete “buy” strategy. EHR vendors have advanced considerably in their ability to create systems that meet common needs in health care. Still, no system exists to date that can fully address all information needs for an organization, in part because the information needs expand as more data and new technologies become available. Additionally, EHR strategies become malleable over time, as commercial software capabilities increase and data become more consistent. As indicated through some of the examples above, organizational strategies may change over time to adapt to these capabilities and needs. Expanding options for health care organizations is the emergence of the notion of the EHR as a platform, where HL7 FHIR data interfaces can be used to read data from, and in some cases write data back to the EHR; HL7 SMART is available to integrate external applications into the native EHR user interface; and more recently, a framework known as HL7 CDS Hooks is

available to interface externally developed alerts and reminders into the EHR.<sup>3</sup>

One consideration that is not always stated in the software selection process, but is significant in its influence over the decision, is how an organization will pay for the application. In organizations where software purchases are requested from the information technology department and budget, overall maintenance costs are considered more prominently, and software that integrates with and is a component of the overall EHR vendor offering is often selected. However, if a clinical department has direct control over their spending for the software, functionality may become a more focal concern. An additional case study illustrates this situation.

*Downtown Hospital recently decided to purchase eCompuChart as the centerpiece of its overall clinical information system strategy. eCompuChart has award-winning modules for the emergency department and intensive care units. However, there are strong complaints about its capabilities for labor and delivery management and radiology. After considering capabilities of best-of-breed options and their ability to integrate with eCompuChart, Downtown Hospital eventually made a split decision. The labor and delivery module for eCompuChart was purchased because other systems with more elaborate functionality could not integrate data as well with the overall EHR. On the other hand, a separate best-of-breed system was purchased for radiology, because interfaces between the systems were seen as an acceptable solution for integrating data.*

### 6.3.3.3 Enhancing Acquired Software

Although most institutions will choose to acquire a system rather than building it from scratch, software engineering is still required to make the systems function effectively. This involves more than just installing and configuring the software to the local environment. There is still a significant need for software development in implementing COTS, because

3 ▶ <https://cbs-hooks.org/> (last accessed June 3, 2020).

(1) applications must be integrated with existing systems, and (2) leading healthcare institutions are increasingly developing custom applications, such as SMART on FHIR applications, that supplement commercial systems.

### 6.3.3.4 Integration with Existing Systems

In all but the most basic health care information technology environments, multiple software applications are used for treatment, payment, and operations purposes. A partial list of applications that might be used in a hospital environment is shown in [Table 6.1](#).

To facilitate the sharing of information among various software applications, standards have emerged for exchanging messages and defining clinical terminology (see [Chap. 8](#)). Message exchange between different software applications enables the following scenario:

1. A patient is admitted to the hospital. A registration clerk uses the bed management system to assign the patient's location and attending physician of record.

**Table 6.1** Partial list of software applications that may be used in a hospital setting

System	Primary Users
Inpatient EHR (Results Review, Order Entry, Documentation)	Physicians, nurses, allied health professionals
Pharmacy Information System	Pharmacists, pharmacy technicians
Laboratory Information System	Laboratory technicians, phlebotomists
Radiology Information System	Radiologists, radiology technicians
Pathology Information System	Pathologists
Registration/Bed Management	Registration staff
Hospital Billing System	Medical coders
Professional Services Billing System	Physicians, medical coders

2. The physician orders a set of routine blood tests for the patient in the inpatient EHR computerized order entry module.
3. The request for blood work is sent electronically to the laboratory information system, where the blood specimen is matched to the patient using a barcode.
4. The results of the laboratory tests are sent to the results review module of the EHR

Message exchange is an effective means of integrating disparate software applications in healthcare when the users rely primarily on a single “workflow system” (e.g., a physician uses the inpatient EHR and a laboratory technician uses the LIS). Because message exchange is handled by a sophisticated “interface engine” (see [Chap. 8](#)), little software development, in the traditional sense, is typically required. When a user accesses multiple workflow systems to perform a task, message exchange may not be sufficient and a deeper level of integration may be required. For example, consider the following addition to the previously described scenario:

5. The physician reviews the patient's blood work and notes that the patient may be suffering from renal insufficiency as evidenced by his elevated creatinine level.
6. The physician would like to review a trend of the patient's creatinine over the past 3 years. Because the hospital installed their commercial EHR less than a year ago, data from prior to that time are available in a legacy results review system that was developed locally. The physician logs into the legacy application (entering her username and password), searches for the correct patient, and reviews the patient's creatinine history.

While it may seem preferable in this scenario to load all data from the legacy system into the new EHR, commercial applications may not support importing such data for various reasons. To simplify and improve the user experience for reviewing information from a legacy application within a commercial EHR, one group of informaticians created the custom application shown in [Fig. 6.5](#). The application is accessed by clicking a link

• **Fig. 6.6** Example screen from a custom billing application integrated into a commercial EHR. This replaced a separate application that was not integrated into the clinicians' workflow

within the commercial EHR and does not require login or patient look-up.

In an example of a more sophisticated level of “workflow integration” is shown in **Fig. 6.6**. In this example, informaticians developed a custom billing application within

an inpatient commercial EHR. Users of the application were part of a physician practice that used a different outpatient EHR with a professional billing module with which they were already familiar. When the physicians in the practice rounded on their patients who

were admitted to the hospital, they documented their work by writing notes within the inpatient EHR, and then used their outpatient EHR to submit their professional service charges. This practice not only required a separate login to submit a bill, but also required duplicate patient lists to be maintained in each application, as well as a duplicate problem list for each patient to be managed in each application. The integrated charge application was accessed from the inpatient EHR but provided the same look-and-feel as the outpatient EHR billing module. Charges were submitted through the outpatient EHR infrastructure and would appear as normal charges in the outpatient system, with the substantial improvement of displaying the information (note name, author, and time) for the documentation that supported the charge.

### 6.3.3.5 Development of Custom Applications that Supplement or Enhance Commercial Systems

Commercial EHRs frequently provide customers with the ability to develop custom software modules. Some EHRs provide a flexible clinical decision support infrastructure that allows customers to develop modules that execute medical logic to generate alerts, reminders, corollary orders, and so on. Vendors may also provide customers with tools to access the EHR database, which allows development of stand-alone applications that make use of EHR data. Additionally, vendors may foster development of custom user interfaces within the EHR by providing an application programming interface through which developers can obtain information on user and patient context.

The ability to provide patient-specific clinical decision support is one of the key benefits of EHRs. Many commercial EHRs either directly support or have been influenced by the **Arden Syntax for Medical Logic Modules** (Pryor and Hripcsak 1993). The Arden Syntax is part of the HL7 family of standards. It encodes medical knowledge as **Medical Logic**

**Modules** (MLMs), which can be triggered by various events within the EHR (e.g., the placing of a medication order) and execute serially as a sequence of instructions to access and manipulate data and generate output. MLMs have been used to generate clinical alerts and reminders, to screen for eligibility in clinical research studies, to perform quality assurance functions, and to provide administrative support (Dupuits 1994; Jenders 2008; Jenders and Shah 2001; Ohno-Machado et al. 1999). Although one goal of the Arden Syntax was to make knowledge portable, MLMs developed for one environment are not easily transferable to another. Developers of clinical decision support logic require skills in both computer programming as well as medical knowledge representation.

An example of a standalone, locally developed software application that relies on EHR data is shown in  Fig. 6.7. The Web-based application, EpiPortal™, provides a comprehensive, electronic hospital epidemiology decision support system. The application can be accessed from a Web browser or directly from within the EHR. It relies on EHR data such as microbiology results, clinician orders, and bed tracking information to provide users with timely information related to infection control and prevention.

In some cases, it is desirable to develop custom applications to address specific clinical needs that are not met by a commercial EHR. For example, most commercial EHRs lack dedicated tools to support patient hand-off activities. For hospitalized patients, hand-offs between providers affect continuity of care and increase the risk of medical errors. Informaticians at one academic medical center developed a collaborative application supporting patient handoff that is fully integrated with a commercial EHR (Fred et al. 2009). An example screen from the application is shown in  Fig. 6.8. The application creates user-customizable printed reports with automatic inclusion of patient allergies, active medications, 24-hour vital signs, recent common laboratory test results, isolation requirements, code status, and other EHR data.

## 6.4 Emerging Influences and Issues

Several trends in software engineering are beginning to significantly influence biomedical information systems. While many of the trends may not be considered new to software engineering in general, they are more novel to the biomedical environment because of the less rapid and less broad adoption of information technology in this field. One area in particular that has received growing attention is **service oriented architectures (SOA)**. Sometimes called “software as a service”, SOA is a software design framework that allows specific processing or information functions (services) to run on an independent computing platform that can be called by simple messages from another computer application. For example, an EHR application might have native functionality to maintain a patient’s medication list, but might call a drug-drug interaction program running on a third party system to check the patient’s medications for potential interactions. This allows the EHR provider to off-load developing this

functionality, while the drug-drug interaction service provider can concentrate efforts on this focused task, and in particular on ensuring that the drug interaction database is kept up-to-date for all users of the service. Since the service is independent of any EHR application, many different EHR providers can call the same service, as can other applications such as patient health record (PHR) applications that are focused on consumer functionality. SOA might also be grouped with the more recently computer phrase “cloud computing”, which includes providing functional services to other applications, but also encompasses running entire applications and storing data in offsite or disconnected locations. A good example of SOA is the HL7 CDS Hooks standard, which specifies how EHR systems can interface with external clinical decision support services to provide point-of-care alerts and reminders to clinical end users.

Another emerging trend, discussed earlier, is the notion of the **EHR as a platform** for third-party applications and services that interface with, and add value to, the EHR. Central to this approach is HL7 FHIR

Fig. 6.8 Example screen from a custom patient handoff application integrated into a commercial EHR. The application creates user-customizable printed

reports with automatic inclusion of patient allergies, active medications, 24-hour vital signs, recent common laboratory test results, isolation requirements, code status, and other EHR data

application programming interface (API), which uses modern Internet technologies and approaches for data exchange, as well as HL7 SMART for application integration and HL7 CDS Hooks for integrating decision support services. While this notion of EHR as a platform is still in its early stages and still maturing, many EHR vendors are strongly supportive of this type of an ecosystem, and promising examples are emerging of how these technologies can be used to deliver value to health care organizations in an EHR-agnostic manner. We anticipate that this approach to health information systems, wherein core EHR systems are augmented by

third-party applications and services, will play an important role in the health IT ecosystem in the years to come.

Another important consideration in clinical information systems is infrastructure to support data sharing, such as through a **health information exchange (HIE)**. HIE infrastructure allows organizations to share information about patients through a common electronic framework. Robust HIE capabilities, which are now being implemented in commercial EHR systems, make it much more efficient to share patient information between organizations versus creating point-to-point interfaces between all the clinical information

systems a particular provider might need to communicate with. Effective sharing of information is predicated on the use standard message formats and terminologies (see ► Chap. 8), or the use of a shared EHR vendor. Where HIE functionality does not exist or is declining (Adler-Milstein et al. 2016), sharing can be coordinated directly between organizations with incentives for sharing, such as in an ambulatory care network (ACN). As health care in the United States increasingly shifts to a payment model that rewards value over volume, data sharing capabilities and the capacity for population-level analytics and health management will become increasingly critical. Moreover, there are also emerging efforts to scale health information exchange to a national scale, and to facilitate patient access to their information using APIs (ONC 2019b).

Software engineering is an ever-evolving discipline, and new ideas are emerging rapidly in this field. It is less than 30 years since the first graphical browser was used to access the World Wide Web, but today Web-based applications are the standard. Access to information through search engines has changed the way that people find and evaluate information. Social networking applications have altered our views on privacy and personal interaction. All of these developments have shaped the development of healthcare software, too. Today it is unimaginable that an EHR would not support a Web-based patient portal. Clinicians and consumers use the Web to search for health-related information in growing numbers and with growing expectations. It is not atypical for patients to discuss health issues in online forums and share intimate details on patient networking sites.

Another development that is impacting virtually all industries, including health care, is **advanced analytics**. Coupled with the rapid increase in the adoption of EHR systems, health care represents a golden opportunity for leveraging powerful computing approaches with large data sets to identify and apply new insights. For example, deep learning techniques can be applied to EHR data to predict important outcomes such as in-hospital mortality. If coupled

with user-centered, workflow-integrated interventions, such insights have the potential to improve clinical decision making and enhance patient care.

## 6.5 Summary

The goal of software engineering in health care is to create a system that facilitates delivery of care. Much has changed in the past decade with EHRs, and today most institutions will purchase rather than build an EHR. But engineering these systems to facilitate care is still challenging, and following appropriate software development practices is increasingly important. The success of a system depends on interaction among designers of healthcare software applications and those that use the systems. Communication among the participants is very difficult when it comes to commercial applications. Informaticians have an important role to play in bridging the gaps among designers and users that result from the wide variety in background, education, experience, and styles of interaction. They can improve the process of software development by specifying accurately and realistically the need for a system and of designing workable solutions to satisfy those needs.

### Suggested Reading

Carter, J. H. (2008). *Electronic health records* (2nd ed.). Philadelphia: ACP Press. Written by a clinician and for clinicians, this is a practical guide for the planning, selection, and implementation of an electronic health record. It first describes the basic infrastructure of an EHR, and then how they can be used effectively in health care. The second half of the book is written more as a workbook for someone participating in the selection and implementation of an EHR.

KLAS Reports. <http://www.klasresearch.com/reports>. These reports are necessary tools for a project manager who needs to know the latest industry and customer information about vendor health information technology products. The reports include information on functionality available from vendors as well as customer

opinions about how vendors are meeting the needs of organizations and whose products are the best in a particular user environment.

McConnell, S. (1996). *Rapid development: Taming wild software schedules*. Redmond: Microsoft Press. For those who would like a deeper understanding of software development and project methodologies like Agile, this is an excellent source. It is targeted to code developers, system architects, and project managers.

President's Council of Advisors on Science and Technology (December 2010). Report to the President Realizing the Full Potential of Health Information Technology to Improve Healthcare for Americans: the Path Forward. <http://www.whitehouse.gov/sites/default/files/microsites/ostp/pcast-health-it-report.pdf>. This PCAST report focuses on what changes could be made in the field of electronic health records to make them more useful and transformational in the future. It gives a good summary of the current state of EHRs in general, and compares the barriers to those faced in adopting information technology in other fields. Time will tell if the suggestions really become the solution.

Stead, W. W., & Lin, H. S. (Eds.). (2009). *Computational technology for effective health care: immediate steps and strategic directions*. Washington, DC: National Academies Press. This is a recent National Research Council report about the current state of health information technology and the vision of the Institute of Medicine about how such technology could be used. It can help give a good understanding of how health IT could be used in health care, especially to technology professionals without a health care background.

Tang, P. C. (2003). *Key capabilities of an electronic health record system*. Washington, DC: National Academies Press. This is a short, letter report from an Institute of Medicine committee that briefly describes the core functionalities of an electronic health record system. Much of the report is tables that list specific capabilities of EHRs in some core functional areas, and indicate their maturity in hospitals, ambulatory care, nursing homes, and personal health records.

Wager, K. A., Lee, F. W., & Glaser, J. P. (2017). *Health care information systems: a practical approach for health care management*. John

Wiley & Sons. This is a textbook giving a good overview of healthcare information systems, used in many academic courses on the subject. It reviews the different environmental factors and contexts that influence the health information landscape nationally, as well as giving guidance on implementation, management and evaluation of systems.

## ? Questions for Discussion

- Reread the hypothetical case study in ► Sect. 6.2.1.
  - What are three primary benefits of the software used in James's care?
  - How many different ways is James's information used to help manage his care?
  - Without the software and information, how might his care be different?
  - How has health care that you have experienced similar or different to this example?
- For what types of software development projects would an agile development approach be better than a waterfall approach? For what types of development would waterfall be preferred?
- What are reasons an institution would choose to develop software instead of purchase it from a vendor?
- How is would various stages in the software development life cycle be different when developing software versus configuring or adding enhancements to an existing software program?
- Reread the case studies in ► Sect. 6.3.3.2.
  - What are the benefits and advantages of the different approaches to development and acquisition among the scenarios?
  - What were the initial costs for each institution for the software? Where will most of the long-term costs be?
- In what ways might new trends in software (small "apps" that accomplish focused tasks) change long-term strategies for electronic health record architectures?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- Why are standards important in biomedical informatics?
- What data standards are necessary to be able to exchange data seamlessly among systems?
- What organizations are active in standards development?
- What aspects of biomedical information management are supported today by standards?
- What is the process for creating consensus standards?
- What factors and organizations influence the creation of standards?
- How have standards development organizations applied modern Internet technologies such as application programming interfaces (APIs) into their interoperability standards?

## 7.1 The Idea of Standards

Ever since Eli Whitney developed interchangeable parts for rifle assembly, standards have been created and used to make things or processes work more easily and economically—or, sometimes, to work at all. A standard can be defined in many physical forms, but essentially it comprises a set of rules and definitions that specify how to carry out a process or produce a product. Sometimes, a standard is useful because it provides a way to solve a problem that other people can use without having to start from scratch. Generally, though, a standard is useful because it permits two or more disassociated people to work in some cooperative way. Every time you screw in a light bulb or play a media file, you are taking advantage of a standard. Some standards make things work more easily. Some standards evolve over time,<sup>1</sup> others are developed deliberately.

1 The current standard for railroad-track gauge originated with Roman chariot builders, who set the axle length based on the width of two horses. This axle length became a standard as road ruts developed,

The first computers were built without standards, but hardware and software standards quickly became a necessity. Although computers work with values such as 1 or 0, and with “words” such as 10101100, humans need a more readable language (see ► Chap. 5). Thus, standard character sets, such as ASCII and EBCDIC, were developed. The first standard computer language, COBOL, was written originally to simplify program development but was soon adopted as a way to allow sharing of code and development of software components that could be integrated. As a result, COBOL was given official standard status by the American National Standards Institute (ANSI).<sup>2</sup> In like manner, hardware components depend on standards for exchanging information to make them as interchangeable as were Whitney’s gun barrels.

A 1987 technical report from the International Standards Organization (ISO) states that “any meaningful exchange of utterances depends upon the prior existence of an agreed upon set of semantic and syntactic rules” (International Standards Organization 1987). In biomedical informatics, where the emphasis is on collection, manipulation, and transmission of information, standards are essential and their importance is widely recognized by clinicians and policy makers. Requirements for implementation of interoperability standards have been written into laws and regulations. Over the past 2 years, the bipartisan 21st Century Cures Act<sup>3</sup> (Hudson and Collins 2017) has codified many standards into everyday use. At present, the standards scene is evolving so rapidly that any description is inevitably outdated within a few months. This chapter

requiring that the wheels of chariots—and all subsequent carriages—be the right distance apart to drive in the ruts. When carriage makers were called on to develop railway rolling stock, they continued to use the same axle standard.

2 Interestingly, medical informaticians were responsible for the second ANSI standard language: MUMPS (now known as M).

3 ► [https://en.wikipedia.org/wiki/21st\\_Century\\_Cures\\_Act](https://en.wikipedia.org/wiki/21st_Century_Cures_Act) (accessed 12/2/19)

emphasizes the need for standards in general, standards development processes, current active areas of standards development, and key participating organizations that are making progress in the development of usable standards.

## 7.2 The Need for Health Informatics Standards

---

Standards are generally required when excessive diversity creates inefficiencies or impedes effectiveness. The healthcare environment has traditionally consisted of a set of loosely connected, organizationally independent units. Patients receive care across primary, secondary, and tertiary care settings, with little bidirectional communication and coordination among the services. Patients are cared for by one or more primary physicians, as well as by specialists. There is little coordination and sharing of data between inpatient care and outpatient care. Both the system and patients, by choice, create this diversity in care. Within the inpatient setting, the clinical environment is divided into clinical specialties that frequently treat the patient without regard to what other specialties have done.

Ancillary departments function as detached units, performing their tasks as separate service units, reporting results without follow-up about how those results are used or whether they are even seen by the ordering physician. Reimbursement requires patient information that is often derived through a totally separate process, based on the fragmented data collected in the patient's medical record and abstracted specifically for billing purposes. The resulting set of diagnosis and procedure codes often correlates poorly with the patient's original information (Jollis et al. 1993). With the transition of the US healthcare system from a fee for service payment model to a value-based care model, the need to share information between healthcare providers and their IT systems in order to coordinate care becomes even more crucial.

### 7.2.1 Early Standards to Support the Use of IT in Health Care

---

Early interest in the development of standards was driven by the need to exchange data between clinical laboratories and clinical systems, and then between independent units within a hospital. Therefore, the first standards were for data exchange and were referred to as messaging standards. Early systems were developed within independent service units, functional applications such as ADT (admission-discharge-transfer) and billing, and within primary care and specialty units. The first uses of computers in hospitals were for billing and accounting purposes and were developed on large, monolithic mainframe computers. Initially the cost of computers restricted expansion into clinical areas. But in the 1960s, hospital information systems (HISs) were developed to support service operations within a hospital. These systems followed a pattern of diversity similar to that seen in the health care system itself.

As new functions were added in the 1970s, they were implemented on mainframe computers and were managed by a data processing staff that usually was independent of the clinical and even of the administrative staff. The advent of the minicomputer supported the development of departmental systems, such as those for the clinical laboratory, radiology department, or pharmacy. With the advent of minicomputers, departmental systems were introduced but connectivity to other parts of the hospital was either by paper or independent electronic systems. It was common to see two terminals sitting side-by-side with an operator typing data from one system to another. Clinical systems, as they developed, continued to focus on dedicated departmental operations and clinical-specialty systems and thus did not permit the practicing physician to see a unified view of the patient. Most HISs were either supported entirely by a single vendor or were still functionally independent and unconnected.

In the 1980s, the need to move laboratory data directly into developing electronic health

records systems (although this term was not used then), early standards were created in ASTM (formerly, the American Society for Testing and Materials, see ► Sect. 8.3.2) for the transfer of laboratory data from local and commercial laboratories (American Society for Testing and Materials 1999). In the late 1980s, Simborg and others developed an HIS by interfacing independent systems using a “Best of Breed” approach to create an integrated HIS (Simborg et al. 1983). Unfortunately, the cost of developing and maintaining those interfaces was prohibitive, and the need for a broader set of standards was realized. This effort resulted in the creation of the **standards developing organization (SDO) Health Level Seven (HL7)** in 1987. Other SDOs were created in this same time frame: EDIFACT by the United Nations and ASC X12N by ANSI to address standards for claims and billing, IEEE for device standards, ACR/NEMA (later DICOM) for imaging standards, and NCPDP for prescription standards. Internationally, the 1990s saw the creation of the European Normalization Committee (CEN) and ISO Technical Committee 215 for Health Informatics (TC251). These organizations are described in more detail in ► Sect. 8.3.2.

### 7.2.2 Transitioning Standards to Meet Present Needs

Early standards were usually applied within a single unit or department in which the standards addressed mainly local requirements. Even then, data acquired locally came from another source introducing the need for additional standards. These many pressures caused health care information systems to change the status quo such that data collected for a primary purpose could be reused in a multitude of ways. Newer models for health care delivery, such as integrated delivery networks, health maintenance organizations (HMOs), preferred provider organizations (PPOs), and now accountable care organizations (ACOs) have increased the need for coordinated, integrated, and consolidated information (see ► Chap. 15), even though the information comes from disparate departments and

institutions. Various management techniques, such as continuous quality improvement and case management, require up-to-date, accurate abstracts of patient data. Post hoc analyses for clinical and outcomes research require comprehensive summaries across patient populations. Advanced tools, such as clinical workstations (► Chap. 5) and decision-support systems (► Chap. 3), require ways to translate raw patient data into generic forms for tasks as simple as summary reporting and as complex as automated medical diagnosis. All these needs must be met in the existing setting of diverse, interconnected information systems—an environment that cries out for implementation of standards.

One obvious need is for standardized identifiers for individuals, health care providers, health plans, and employers so that such participants can be recognized across systems. Choosing such an identifier is much more complicated than simply deciding how many digits the identifier should have. Ideal attributes for these sets of identifiers have been described in a publication from the ASTM (1999). The identifier must include a check digit to ensure accuracy when the identifier is entered by a human being into a system. A standardized solution must also determine mechanisms for issuing identifiers to individuals, facilities, and organizations; for maintaining databases of identifying information; and for authorizing access to such information (also see ► Chap. 5).

The Centers for Medicare and Medicaid Services (CMS), has defined a National Provider Identifier (NPI) as a national standard. This number is a seven-character alphanumeric base identifier plus a one-character check digit. No meaning is built into the number, each number is unique, it is never reissued, and alpha characters that might be confused with numeric characters have been eliminated (e.g., 0, 1, 2, 4, and 5 can be confused with O, I or L, Z, Y, and S). CMS was tasked to define a Payer ID for identifying health care plans. The Internal Revenue Service’s employer identification number has been adopted as the Employer Identifier.

The most controversial issue is identifying each individual or patient. Many people

consider assignment and use of such a number to be an invasion of privacy and are concerned that it could be easily linked to other databases. Public Law 104–191, passed in August 1996 (see ► Sect. 8.3.2), required that Congress formally define suitable identifiers. Pushback by privacy advocates and negative publicity in the media resulted in Congress declaring that this issue would not be moved forward until privacy legislation was in place and implemented (see ► Chap. 14). The Department of Health and Human Services has recommended the identifiers discussed above, except for the person identifier. This problem has still not been resolved, although the momentum for creating such a unique personal identifier seems to be increasing. A work-around non-solution is algorithmic patient matching based on electronic health record (EHR) data. The United States is one of the few developed countries without such an identifier Stead et al. 2005).

### 7.2.3 Settings Where Standards Are Needed

---

The patient care process, which can be varied and complicated, also include numerous processes that can be improved with standardization. A hospital admissions system records that a patient has the diagnosis of diabetes mellitus, a pharmacy system records that the patient has been given gentamicin, a laboratory system records that the patient had certain results on kidney function tests, and a radiology system records that a doctor has ordered an X-ray examination for the patient that requires intravenous iodine dye. Other systems need ways to store these data, to present the data to clinical users, to send warnings about possible drug-drug interactions, to recommend dosage changes, and to follow the patient's outcome. A standard for coding patient data is nontrivial when one considers the need for agreed-on definitions, use of qualifiers, differing (application-specific) levels of granularity in the data, and synonymy, not to mention the breadth and depth that such a standard would need to have.

The inclusion of medical knowledge in clinical systems is becoming increasingly important and commonplace. Sometimes, the knowledge is in the form of simple facts such as the maximum safe dose of a medication or the normal range of results for a laboratory test. Much medical knowledge is more complex, however. It is challenging to encode such knowledge in ways that computer systems can use (see ► Chap. 26), especially if one needs to avoid ambiguity and to express logical relations consistently. Thus the encoding of clinical knowledge using an accepted standard would allow many people and institutions to share the work done by others. One standard designed for this purpose is the Arden Syntax, discussed in ► Chap. 3, as well as the HL7 standard Clinical Quality Language (Odigie et al. 2019).

Because the tasks we have described require coordination of systems, methods are needed for transferring information from one system to another. Such transfers were traditionally accomplished through custom-tailored point-to-point interfaces, but this technique has become unworkable as the number of systems and the resulting permutations of necessary connections have grown. A current approach to solving the multiple-interface problem is through the development of messaging standards. Such messages must depend on the preexistence of standards for patient identification and data encoding.

Over the past decade, non-healthcare domains such as travel, package delivery and e-commerce have adopted, implemented and published standard application programming interfaces (APIs) in order to streamline their business processes and improve efficiency. The adoption of open APIs especially the HL7 Fast Healthcare Interoperability Resources (FHIR<sup>®</sup>) has increased dramatically and cited proposed regulations as an enabler of improved data sharing (Braunstein 2018).

Data sharing has become an expected functionality for any health IT system. Many of the new initiatives in health require data sharing. Data sharing is essential not only for patient care, but for aggregating data across multiple sites for research. Security must also

be addressed before such exchanges can be allowed to take place. Before a system can divulge patient information, it must ensure that requesters are who they say they are and that they are permitted access to the requested information (see ► Chap. 5). Standards exist for this functionality. Although each clinical system can have its own security features, system builders would rather draw on available standards and avoid reinventing the wheel. Besides, the secure exchange of information requires that interacting systems use standard technologies. Electronic Health Record systems (EHRs) are increasingly adopting standard authorization (OAuth2) and identification (OpenID) by implementing **Substitutable Medical Applications Reusable Technology (SMART)** on FHIR which allows platform independent applications to be launched within the EHR workflow and utilize EHR data via FHIR (Payne et al. 2015).

### 7.3 Standards Undertakings and Organizations

It is helpful to separate our discussion of the general process by which standards are created from our discussion of the specific organizations and the standards that they produce. The process is relatively constant, whereas the organizations form, evolve, merge, and are disbanded. This section will discuss how standards are created then identify the many SDOs and an overview of the types of standards they create. This section will also identify other groups and organizations that contribute or relate to standards activities.

#### 7.3.1 The Standards Development Process

The process of creating standards is biased and highly competitive. Most standards are created by volunteers who represent multiple, disparate stakeholders. They are influenced by direct or indirect self-interest rather than judgment about what is best or required. The process is generally slow and inefficient; multiple international groups create competitive

standards; and new groups continue to be formed as they become aware of the need for standards and do not look to see what standards exist. Yet, the process of creating standards largely works, and effective standards are created.

There are four ways in which a standard can be produced:

1. **Ad hoc method:** A group of interested people and organizations (e.g., laboratory-system and hospital-system vendors) agree on a standard specification. These specifications are informal and are accepted as standards through mutual agreement of the participating groups. A standard example produced by this method is the DICOM standard for medical imaging.
2. **De facto method:** A single vendor controls a large enough portion of the market to make its product the market standard. An example is Microsoft's Windows. A more recent example are the **Argonaut Implementation Guides**.<sup>4</sup> In this case, a collaborative of vendors and academic health systems are creating consensus standards for their requirements.
3. **Government-mandate method:** A government agency, such as CMS or the National Institute for Standards and Technology (NIST) creates a standard and legislates its use. An example is the HIPAA standard. Another example is the **Consolidated Clinical Data Architecture (CCDA)**,<sup>5</sup> a standard that resulted from the US Government's creating a set of requirements and driving a standard to meet those requirements.
4. **Consensus method:** A group of volunteers representing interested parties works in an open process to create a standard. Most health care standards are produced by this method. An example is the Health Level 7 (HL7) standard for clinical-data interchange (► Fig. 7.1).

4 ► <http://fhir.org/guides/argonaut/> (accessed 12/2/19)

5 ► <https://www.healthit.gov/topic/standards-technology/consolidated-cda-overview> (accessed 12/2/19)

**Fig. 7.1** Standards development meetings. The development of effective standards often requires the efforts of dedicated volunteers, working over many years. Work is often done in small committee meetings and then presented to a large group to achieve consensus. Here we see meetings of the HL7. Vocabulary Technical Committee (*top*) and an HL7 plenary meeting (*bottom*). See ▶ Sect. 8.5.2 for a discussion on HL7; Photo courtesy of Ken Rubin Photography

The process of creating a standard proceeds through several stages (Libicki 1995). It begins with an identification stage, during which someone becomes aware that there exists a need for a standard in some area and that technology has reached a level that can support such a standard. For example, suppose there are several laboratory systems sending data to several central hospital systems—a standard message format would allow each laboratory system to talk to all the hospital systems without specific point-to-point interface programs being developed for each possible laboratory-to-laboratory or laboratory-to-hospital combination. If the time for a standard is ripe, then several individuals can be identified and organized to help with the conceptualization stage, in which the characteristics of the standard are defined. What must the standard do? What is the scope of the standard? What will

be its format? In the early years of standards development, this approach led the development of standards, and the process was supported by vendors and providers.

As those early standards have become successful, the need for “gap-standards” has arisen. These gap-standards have no champion but are necessary for completeness of an interoperable data exchange network. The need for these standards is not as obvious as for the primary standards, people are less likely to volunteer to do work, putting stress on the voluntary approach. In such cases, the need of such standards must be sold to the volunteers or developed by paid professionals.

Let us consider, for purposes of illustration, how a standard might be developed for sending laboratory data in electronic form from one computer system to another in the form of a message. The volunteers for the development might include laboratory system vendors, clinical users, and consultants. One key discussion would be on the scope of the standard. Should the standard deal only with the exchange of laboratory data, or should the scope be expanded to include other types of data exchange? Should the data elements being exchanged be sent with a XML tag identifying the data element, or should the data be defined positionally? In the ensuing discussion stage, the participants will begin to create an outline that defines content, identifies critical issues, and produces a timeline. In the discussion, the pros and cons of the various concepts are discussed. What will be the specific form for the standard? For example, will it be message based or document based? Will the data exchange be based on a query or on a trigger event? Will the standard define the message content, the message syntax, the terminology, the network protocol, or a subset of these issues? How will a data model or information model be incorporated?

The participants are generally well informed in the domain of the standard, so they appreciate the needs and problems that the standard must address. Basic concepts are usually topics for heated discussion; subsequent details may follow at an accelerated pace. Many of the participants will have experience in solving problems to be addressed

by the standard and will protect their own approaches. The meanings of words are often debated. Compromises and loosely defined terms are often accepted to permit the process to move forward. For example, the likely participants would be vendors of competing laboratory systems and vendors of competing HISs. All participants would be familiar with the general problems but would have their own proprietary approach to solving them. Definitions of basic concepts normally taken for granted, such as what constitutes a test or a result, would need to be clearly stated and agreed on.

The writing of the draft standard is usually the work of a few dedicated individuals—typically people who represent the vendors in the field. Other people then review that draft; controversial points are discussed in detail and solutions are proposed and finally accepted. Writing and refining the standard is further complicated by the introduction of people new to the process who have not been privy to the original discussions and who want to revisit points that have been resolved earlier.

The balance between moving forward and being open is a delicate one. Most standards-writing groups have adopted an **open standards development policy**: Anyone can join the process and can be heard. Most standards development organizations—certainly those by accredited groups—support an open balloting process. A draft standard is made available to all interested parties, inviting comments and recommendations. All comments are considered. Negative ballots must be addressed specifically. If the negative comments are persuasive, the standard is modified. If they are not, the issues are discussed with the submitter in an attempt to convince the person to remove the negative ballot. If neither of these efforts is successful, the comments are sent to the entire balloting group to see whether the group is persuaded to change its vote. The resulting vote then determines the content of the standard. Issues might be general, such as deciding what types of laboratory data to include (pathology? blood bank?), or specific, such as deciding the specific meanings of spe-

cific fields (do we include the time the test was ordered? specimen drawn? test performed?).

A standard will generally go through several versions on its path to maturity. The first attempts at implementation are frequently met with frustration as participating vendors interpret the standard differently and as areas not addressed by the standard are encountered. These problems may be dealt with in subsequent versions of the standard. Backward compatibility is a major concern as the standard evolves. How can the standard evolve, over time, and still be economically responsible to both vendors and users? An implementation guide is usually produced to help new vendors profit from the experience of the early implementers.

Connectathons have become increasingly important in the standards development. In the past, standards development and standards implementation have been generally separated. Today, standards are tested during one or two day connectathons where implementers bring client and server applications to test against one another. The successes reinforce the validity of the standard while failures identify gaps and errors which need to be addressed.

A critical stage in the life of a standard is early implementation, when acceptance and rate of implementation are important to success. This process is influenced by accredited standards bodies, by the federal government, by major vendors, and the marketplace. The maintenance and promulgation of the standard are also important to ensure widespread availability and continued value of the standard. Some form of conformance testing is ultimately necessary to ensure that vendors adhere to the standard and to protect its integrity.

Producing a standard is an expensive process in terms of both time and money. Vendors and users must be willing to support the many hours of work, usually on company time; the travel expense; and the costs of documentation and distribution. In the United States, the production of a consensus standard is voluntary, in contrast to in Europe and elsewhere, where most standards development

is funded by governments. In the US, a new model for funding standards development work has emerged. The **Da Vinci Project**<sup>6</sup> and the **CARIN Alliance**<sup>7</sup> are two collaboratives funded by payers and technology vendors to address interoperability needs between patients, providers and payers. These group share the cost of standards development and benefit from the accelerated pace.

An important aspect of standards is conformance, a concept that covers compliance with the standard and also usually includes specific agreements among users of the standard who affirm that specific rules will be followed. A conformance document identifies specifically what data elements will be sent, when, and in what form. Even with a perfect standard, a conformance document is necessary to define business relationships between two or more partners. Unlike past standards, recent standards have built conformance testing directly into the standard artifacts which are not only human readable documents but also machine readable.

The creation of the standard is only the first step. Ideally the first standard would be a **Standard for Trial Use (STU)**, and two or more vendors would implement and test the standard to identify problems and issues. Those items would be corrected, and in a short period of time (usually 1 year), the standards would be advanced to a normative stage. A normative standard specifies to what implementers must conform. Even then, the process is only beginning. Implementation that conforms to the standard is essential if the true value of the standard is to be realized. The use of most standards is enhanced by a certification process in which a neutral body certifies that a vendor's product, in fact, does comply and conform to the standard.

There is currently no body that certifies conformance of specific standards from a ven-

dor. There is, however, the certification of an application that uses standards. In 2010, the Office of the National Coordinator (ONC)<sup>8</sup> engaged with the CCHIT to certify EHR products. That certification process evolved in 2011 to include eight groups that could certify EHR products, and to date over 500 EHR products have been certified. The certification process is still undergoing change.

### 7.3.2 Data Standards Organizations

Sometimes, standards are developed by organizations that need the standard to carry out their principal functions; in other cases, coalitions are formed for the express purpose of developing a particular standard. The latter organizations are discussed later, when we examine the particular standards developed in this way. There are also standards organizations that exist for the sole purpose of fostering and promulgating standards. In some cases, they include a membership with expertise in the area where the standard is needed. In other cases, the organization provides the rules and framework for standard development but does not offer the expertise needed to make specific decisions for specific standards, relying instead on participation by knowledgeable experts when a new standard is being studied.

This section describes several of the best known and most influential health-related SDOs. Since most standards continue to evolve to accommodate changes in technology, policy, regulations, and requirements, links are provided to selected standards and SDO information. For a detailed understanding of an organization or the standards it has developed, you will need to refer to current primary resources. Many of the organizations maintain Web sites with excellent current information on their status.

### 7.3.2.1 American National Standards Institute

ANSI is a private, nonprofit membership organization founded in 1918. It originally served to coordinate the U.S. voluntary census standards systems. Today, it is responsible for approving official American National Standards. ANSI membership includes over 1100 companies; 30 government agencies; and 250 professional, technical, trade, labor, and consumer organizations.

ANSI does not write standards; rather, it assists standards developers and users from the private sector and from government to reach consensus on the need for standards. It helps them to avoid duplication of work, and it provides a forum for resolution of differences. ANSI administers the only government-recognized system for establishing American National Standards. ANSI also represents U.S. interests in international standardization. ANSI is the U.S. voting representative in the ISO and the International Electrotechnical Commission (IEC). There are three routes for a standards development body to become ANSI approved so as to produce an American National Standard: Accredited Organization; Accredited Standards Committee (ASCs); and Accredited Canvass.

An organization that has existing organizational structure and procedures for standards development may be directly accredited by ANSI to publish American National Standards, provided that it can meet the requirements for due process, openness, and consensus. HL7 (discussed in ► Sect. 8.5.2) is an example of an ANSI Accredited Organization.

#### 7.3.2.2 ASC X12

ANSI may also create internal ASCs to meet a need not filled by an existing Accredited Organization. ASC X12 is an example of such a committee.

The final route, Accredited Canvass, is available when an organization does not have the formal structure required by ANSI. Through a canvass method that meets the criterion of balanced representation of all interested parties, a standard may be

approved as an American National Standard. X12 develops transaction sets that transcend across a broad range of business domains.

Link to transaction sets: ► <http://www.x12.org/x12-work-products/x12-transaction-sets.cfm>

Link to EDI standards: ► <http://www.x12.org/x12-work-products/x12-edi-standards.cfm>

### 7.3.2.3 ASTM International

ASTM (formerly known as the American Society for Testing and Materials) develops standard test methods for materials, products, systems, and services. ASTM is the largest non-government of standards in the US. ASTM Committee E31 on Computerized Systems is responsible for the development of the medical information standards. The scope of this committee is the promotion of knowledge and development of standard classifications, guides, specifications, practices, and terminology for the architecture, content, storage and communication of information used within healthcare, including patient-specific information and medical knowledge. Standard also address policies for integrity and confidentiality and computer procedures that support the uses of data and healthcare decision making.

Link to E31 Standards: ► <https://www.astm.org/COMMITTEE/E31.htm>

### 7.3.2.4 Clinical Data Interchange Standards (CDISC)

CDISC creates standards in support of the clinical research community. Its membership includes pharma, academic researchers, vendors and others. CDISC was created in 2000 in order to facilitate electronic regulatory submission of clinical trial data. The current standards include a study data model, a data analysis model, a lab data model and an operational data model that supports audit trails and **metadata**. In 2007, CDISC began a collaborative project with HL7, the National Institutes of Health and the US FDA to link research data with data derived from clinical care. This modeling effort, BRIDG

(Biomedical Research Integrated Domain Group; Becnel et al. 2017), has created a domain analysis model of clinical research.

Link to BRIDG: ► <http://www.hl7.org/Special/committees/bridg/index.cfm>

### 7.3.2.5 Digital Imaging and Communications in Medicine (DICOM)

DICOM was created through a joint effort by the American College of Radiology and National Electrical Manufacturers Association (NEMA) to develop standards for imaging and waveforms. The DICOM standard has been developed with an emphasis on diagnostic medical imaging as practiced in radiology, cardiology, pathology, dentistry, ophthalmology and related disciplines, and image-based therapies such as interventional radiology, radiotherapy and surgery.

Link to standard: ► [www.dicomstandard.org/current](http://www.dicomstandard.org/current)

Link to history: ► [www.dicomstandard.org/history/](http://www.dicomstandard.org/history/)

### 7.3.2.6 European Committee for Standardization Technical Committee 251

The European Committee for Standardization (CEN) established, in 1991, Technical Committee 251 (TC 251—not to be confused with ISO TC 215 described below) for the development of standards for health care informatics. The major goal of TC 251 is to develop standards for communication among independent medical information systems so that clinical and management data produced by one system could be transmitted to another system. The organization of TC 251 parallels efforts in the United States through various working groups. These groups similarly deal with data interchange standard, medical record standards, code and terminology standards, imaging standards, and security, privacy and confidentiality.

CEN has made major contributions to data standards in health care. One important CEN pre-standard ENV 13606 on the electronic health record (EHR) is being advanced by CEN as well as significant input from Australia and the OpenEHR Foundation. There is an increasing cooperation among the CEN participants and several of the U.S. standards bodies.

Link: ► <http://www.ehealth-standards.eu/>

Link to projects: ► <http://www.ehealth-standards.eu/en/projects/>

### 7.3.2.7 GS1

GS1 (for “Global Standard 1”) is a global standards organization that develops and maintains global standards for business communication. With over 1.5 million members worldwide, it has a presence in over 100 countries. Its primary standards relate to the supply chain and for assigning object identifiers and standards for barcodes. GS1 standards are designed to improve the efficiency, safety and visibility of supply chains across physical and digital channels in 25 sectors. They form a business language that identifies, captures and shares key information about products, locations, assets and more.

Link: ► [www.gs1.org](http://www.gs1.org)

### 7.3.2.8 Health Level Seven International (HL7)

Health Level 7 was founded as an ad hoc standards group in March 1987 to create standards for the exchange of clinical data, adopting the name “HL7” to reflect the application (seventh) level of the OSI reference model. The primary motivation was the creation of a Hospital Information System from “Best of Breed” components. The HL7 data interchange standard (version 2.n series) reduced the cost of interfacing between disparate systems to an affordable cost. Today HL7 is one of the premier SDOs in the world. It has become an international standards body with approximately 40 Affiliates, over 500 organizational members and over 2200 individual members. HL7 is ANSI accredited, and many of the HL7 standards are required by the

U.S. government as part of the certification requirements of Meaningful Use.

### 7.3.2.9 Institute of Electrical and Electronic Engineering (IEEE)

IEEE is an international SDO organization that is a member of both ANSI and ISO. Through IEEE, many of the world's standards in telecommunications, electronics, electrical applications, and computers have been developed.

IEEE 1073, Standard for Medical Device Communications, has produced a family of documents that defines the entire seven-layer communications requirements for the **Medical Information Bus** (MIB; Gottschalk 1991). The MIB is a robust, reliable communication service designed for bedside devices in the intensive care unit, operating room, and emergency room. These standards have been harmonized with work in CEN, and the results are released as ISO standards. IEEE and HL7 have collaborated on several key standards, including those for mobile medical devices.

Link: ► [www.ieee.org](http://www.ieee.org)

Link to standards: ► <https://standards.ieee.org/standard/index.html>

### 7.3.2.10 ISO Technical Committee 215—Health Informatics

In 1989, interests in the European Committee for Standardization (CEN) and the United States led to the creation of Technical Committee (TC) 215 for Health Information within ISO.

TC 215 meets once in a year as a TC and once as a Joint Working Group. TC 215 follows rather rigid procedures to create ISO standards. Thirty-five countries are active participants in the TC with another 23 countries acting as observers. While the actual work is done in the working groups, the balloting process is very formalized—one vote for each

participating country. For most work, there are a defined series of steps, beginning with a New Work Item Proposal and getting five countries to participate; a Working Document, a Committee Document; a Draft International Standard, a Final Draft International Standard (FDIS); and finally an International Standard. This process, if fully followed, takes several years to produce an International Standard. Under certain conditions, a fast track to FDIS is permitted. Technical Reports and Technical Specifications are also permitted.

The United States has been assigned the duties of Secretariat, and that function is carried out, at this time, by ANSI. ANSI also serves as the U.S. Technical Advisory Group Administrator, which represents the U.S. position in ISO.

Link: ► <https://www.iso.org/standards.html>

### 7.3.2.11 Integrating the Healthcare Enterprise

The goal of the Integrating the Healthcare Enterprise (IHE) initiative is to stimulate integration of healthcare information resources. IHE is sponsored jointly by the Radiological Society of North America (RSNA) and the HIMSS. Using established standards and working with direction from medical and information technology professionals, industry leaders in healthcare information and imaging systems cooperate under IHE to agree upon implementation profiles for the transactions used to communicate images and patient data within the enterprise. Their incentive for participation is the opportunity to demonstrate that their systems can operate efficiently in standards-based, multi-vendor environments with the functionality of real HISs. Moreover, IHE enables vendors to direct product development resources toward building increased functionality rather than redundant interfaces.

Link to IHE domains: ► [https://www.ihe.net/ihe\\_domains/](https://www.ihe.net/ihe_domains/)

### 7.3.2.12 National Council for Prescription Drug Program (NCPDP)

NCPDP is a not-for-profit, multi-stakeholder forum for developing and promoting industry standards and business solutions that improve patient safety and health outcomes, while also decreasing costs. NCPDP is an ANSI accredited SDO and uses a consensus-building process to create national standards for real-time, electronic exchange of healthcare information. Their primary focus is on information exchange for prescribing, dispensing, monitoring, managing and paying for medications and pharmacy services crucial to quality healthcare.

Link: ► [www.ncdp.org/home](http://www.ncdp.org/home)

Link to standards: ► [www.ncdp.org/standards-Development](http://www.ncdp.org/standards-Development)

### 7.3.2.13 OpenEHR

OpenEHR is the name of a technology for e-health, consisting of open specifications, clinical models and software that can be used to create standards and build information and interoperability solutions for healthcare. The various artefacts of openEHR are produced by the openEHR community and managed by the openEHR Foundation, an international non-profit organization established in the year 2003.

Link to Specification Program: ► [openehr.org/programs/specification](http://openehr.org/programs/specification)

### 7.3.2.14 Personal Connected Health Alliance (PCHA)

The PCHA publishes the Continua Design Guidelines to enable a flexible implementation framework for end-to-end interoperability of personal connected health devices and systems. These Guidelines are recognized by the International Telecommunications Union (ITU) as the international standard for safe,

secure and reliable exchange of data to and from personal health devices.

Link to guidelines: ► [www.pchalliance.org/continua-design-guidelines](http://www.pchalliance.org/continua-design-guidelines)

### 7.3.2.15 SNOMED International

SNOMED International (previously called IHTSDO) was founded in 2007 with nine charter members. Currently 19 countries, including the United States, are members. The primary purpose of IHTSDO is the continued development and maintenance of the Systematized Nomenclature of Medicine – Clinical Terms (SNOMED-CT; see ► Sect. 7.4.4.4, below). Member countries make SNOMED-CT freely available to its citizens. SNOMED has a number of Special Interest Groups: Anesthesia, Concept Model, Education, Implementation, International Pathology & Laboratory Medicine, Mapping, Nursing, Pharmacy, and Translation.

Link: ► <http://www.snomed.org/>

### 7.3.2.16 OHDSI

The Observational Health Data Sciences and Informatics (OHDSI) program is a multi-stakeholder, interdisciplinary open-source collaborative to leverage the value of health data through large-scale analytics. OHDSI has established an international network of researchers and observational health databases. OHDSI enables active engagement across multiple disciplines, including clinical medicine, biostatistics, computer science, epidemiology, and life sciences (■ Fig. 7.2).

## 7.4 Detailed Clinical Models, Coded Terminologies, Nomenclatures, and Ontologies

The capture, storage, and use of clinical data in computer systems is complicated by lack of agreement on terms and meanings. In recent years there has also been a growing recognition that just standardizing the terms and codes used in medicine is not sufficient to enable interoperability. The structure or form

# Extensive vocabularies

**Fig. 7.2** Extensive International Vocabularies, George Hripcsak, MD (by permission). A critical challenge to data analytics across international domains

continues to be the requirement for integrating data sources among multiple vocabularies. (Photo courtesy of George Hripcsak, MD, with permission)

of medical data provides important context for computable understanding of the data. Terms and codes need to be interpreted in the context of clinical information models. The many terminologies and detailed clinical modeling activities discussed in this section have been developed to ease the communication of coded medical information.

## 7.4.1 Motivation for Structured and Coded Data

The structuring and encoding of medical information is a basic function of most clinical systems. Standards for such structuring and encoding can serve two purposes. First, they can save system developers from reinventing the wheel. For example, if an application allows caregivers to compile problem lists about their patients, using a standard structure and terminology saves developers from having

to create their own. Second, using commonly accepted standards can facilitate exchange of data, applications, and clinical decision support logic among systems. For example, if a central database is accepting clinical data from many sources, the task is greatly simplified if each source is using the same logical data structure and coding scheme to represent the data. System developers often ignore available standards and continue to develop their own solutions. It is easy to believe that the developers have resisted adoption of standards because it is too much work to understand and adapt to any system that was “not invented here.” The reality, however, is that the available standards are often inadequate for the needs of the users (in this case, system developers). As a result, no standard terminology enjoys the wide acceptance sufficient to facilitate the second function: exchange of coded clinical information.

The need for detailed clinical models is directly related to the second goal dis-

cussed above, that of creating interoperability between systems. The subtle relationship between terminologies and models is best understood using a couple of examples. If a physician wants to record the idea that a patient had “chest pain that radiates to the back”, the following coded terms could be used from SNOMED-CT.

### 7.4.2 Detailed Clinical Models

The creation of unambiguous data representation is a combination of creating appropriate structures (models) for representing the form of the data and then linking or “binding” specific sets of codes to the coded elements in the structures. Several modeling languages or formalisms have been found to be useful in describing the structure of the data. They include:

- UML – the Unified Modeling Language, Object Management Group
- ADL – Archetype Definition Language, OpenEHR Foundation
- CDL – Constraint Definition Language, General Electric and Intermountain Health care
- MIF – Model Interchange Format, Health Level Seven International Inc.
- OWL – Web Ontology Language, World Wide Web Consortium

All languages used for clinical modeling need to accomplish at least two major things: they need to show the “logical” structure of the data, and they need to show how sets of codes from standard terminologies participate in the logical structure. Defining the logical structure is simply showing how the named parts of a model relate to one another. Model elements can be contained in other elements, creating hierarchies of elements. It is also important to specify which elements of the model can occur more than once (cardinality), which elements are required, and which are optional. Terminology binding is the act of creating connections between the elements in a model and concepts in a coded terminology. For each coded element in a model, the set of allowed values for the coded element

are specified. The HL7 Vocabulary Working Group has created a comprehensive discussion of how value sets can be defined and used with information models.

There are many clinical information modeling activities worldwide. Some of the most important activities are briefly listed below.

- HL7 Activities
  - HL7 Detailed Clinical Models – This group has developed a method for specifying clinical models based on the HL7 Reference Information Model (RIM) that guarantees that data that conforms to the model could be sent in HL7 Version 3 messages.
  - HL7 Clinical Document Architecture (CDA) Templates – This group has defined a standard way of specifying the structure of data to be sent in XML documents that conform to the CDA standard.
  - HL7 TermInfo – This Workgroup of HL7 has specified a set of guidelines for how SNOMED-CT codes and concepts should be used in conjunction with the HL7 RIM to represent data sent in HL7 Version 3 messages.
  - HL7 Clinical Information Modeling Initiative – A formerly independent group now organized as and HL7 Workgroup is chartered to develop implementable clinical information models.
- The openEHR Foundation is developing models based on a core reference model and the Archetype Definition Language. This approach has been adopted by several national health information programs.
- EN 13606 is developing models based on the ISO/CEN 13606 standard and core reference model.
- The US Veterans Administration (VA) is creating models for integrating data across all VA facilities and for integration with military hospitals that are part of the US Department of Defense. The modeling is done primarily using Unified Modeling Language.
- US Department of Defense is creating models for integrating data across all DoD facilities and for integration with VA

facilities. The modeling is done primarily using Unified Modeling Language.

- The National Health Service in the United Kingdom (UK) is developing the Logical Record Architecture to provide models for interoperability across all health care facilities in the UK. The modeling is done primarily using UML.
- Clinical Element Models – Intermountain Health care and General Electric have created a set of detailed clinical models using a core reference model and Constraint Definition Language. The models are free-for-use and are available for download from the Internet.
- SHARE Models – CDISC is creating models to integrate data collected as part of clinical trials.
- SMART Team – This group at Boston Children’s Hospital is defining standard application programming interfaces (APIs) for securely connecting with EHRs.
- Clinical Information Modeling Initiative (CIMI) – This is an international consortium that has the goal of establishing a free-for-use repository of detailed clinical models, where the models are expressed in a single common modeling language with explicit bindings to standard terminologies.
- OMOP – The OMOP Common Data Model enables the systematic analysis of disparate observational claims-based data. The initial approach was to transform data contained within claims databases into a common format (data model) as well as a common representation (terminologies, vocabularies, coding schemes). OMOP has been primarily used by the OHDSI community (see ► Sect. 7.3.2.16), but is being examined by other consortia seeking to share patient-level clinical information.

### 7.4.3 Vocabularies, Terminologies, and Nomenclatures

---

In discussing coding systems, the first step is to clarify the differences among a **terminology**, a **vocabulary**, and a **nomenclature**. These terms

are often used interchangeably by creators of coding systems and by authors discussing the subject. Fortunately, although there are few accepted standard terminologies, there is a generally accepted standard about terminology: ISO Standard 1087 (Terminology—Vocabulary).

Finally, we should consider the methods by which the terminology is maintained. Every standard terminology must have an ongoing maintenance process, or it will rapidly become obsolete. The process must be timely and must not be too disruptive to people using an older version of the terminology. For example, if the creators of the terminology choose to rename a code, what happens to the data previously recorded with that code?

### 7.4.4 Specific Terminologies

---

With these considerations in mind, let us survey some of the available controlled terminologies. There are introductory descriptions of a few current and common terminologies. New terminologies appear annually, and existing proprietary terminologies often become publicly available. When reviewing the following descriptions, try to keep in mind the background motivation for a development effort. All these standards are evolving rapidly, and one should consult the Web sites or other primary sources for the most recent information.

#### 7.4.4.1 International Classification of Diseases and Its Clinical Modifications

One of the most recognized terminologies is the International Classification of Diseases (ICD). First published in 1893, it has been revised at roughly 10-year intervals, first by the Statistical International Institute and later by the World Health Organization (WHO). The Ninth Edition (ICD-9) was published in 1977 (World Health Organization 1977) and the Tenth Edition (ICD-10) in 1992 (World Health Organization 1992). The ICD-9 coding system consists of a core classification of three-digit codes that are the minimum required for reporting mortality statistics to WHO. A fourth digit (in the first decimal

place) provides an additional level of detail; usually .0 to .7 are used for more specific forms of the core term, .8 is usually “other,” and .9 is “unspecified.” Codes in the ICD-10 coding system start with an alpha character and consist of three to seven characters. In both systems, terms are arranged in a strict hierarchy, based on the digits in the code. In addition to diseases, ICD includes several “families” of terms for medical-specialty diagnoses, health status, disease-related events, procedures, and reasons for contact with health care providers.

In June of 2018, the World Health Organization (WHO) replaced ICD-10 with ICD-11, with the intention to make a more comprehensive and computable version that could be maintained without the need for major version changes in the future. ICD-11 includes many new features, such as a semantic network, a polyhierarchy, a formal information model, and a set of “linearization” that constrain the terms in strict hierarchies, designed to support various functions (Chute (2018)). The US National Committee for Vital and Health Statistics (NCVHS) is currently considering the timing and method for transition to ICD-11, so close on the 2015 adoption of ICD-10.

#### 7.4.4.2 Current Procedural Terminology

The American Medical Association developed the Current Procedural Terminology (CPT) in 1966 (American Medical Association, updated annually) to provide a pre coordinated coding scheme for diagnostic and therapeutic procedures that has since been adopted in the United States for billing and reimbursement. Like the DRG codes, CPT codes specify information that differentiates the codes based on cost. For example, there are different codes for pacemaker insertions, depending on whether the leads are “epicardial, by thoracotomy” (33200), “epicardial, by xiphoid approach” (33201), “transvenous, atrial” (33206), “transvenous, ventricular” (33207), or “transvenous, atrioventricular (AV) sequential” (33208). CPT also provides information about the reasons for a procedure. For example, there are codes for arterial punctures for “withdrawal of blood for diagnosis” (36600), “monitoring” (36620), “infusion therapy” (36640), and “occlusion

therapy” (75894). Although limited in scope and depth (despite containing over 8000 terms), CPT-4 is the most widely accepted nomenclature in the United States for reporting physician procedures and services for federal and private insurance third-party reimbursement.

#### 7.4.4.3 Diagnostic and Statistical Manual of Mental Disorders

The American Psychiatric Association published the Fifth Edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) in May 2013 (American Psychiatric Association Committee on Nomenclature and Statistics (2013)). DSM-5 is the standard classification of mental disorders used by mental health professionals in the U.S. and contains a listing of diagnostic criteria for every psychiatric disorder recognized by the U.S. healthcare system.<sup>9</sup> The previous edition, DSM-IV, was originally published in 1994 and revised in 2000 as DSM-IV-TR. DSM-5 is coordinated with ICD-10.

#### 7.4.4.4 SNOMED Clinical Terms and Its Predecessors

Drawing from the New York Academy of Medicine’s Standard Nomenclature of Diseases and Operations (SNDO) (Plunkett 1952; Thompson and Hayden 1961; New York Academy of Medicine 1961), the College of American Pathologists (CAP) developed the Standard Nomenclature of Pathology (SNOP) as a multiaxial system for describing pathologic findings (College of American Pathologists 1971) through post-coordination of topographic (anatomic), morphologic, etiologic, and functional terms. SNOP has been used widely in pathology systems in the United States; its successor, the Systematized Nomenclature of Medicine (SNOMED) has evolved beyond an abstracting scheme to become a comprehensive coding system.

Largely the work of Roger Côté and David Rothwell, SNOMED was first published in 1975, was revised as SNOMED II in 1979, and then greatly expanded in 1993 as the

9 ► <https://www.psychiatry.org/psychiatrists/practice/dsm> (last accessed 12/2/2019)

Systematized Nomenclature of Human and Veterinary Medicine—SNOMED.

International (Côté and Rothwell 1993). Each of these versions was **multi-axial**; coding of patient information was accomplished through the post-coordination of terms from multiple axes to represent complex terms that did not exist as single codes in SNOMED. In 1996, SNOMED changed from a multi-axial structure to a more logic-based structure called a Reference Terminology (Campbell et al. 1998; Spackman et al. 1997a, 1997b), intended to support more sophisticated data encoding processes and resolve some of the problems with earlier versions of SNOMED (see ■ Fig. 7.2). In 1999, CAP and the NHS announced an agreement to merge their products into a single terminology called SNOMED Clinical Terms (SNOMED-CT) (Spackman 2000), containing terms for over 344,000 concepts (see ■ Fig. 7.3). SNOMED-CT is currently maintained by a not-for-profit association once called the International Health Terminology Standards Development Organization (IHTSDO), but now simply SNOMED International.

Despite the broad coverage of SNOMED-CT, it continues to allow users to create new, ad hoc terms through post-coordination of existing terms. While this increases the expressivity, users must be careful not to be too expressive because there are few rules about how the post-coordination coding should be done, the same expression might end up being represented differently by different coders. For example, “acute appendicitis” can be coded as a single disease term, as a combination of a modifier (“acute”) and a disease term (“appendicitis”), or as a combination of a modifier (“acute”), a morphology term (“inflammation”) and a topography term (“vermiform appendix”). Users must therefore be careful when post-coordinating terms, not to recreate a meaning that is satisfied by an already existing single code. SNOMED-CT’s description logic, such as the example in ■ Fig. 7.2, can help guide users when selecting modifiers.

Concept: Bacterial pneumonia

■ Fig. 7.3 Description-logic representation of the SNOMED-CT term “Bacterial Pneumonia.” The “Is a” attributes define bacterial pneumonia’s position in SNOMED-CT’s multiple hierarchy, while attributes such as “Causative Agent” and “Finding Site” provide definitional information. Other attributes such as “Onset” and “Severities” indicate ways in which bacterial pneumonia can be postcoordinated with other terms, such as “Acute Onset” or any of the descendants of the term “Severities.” “Descriptions” refers to various text strings that serve as names for the term, while “Legacy Codes” provide back-ward compatibility to SNOMED and Read Clinical Terms (NHS Centre for Coding and Classification (1994))

#### 7.4.4.5 GALEN

In Europe, a consortium of universities, agencies, and vendors, with funding from the Advanced Informatics in Medicine initiative (AIM), has formed the GALEN project

to develop standards for representing coded patient information (Rector et al. 1995). GALEN developed a reference model for medical concepts using a formalism called Structured Meta Knowledge (SMK) and a formal representation language called GALEN Representation and Integration Language (GRAIL). Using GRAIL, terms are defined through relationships to other terms, and grammars are provided to allow combinations of terms into sensible phrases. The reference model is intended to allow representation of patient information in a way that is independent of the language being recorded and of the data model used by an electronic medical record system. The GALEN developers are working closely with CEN TC 251 (see ► Sect. 8.3.2) to develop the content that will populate the reference model with actual terms.

#### 7.4.4.6 Logical Observations, Identifiers, Names, and Codes

An independent consortium, led by Clement J. McDonald and Stanley M. Huff, has created a naming system for tests and observations. The system is called Logical Observation Identifiers Names and Codes (LOINC).<sup>10</sup> The coding system contains names and codes for laboratory tests, patient measurements, assessment instruments, document and section names, and radiology exams. ■ Figure 7.4 shows some typical fully specified names for common laboratory tests. The standard specifies structured coded semantic information about each test, such as the substance measured and the analytical method used.

#### 7.4.4.7 Nursing Terminologies

Nursing organizations and research teams have been extremely active in the development of standard coding systems for documenting and evaluating nursing care. One review counted a total of 12 separate projects active worldwide (Coenen et al. 2001),

including coordination with SNOMED and LOINC. These projects have arisen because general medical terminologies fail to represent the kind of clinical concepts needed in nursing care. For example, the kinds of problems that appear in a physician's problem list (such as "myocardial infarction" and "diabetes mellitus") are relatively well represented in many of the terminologies that we have described, but the kinds of problems that appear in a nurse's assessment (such as "activity intolerance" and "knowledge deficit related to myocardial infarction") are not. Preeminent nursing terminologies include the North American Nursing Diagnosis Association (NANDA) codes, the Nursing Interventions Classification (NIC), the Nursing Outcomes Classification (NOC), the Georgetown Home Health Care Classification (HHCC), and the Omaha System (which covers problems, interventions, and outcomes).

Despite the proliferation of standards for nursing terminologies, gaps remain in the coverage of this domain (Park and Cho 2009). The International Council of Nurses and the International Medical Informatics Association Nursing Informatics Special Interest Group have worked together to produce the International Classification for Nursing Practice (ICNP®). This system uses a post-coordinated approach for describing nursing diagnoses, actions, and outcomes.

#### 7.4.4.8 Drug Codes

A variety of public and commercial terminologies have been developed to represent terms used for prescribing, dispensing and administering drugs. The WHO Drug Dictionary is an international classification of drugs that provides proprietary drug names used in different countries, as well as all active ingredients and the chemical substances, with Chemical Abstract numbers. Drugs are classified according to the Anatomical-Therapeutic-Chemical (ATC) classification, with cross-references to manufacturers and reference sources. The current dictionary contains 25,000 proprietary drug names, 15,000 single ingredient drugs, 10,000 multiple ingredient drugs, and 7000

10 5 ► [loinc.org](http://loinc.org) (accessed 5/30/19)

**Fig. 7.4** Examples of codes in SNOMED-CT, showing some of the hierarchical relationships among bacterial pneumonia terms. Tuberculosis terms and certain terms that are included in SNOMED-CT for compatibility with other terminologies are not shown. Note that some terms such as “Congenital group A hemolytic streptococcal pneumonia” appear under multiple parent terms, while other terms, such as “Congenital staphylococcal pneumonia” are not listed under all possible parent terms (e.g., it is under “Congenital pneumonia” but not under “Staphylococcal pneumonia”). Some terms, such as “Pneumonic plague” and “Mycoplasma pneumonia” are not classified under Bacterial Pneumonia, although the causative agents in their descriptions (“*Yersinia pestis*” and “*Mycoplasma pneumoniae*”, respectively) are classified under “Bacterium”, the causative agent of Bacterial pneumonia

## Pneumonia

### Bacterial pneumonia

- Proteus pneumonia
- Legionella pneumonia
- Anthrax pneumonia
- Actinomycotic pneumonia
- Nocardial pneumonia
- Meningococcal pneumonia
- Chlamydial pneumonia
  - Neonatal chlamydial pneumonia
  - Ornithosis
    - Ornithosis with complication
    - Ornithosis with pneumonia
- Congenital bacterial pneumonia
  - Congenital staphylococcal pneumonia
  - Congenital group A hemolytic streptococcal pneumonia
  - Congenital group B hemolytic streptococcal pneumonia
  - Congenital *Escherichia coli* pneumonia
  - Congenital pseudomonal pneumonia
- Chlamydial pneumonitis in all species except pig
  - Feline pneumonitis
- Staphylococcal pneumonia
- Pulmonary actinobacillosis
- Pneumonia in Q fever
- Pneumonia due to Streptococcus
  - Group B streptococcal pneumonia
  - Congenital group A hemolytic streptococcal pneumonia
  - Congenital group B hemolytic streptococcal pneumonia
- Pneumococcal pneumonia
  - Pneumococcal lobar pneumonia
  - AIDS with pneumococcal pneumonia
- Pneumonia due to Pseudomonas
  - Congenital pseudomonal pneumonia
- Pulmonary tularemia
- Enzootic pneumonia of calves

- Corynebacterial pneumonia of foals
- Pneumonia due to *Escherichia coli*
- Pneumonia due to *Proteus mirabilis*

chemical substances. The dictionary now covers drugs from 34 countries and grows at a rate of about 2000 new entries per year.

The National Drug Codes (NDC), produced by the U.S. Food and Drug Administration (FDA), is applied to all drug packages. It is widely used in the United States, but it is not as comprehensive as the WHO codes. The FDA designates part of the code based on drug manufacturer, and each manufacturer defines the specific codes for their own products. As a result, there is no uniform class hierarchy for the codes, and codes may be reused at the manufacturer's discretion. Due in part to the inadequacies of the NDC codes, pharmacy information systems typically purchase proprietary terminologies from knowledge base vendors. These terminologies map to NDC, but provide additional information about therapeutic classes, allergies, ingredients, and forms.

The need for standards for drug terminologies led to a collaboration between the FDA, the U.S. National Library of Medicine (NLM), the Veterans Administration (VA), and the pharmacy knowledge base vendors that has produced a representational model for drug terms called RxNorm. The NLM provides RxNorm to the public as part of the Unified Medical Language System (UMLS) (see below) to support mapping between NDC codes, the VA's National Drug File (VANDF) and various proprietary drug terminologies (Nelson et al. 2002). RxNorm currently contains 14,000 terms.

#### 7.4.4.9 Medical Subject Headings

The Medical Subject Headings (MeSH), maintained by the NLM (updated annually), is the terminology by which the world medical literature is indexed. MeSH arranges terms in a structure that breaks from the strict hierarchy used by most other coding schemes. Terms are organized into hierarchies and may appear in multiple places in the hierarchy (■ Fig. 7.5). Although it is not generally used as a direct coding scheme for patient information, it plays a central role in the UMLS.

#### 7.4.4.10 RadLex

RadLex is a terminology produced by the Radiology Society of North America (RSNA). With more than 30,000 terms, RadLex is intended to be a unified language of radiology terms for standardized indexing and retrieval of radiology information resources. RadLex includes the names of anatomic parts, radiology devices, imaging exams and procedure steps performed in radiology. Given the scope of the radiology domain, many RadLex terms overlap with SNOMED-CT, and LOINC.

#### 7.4.4.11 Bioinformatics Terminologies

For the most part, the terminologies discussed above fail to represent the levels of detail needed by biomolecular researchers. This has become a more acute problem with the advent of bioinformatics and the sequencing of organism genomes (see ► Chap. 11). As in other domains, researchers have been forced to develop their own terminologies. As these researchers have begun to exchange information, they have recognized the need for standard naming conventions as well as standard ways of representing their data with terminologies. Prominent efforts to unify naming systems include the Gene Ontology (GO) (Harris et al. 2004) from the Gene Ontology Consortium and the gene naming database of the HUGO Gene Nomenclature Committee (HGNC). A related resource is the RefSeq database of the National Center for Biotechnology Information (NCBI) which contains identifiers for reference sequences.

#### 7.4.4.12 Unified Medical Language System

In 1986, Donald Lindberg and Betsy Humphreys, at the NLM, began working with several academic centers to identify ways to construct a resource that would bring together and disseminate controlled medical terminologies. An experimental version of the UMLS was first published in 1989 (Humphreys 1990); the UMLS has been updated annually since then. Its principal component is the

■ **Fig. 7.5** Examples of common laboratory test terms as they are encoded in LOINC. Metathesaurus, which contains over 8.9 million terms collected from over 160 different sources (including many of those that we have discussed), and attempts to relate synonymous and similar terms from across the different sources into over 2.6 million concepts (■ Fig. 7.6). ■ Figure 7.7 lists the preferred names for many of the pneumonia concepts in the Metathesaurus; ■ Fig. 7.8 shows how like terms are grouped into concepts and are tied to other concepts through semantic relationships. ■ Figure 7.9 shows some of the information available in the Unified Medical Language System about selected pneumonia concepts.

## 7.5 Data Interchange Standards

The recognition of the need to interconnect health care applications led to the development and enforcement of **data interchange standards**. The conceptualization stage began in 1980 with discussions among individuals in an organization called the American Association for Medical Systems and Informatics (AAMSI). In 1983, an AAMSI task force was established to pursue those interests in developing standards.

The development phase was multifaceted. The AAMSI task force became subcommittee E31.11 of the ASTM and developed and pub-

```

■ **Fig. 7.6** Partial tree structure for the Medical Subject Headings showing pneumonia terms. Note that terms can appear in multiple locations, although they may not always have the same children, implying that they have somewhat different meanings in different contexts. For example, Pneumonia means “lung inflammation” in one context (line 3) and “lung infection” in another (line 16)

■ **Fig. 7.7** Growth of the UMLS. The UMLS Metathesaurus contains 3.85 million concepts and 14.6 million unique concept names from 210 source vocabularies. The content continues to grow dynamically in response to user needs (Source: U.S. National Library of Medicine)

lished ASTM standard 1238 for the exchange of clinical-laboratory data. Two other groups were formed to develop standards, each with a slightly different emphasis: HL7 and Institute of Electrical and Electronics Engineering (IEEE) Medical Data Interchange (“Medix”) Standard. The American College of Radiology (ACR) joined with the National Electronic Manufacturers Association (NEMA) to develop a standard for the transfer of image data. Two other groups developed related standards independent of the biomedical informatics community: (1) ANSI X12 for the transmission of commonly used business transactions, including health care claims and benefit data, and (2) National Council for Prescription Drug Programs (NCPDP) for the transmission of third-party drug claims.

### 7.5.1 General Concepts and Requirements

The purpose of a data-interchange standard is to permit one system, the **sender**, to transmit to another system, the **receiver**, all the data required to accomplish a specific communication, or **transaction set**, in a precise, unambiguous fashion. To complete this task successfully, both systems must know what format and content is being sent and must understand the words or terminology, as well as the delivery mode.

A communications model, called the Open Systems Interconnection (OSI) reference model (ISO 7498–1), has been defined by the ISO (see ► Chap. 5 and the discussion of software for network communications). It describes seven levels of requirements or specifications for a communications exchange: physical, data link, network, transport, session, presentation, and application (Rose 1989; Stallings 1987; Tanenbaum 1987). Level 7, the application level, deals primarily with the semantics or data-content specification of the transaction set or message. For the data-interchange standard, HL7 requires the definition of all the data elements to be sent in

response to a specific task, such as the admission of a patient to a hospital. In many cases, the data content requires a specific terminology that can be understood by both sender and receiver.

Presentation, the sixth level of Interoperability, addresses the syntax of the message, or how the data are formatted. There are both similarities and differences at

this level across the various standards bodies. Two philosophies are used for defining syntax: one proposes a position-dependent format; the other uses a tagged-field format. In the position-dependent format, the data content is specified and defined by position.

The remaining OSI levels—session, transport, network, data link, and physical—govern the communications and networking

**Fig. 7.9** Some of the information available in the Unified Medical Language System about selected pneumonia concepts. Concept's preferred names are shown in italics. Sources are identifiers for the concept in other terminologies. Synonyms are names other than the preferred name. ATX is an associated Medical Subject Heading expression that can be used for Medline searches. The remaining fields (Parent, Child, Broader, Narrower, Other, and Semantic) show relationships among concepts in the Metathesaurus. Note that concepts may or may not have hierarchical relations to each other through Parent–Child, Broader–Narrower, and Semantic (is-a and inverse is-a) relations. Note also that Pneumonia, Streptococcal and Pneumonia due to Streptococcus are treated as separate concepts, as are Pneumonia in Anthrax and Pneumonia, Anthrax

protocols and the physical connections made to the system. Obviously, some understanding at these lower levels is necessary before a linkage between two systems can be successful. Increasingly, standards groups are defining scenarios and rules for using various protocols at these levels, such as TCP/IP. Much of the labor in making existing standards work lies in these lower levels.

Typically, a transaction set or message is defined for a particular event, called a **trigger event**. This trigger event, such as a hospital admission, then initiates an exchange of messages. The message is composed of several

data segments; each data segment consists of one or more data fields. Data fields, in turn, consist of data elements that may be one of several data types. The message must identify the sender and the receiver, the message number for subsequent referral, the type of message, special rules or flags, and any security requirements. If a patient is involved, a data segment must identify the patient, the circumstances of the encounter, and additional information as required. A reply from the receiving system to the sending system is mandatory in most circumstances and completes the communications set.

It is important to understand that the sole purpose of the data-interchange standard is to allow data to be sent from the sending system to the receiving system; the standard is not intended to constrain the application system that uses those data. Application independence permits the data-interchange standard to be used for a wide variety of applications. However, the standard must ensure that it accommodates all data elements required by the complete application set.

## 7.5.2 Specific Data Interchange Standards

As health care increasingly depends on the connectivity within an institution, an enterprise, an integrated delivery system, a geographic system, or even a national integrated system, the ability to interchange data in a seamless manner becomes critically important. The economic benefits of data-interchange standards are immediate and obvious. Consequently, it is in this area of healthcare standards that most effort has been expended. All of the SDOs in health care have some development activity in data-interchange standards.

The following sections summarize many of the current standards for data-interchange. Examples are provided to give you a sense of the technical issues that arise in defining a data-exchange standard, but details are beyond the scope of this effort. In fact, the pace of change is so great that many of the referenced standards will have been improved at the time of publication. Rather than providing an exhaustive list of standards, links to the standards and standards platforms will provide access to the most recent technical information and its implementation.

### 7.5.2.1 HL7 Standards

HL7 has provided standards that have been adopted world-wide. In the United States and in many other countries, these standards are codified in legislation and in regulation. The changes in these standards most often reflect

new governmental policies, new science (both clinical and pre-clinical), new care paradigms, and new models for payment models.

## Compendium of HL7 Standards

### ■ Introduction to HL7 Standards

HL7 provides a framework, as well as related standards, for the exchange, integration, sharing, and retrieval of electronic health information. These standards define how information is packaged and communicated from one party to another, setting the language, structure and data types required for seamless integration between systems. HL7 standards support clinical practice and the management, delivery, and evaluation of health services, and are recognized as the most commonly used in the world.

► <http://www.hl7.org/implement/standards/index.cfm?ref=nav>

### ■ HL7 Primary Standards

Primary standards are the most widely implemented standards and are fundamental for system integrations, inter-operability and compliance. The most frequently used standards are defined in this category

► [http://www.hl7.org/implement/standards/product\\_section.cfm?section=1&ref=nav](http://www.hl7.org/implement/standards/product_section.cfm?section=1&ref=nav)

### ■ HL7 Foundational Standards

Foundational standards define the fundamental tools and building blocks used to create the standards, and the technology infrastructure that implementers of HL7 standards must manage.

► [http://www.hl7.org/implement/standards/product\\_section.cfm?section=2&ref=nav](http://www.hl7.org/implement/standards/product_section.cfm?section=2&ref=nav)

### ■ HL7 Clinical & Administrative Domains

Messaging and document standards for clinical specialties and groups are found in this section. These standards are usually implemented once primary standards for the organization are operational.

► [http://www.hl7.org/implement/standards/product\\_section.cfm?section=3](http://www.hl7.org/implement/standards/product_section.cfm?section=3)

### ■ HL7 EHR Profiles

These standards provide *functional models* and profiles that enable the constructs for management of electronic health records. EHR System Functional Model (EHR-S FM) outlines important features and functions that should be contained in an EHR system.

► [http://www.hl7.org/implement/standards/product\\_section.cfm?section=4](http://www.hl7.org/implement/standards/product_section.cfm?section=4)

### ■ HL7 Implementation Guides

Implementation guides and their supporting documents are intended to be used in conjunction with an existing standard. The supporting documents serve as supplemental material for a parent standard. Implementation guides provide the road map for transforming the technical standard into an effective working solution.

► [http://www.hl7.org/implement/standards/product\\_section.cfm?section=5](http://www.hl7.org/implement/standards/product_section.cfm?section=5)

### ■ HL7 Standards Rules & References

These references provide the technical specifications, programming structures and guidelines for software and standards development. They are not stand alone solutions, but rather provide support for a standard or for a family of standards.

► [http://www.hl7.org/implement/standards/product\\_section.cfm?section=6](http://www.hl7.org/implement/standards/product_section.cfm?section=6)

### ■ HL7 Current Projects & Education

This is a resource for Standards for Trial Use (STUs) and for ongoing projects and standards. The link also provides helpful resources and tools to further supplement understanding and adoption of HL7 standards.

► [http://www.hl7.org/implement/standards/product\\_section.cfm?section=7](http://www.hl7.org/implement/standards/product_section.cfm?section=7)

### ■ HL7 Standards Master Grid

This is a convenient navigation tool for all HL7 standards. Because HL7 encompasses the complete life cycle of a standards specification, including the development, adoption, market recognition, utilization, and adher-

ence. There is also an explanation of the IP Policy that provides more information about how members and non-members can use the standard

► [http://www.hl7.org/implement/standards/product\\_matrix.cfm?ref=nav](http://www.hl7.org/implement/standards/product_matrix.cfm?ref=nav)

### Clinical Document Architecture

Since its initial development in 2001, the Clinical Document Architecture (CDA) standard has become globally adopted for a broad range of use (Ferranti et al. 2006). Now an ISO standard and advanced to Release 2, CDA is a document markup standard for the structure and semantics of an exchanged “clinical document.” CDA is built upon the RIM and relies upon reusable templates for its ease of implementation. A CDA document is a defined and complete information object that can exist outside of a message and can include text, images, sounds, and other multimedia content. CDA supports the following features: persistence, stewardship, potential for authentication, context, wholeness, and human-readability. In the US, CDA is one of the core components of data exchange for Meaningful Use. The competing implementation processes for CCD profile development were successfully harmonized into a broadly adopted *Consolidated* Continuity of Care Document (CCCD).

In order to ease the path to implementation of CDA, HL7 has developed a more narrowly defined specification called greenCDA, which limits the requirements of the RIM, provides greater ease of template composition, and consumes much less bandwidth for transmission. An additional effort to promote CDA adoption was achieved with the release of the CDA Trifolia repository, which, in addition to offering a library of templates, includes tooling for template modification as well as a template-authoring language. This has enabled the adoption of native CDA for exchange of laboratory data, clinical summaries, and electronic prescriptions and well as for clinical decision support.

## HL7 Fast Healthcare Interoperability Resources

FHIR (see ► Sect. 7.2.3) is a new highly innovative approach to standards development, first introduced by HL7 in 2011. FHIR was created in order to overcome the complexity of development based upon the HL7 Reference Information Model (RIM), without losing the successful interoperability that model-driven data interchange demands. At the same time, FHIR delivers greater ease of implementation than other high-level development processes. It is designed to be compatible with legacy systems that conform to V2 and/or V3 messaging, and it supports system-development utilizing broadly deployed Clinical Document Architecture (CDA) platforms and ubiquitous templated CDA implementations, such as *Consolidated CDA*.

Although FHIR is built upon more than a decade of the development and refinement of the RIM, FHIR utilizes unique methodologies, artifacts, tooling, and publishing approach. While FHIR is based upon the RIM, it does not require implementers to know the RIM or know the modeling language upon which it was built. FHIR defines a limited set of data models (or *resources*) as XML or JSON objects, but provides extension mechanisms for creating any elements which are incomplete or missing. The resulting structures are native XML/JSON objects which do not require knowledge of the RIM abstraction in order to be implemented. Fundamentally, each clinical concept is created as a single resource, which need not change over time. The resources remain as the smallest unit of abstraction, and the creation of each resource is based upon **RESTful design** principles. Base FHIR resources can be further refined by creating *profiles* which constrain existing data elements or add elements as extensions.

Inherently, development can precede around a *services* (SOA) model, which will support cloud-based applications. While a RESTful framework is enabled, it is not required. In addition, a well-defined ontology persists in the background, but knowledge of the terminology is not necessary for

implementation. Fundamental to FHIR, all resources, as well as all resource attributes have a free-text expression, an encoded expression or both. Thus, FHIR supports a human-readable format, which is so valuable to the implementations supported by CDA.

Finally, FHIR is built with new *data types*, conformant with the familiar ISO 21090 format. As such, these data types are far simpler to use, with much of the complexity captured in the *extensions*. This allows mapping to other models, including those developed using *archetypes*, upon which the CEN format for electronic medical records is predicated. This allows an inherently much smaller library of resources, all mapped to the HL7 RIM, and which can be maintained in perpetuity. FHIR developers have estimated that fewer than 150 such resources will define all of health care. Other concepts can be described as extensions.

This provides a unique opportunity for creation of both new applications in mature computing environments and for low and medium resource countries without legacy implementations. Nonetheless, migrations from V2 or V3 environments to FHIR implementations are achievable through native tooling.

FHIR APIs and resources can be implemented in SMART applications and thereby extending the utility of EHR data to support externalized clinical decision support, data visualization and combining EHR data with remote monitoring devices. SMART Health IT is an open, standards based technology platform that enables innovators to create apps that seamlessly and securely run across the healthcare system (► <https://smarthealthit.org/>) SMART was created at the Boston Children's Hospital through a grant from the Office of the National Coordinator for Healthcare IT. SMART on FHIR enables cross-platform and intersystem exchange of data by enabling ISO standards-based solutions for security and authentication.

With Clinical Decision Support Hooks (CDS-Hooks; Spineth et al. 2018), triggers can be built into the EHR workflow and trigger external CDS services. One example application developed with support from the Centers

for Disease Control is an opioid medication management tool which can be automatically launched when a physician orders an opioid medication. This tool provides guidance to the provider based on the patient's history of opioid prescriptions as well as the current prescriber's intended order.

Link to CDSHooks: ► <https://cds-hooks.hl7.org/>

Most often, HL7 is recognized for its messaging standards, but there is a large contribution to technical specifications that support the development and implementation of these messaging standards.

### 7.5.2.2 American Dental Association Standards

In 1983, the American Dental Association (ADA) committee MD 156 became an ANSI-accredited committee responsible for all specifications for dental materials, instruments, and equipment. In 1992, a Task Group of the ASC MD 156 was established to initiate the development of technical reports, guidelines, and standards on electronic technologies used in dental practice. These include digital radiography, digital intraoral video cameras, digital voice-text-image transfer, periodontal probing devices, and CAD/CAM. Proposed standards include Digital Image Capture in Dentistry, Infection Control in Dental Informatics, Digital Data Formats for Dentistry, Construction and Safety for Dental Informatics, Periodontal Probe Standard Interface, Computer Oral Health Record, and Specification for the Structure and Content of electronic medical record integration.

### 7.5.2.3 Health Industry Business Communications Council Standards

The Health Industry Business Communications Council (HIBCC) has developed the Health Industry Bar Code (HIBC) Standard, composed of two parts. The HIBC Supplier Labeling Standard describes the data structures and bar code symbols for bar coding of health care products. The HIBCC Provider Applications Standard describes data structures and bar code symbols for bar coding of

identification data in a health care provider setting. HIBCC also issues and maintains Labeler Identification Codes that identify individual manufacturers. The HIBCC administers the Health Industry Number System, which provides a unique identifier number and location information for every health care facility and provider in the United States. The HIBCC also administers the Universal Product Number Repository, which identifies specific products and is recognized internationally.

Link: ► <https://www.hibcc.org/>

### 7.5.2.4 The Electronic Data Interchange for Administration, Commerce, and Transport Standard

The EDI for Administration, Commerce, and Transport (EDIFACT) is a set of international standards, projects, and guidelines for the electronic interchange of structured data related to trade in goods and services between independent computer-based information systems (National Council for Prescription Drug Programs Data Dictionary 1994). The standard includes application-level syntax rules, message design guidelines, syntax implementation guidelines, data element dictionary, code list, composite data-elements dictionary, standard message dictionary, uniform rules of conduct for the interchange of trade data by transmission, and explanatory material.

The basic EDIFACT (ISO 9735) syntax standard was formally adopted in September 1987 and has undergone several updates. In addition to the common syntax, EDIFACT specifies standard messages (identified and structured sets of statements covering the requirements of specific transactions), segments (the groupings of functionally related data elements), data elements (the smallest items in a message that can convey data), and code sets (lists of codes for data elements). The ANSI ASC X12 standard is similar in purpose to EDIFACT, and work is underway to coordinate and merge the two standards.

EDIFACT is concerned not with the actual communications protocol but rather with the structuring of the data that are sent.

EDIFACT is independent of the machine, media, system, and application and can be used with any communications protocol or with physical magnetic tape.

## 7.6 Today's Reality and Tomorrow's Directions

---

In the current environment, the seamless exchange of data that can be used for any purpose remains a challenge. As we move closer to semantic interoperability (► [https://en.wikipedia.org/wiki/Semantic\\_interoperability](https://en.wikipedia.org/wiki/Semantic_interoperability)) for healthcare and biomedical data, the challenge of true plug-and-play interoperability is still elusive. The meaning of many concepts and terms remains ambiguous, controversial, disputed, or poorly understood. Instead, the standards community has built a system of interchange that often requires mapping between terminologies and standards to overcome these issues.

### 7.6.1 The Interface: Standards and Systems

---

Historically, interchange standards evolved to support sharing of information over complex networks of distributed systems. This served a simple business model in which data was pushed from disparate repositories with inconsistent architectures and data structures. This permitted the exchange of data for both business needs and patient care.

In today's medical environment, there are several competing forces that place a burden on standards requirements. The traditional scope of data sources included business level information, principally for payment needs. These were developed utilizing coding methodologies and business architecture that did not rely upon inclusion of primary clinical data into the reimbursement decision. With the advent of statutory requirements that demand justification of insurance claims and reimbursement, additional data forms

and formats became essential. This led to the development of claims attachment standards (see X12, above) that enabled more complex adjudication, comparative effectiveness, and accountable care. These standards will most certainly require structured, coded data rather than free-text and unstructured narrative.

Complexity of data requirements is constantly growing to better support evidence-based medicine, clinical decision support, personalized medicine, and accountable care. Each of these has overlapping, but fundamentally unique data streams. Moreover, the data provided at the point of care, if unfiltered, is likely to overwhelm the clinical decision making process. Elements of clinical data, such as events in pediatric years, must not compete for the attention of the caregiver. To an extent, this was solved with specifications, such as FHIRcast, which were developed to provide context aware data to that process. There are growing demands for increasing the depth and breadth of data delivered to that clinical environment. In addition, these standards must support the implicit policy decisions about the nature of this data.

To date, clinical and preclinical information populates many of the alerts that clinicians receive at the point of care. Typically, these range from information supporting complex decision trees to the selection of testing and interventions. This has been abetted by increasing knowledge of genomic data and implication for therapeutic decisions. Although this has had its greatest impact on the chemotherapy of cancer, the importance in many other clinical domains, for more common conditions (including the treatment of diabetes, hypertension, and arthritis) is now recognized. Current architectural systems are ill-prepared to manage this process. Moreover, data formats for genomic and genetic information are disparate and often incompatible.

Data privacy requirements, and the variability of these requirements among legal entities, currently pose a different set of demands for information access technologies. For example, some states permit line-item exclusion of clinical data that is transferred between providers, based on the primacy of

the information and the role of the caregiver. Other jurisdictions allow participation of health information exchanges to those individuals who agree only to dissemination of data from complete sources.

Existing data architectures enable a constant stream of data to be passed in an untended and unmonitored fashion. In evolving models, data request and acknowledgement require a more complex query and response logic. In fact, most inquiries demand the validation of the provider system and privileges that are afforded to both the caregiver and the primary data repository. This places another component of interface design between the respective systems and necessitated the development of analogous provider indices and provider repositories. Concerns of both privacy and security must be met by these specifications. The system effectively asks not only who you are but why you want the information.

Much of this process overhead has been addressed by the design and architecture of health information exchanges. Often the business case supersedes the demand for clinical knowledge. At the same time, these exchanges are designed to behave in an entirely agnostic fashion, placing no demand on either the sender or recipient for data quality, other than source identification. In fact, the metadata, so responsible for the value of the information, is often capable of specifying only its origin and value sets.

In today's clinical environment, there has been very little attention paid to the capture and validation of patient-initiated data. While so very critical to diagnosis and ongoing management, only scant standards exist for embedding patient derived information into the clinical record without intermediate human interaction and adjudication. When allowed by current systems, data provided by patients often lies within the audit trail, as a comment, rather than in the record as source data. Steps are sorely needed to define and attribute such data since it is so critical to many aspects of accountable care. Data obtained directly from patient sources is often attributed to "subjective" status, but it is no less objective than many clinician observa-

tions. Perhaps justification for that lies in the fact that this patient derived data is neither quantifiable nor codeable. This is supported by valid concerns about the patient's health care literacy, or lack thereof, but is no less required than validated decision support for caregivers.

Data obtained from clinical research and clinical data provided to inform clinical studies suffer from other concerns of failed interoperability. This is attributed, and rightfully so, to disparities of terminologies utilized for patient care and those used in clinical research. This is most dramatically highlighted in the terminology deployed by regulation for adverse event reporting (MedDRA; Medical Dictionary of Regulatory Affairs). Mapping between the MedDRA dictionary and other clinical terminologies (SNOMED-CT, LOINC, ICD, and CPT) has not proven successful. Moreover, many aspects pertaining to study subject inquiries in clinical research are often designed to elicit yes-no responses (Have you smoked in the last 5 years), rather than data that many caregivers deem relevant. Yet, today, it is more critical than ever to enable clinical research to inform patient care and care derived data to enable clinical trials. The business model of developing drugs for billion dollar markets ("blockbuster drugs") has proven itself to be unsustainable, as the cost of developing a new drug entity has now exceeded a billion dollars. From the clinical perspective, current estimates suggest that information from basic science research experiences delays of nearly 17 years before that knowledge can be incorporated into clinical care (Balas and Boren 2000).

Semantic interoperability of clinical data inherently requires *data reuse*. It is not sufficient for systems to unambiguously exchange machine readable data. Data, once required only for third party payment, must be shared by other partners in the wellness and health care delivery ecosystems. Certainly, these data must be presented to research systems, as noted above. The data must also be available for public health reporting and analysis, for comparative effectiveness research, for accountable care measurement and for enhancement of decision support systems

(including those for patients and their families). The immediate beneficiaries have been systems developed to support biosurveillance and pharmacovigilance. In practical terms, the business practices that govern our delivery systems (and the government policies and regulations that enable them) must enable these data streams to both enhance care and control costs.

### 7.6.2 Future Directions

The new models for health care require a very different approach. The concept of a patient-centric EHR (► Chap. 19) requires the aggregation of any and all data created from, for, and about a patient into a single real or virtual record that provides access to the required data for effective care at the place and time of care. Health information exchange (HIE; see ► Chap. 20) at regional, state, national, and potentially at a global level is now the goal. This goal can only be reached through the effective use of information technology, and that use can only be accomplished through the use of common global standards that are ubiquitously implemented across all sites of care.

Three other future trends influence the need for new and different standards. The first is secondary use of data by multiple stakeholders. This requirement can only be met through semantic interoperability – a universal ontology that covers all aspects of health, health care, clinical research, management, and evaluation. Standards for expressing what is to be exchanged and under what circumstances are important as well as standards for the exchange of data. Included in multiple uses of data is reporting to other organizations such as immunization and infectious disease reports to the **Centers for Disease Control and Prevention (CDC)**, performance reports to the **National Quality Forum (NQF)** and audit reports to **The Joint Commission (TJC)**. Such systems as described also enable population health studies and health surveillance for natural and bioterrorism outbreaks.

The second trend area is the expansion of the types of data that are to be included in

the EHR. The new emphasis on translational informatics will require new standards for the transport, inclusion into the EHR, and use of genetic information including genes, biomarkers, and phenotypic data. Imaging, videos, waveforms, audio, and consumer-generated data will require new types of standards. Effective use of these new types of data as well as exponential increases in the volume of data will require standards for decision support, standards for creating effective filters for presentation and data exchange, and new forms of presentation including visualization. New sources of data will include geospatial coding, health environmental data, social and community data, financial data, and cultural data. Queries and navigation of very large databases will require new standards. Establishing quality measures and trust will require new standards. Ensuring integrity and trust as data is shared and used by other than the source of data will require new standards addressing provenance and responsibility.

The third trend area is the use of mobile devices, smart devices, and personal health devices. How, when and where such devices should be used is still being explored. Standards will be required for safe design, presentation, interface, integrity, and protection from interference.

True global interoperability will require a suite of standards starting with the planning of systems, the definition and packaging of the data, collection of the data including usability standards, the exchange of data, the storage and use of data, and a wealth of applications that enable the EHR for better care. IT systems must turn data collected into information for use – a process that will require the use of knowledge in real time with data to produce information for patient care. Selecting the correct knowledge from literature, clinical trials, and other forms of documentation will require standards. Knowledge representation, indexing, and linkages will require standards.

A major, and challenging, requirement to address these new types and use of data will be effective standards for privacy and security. These standards must protect, but not restrict the use of data and access to that data for

determining and giving the best care possible. The aggregation of data requires an error-free way for patient identification that will permit merger of data across disparate sources. Sharing data also requires standards for the de-identification of patient data.

The effective management of all of these resources will require additional output from the standards communities. Standards for defining the required functionality of systems and ways for certifying adherence to required functionality is essential for connecting a seamless network of heterogeneous EHRs from multiple vendors. Testing of standards, including IHE Connectathons before widespread dissemination and perhaps mandated use of standards is critical to use and acceptance. Standards for registries, standards for the rules that govern the sharing of research data, standards for patient consent, and standards for identification of people, clinical trials, collaboration, and other similar areas are necessary. Profiles for use and application from the suite of standards are a necessity. Detailed implementation guides are key to use and implementation of standards. Tools that enable content population and use of standards are mandatory for easy use of standards.

Standards for these new and evolving business and social needs must be supported by changes in standards development methodologies and harmonization. Legacy systems are not easily discarded. Recommendations for complete replacement of existing standards are neither politically expedient nor fiscally supportable. Currently, there is increasing attention to new approaches to standards development that speeds the creation process and improves the quality of standards that are developed. These evolving development platforms pay appropriate homage to existing standards and leverage previously developed models of development and analysis.

The use of the FHIR may provide a much needed solution while relying upon historically developed and refined interoperability specifications, it hides the complexity of authoring messages within the FHIR development process. This leads to more usable specifications, created in a dramatically abbreviated time

frame. Other approaches to standards development, such as those focused upon services, are rapidly evolving. These services-aware architectures are governed by strict development principles that help ensure both interoperability and the ability of components to be reused.

Increasingly large data stores (“big data”) have demanded some of these changes. These data have emanated from a highly diverse universe of scientific development. In fact, some of the new bio-analytic platforms for *in vitro* cellular research are generating data at a rate, which by some estimates, is faster than the data can be analyzed. Medical images, for which storage requirements are growing, must now be principally evaluated by human inspection. Newly evolving algorithms and the technologies to support them, initially developed for “star wars” type image analysis, are replacing radiologist and pathologists for the establishment of diagnoses. These machines have proven to be faster and more accurate than their human counterparts. In the very near future, such instrumentation will supplant medical scientists the same way that comparable technologies replaced human inspection in the estimation of cell differentials for blood counts. These new technologies are demanding the development of specifications and the terminologies to support them.

Tomorrow’s technologies will transition from early vision through prototyping to commercial products in a more compressed life cycle. A model for this process in biomedical science was established with the emergence of the Human Genome Project (see ► Chap. 11). Within the next decade, routine genome determination and archiving, as well as their application to disease management, will require greatly enhanced solutions for data management and analysis. Innovative strategies for recognizing and validating biomarkers will grow exponentially from the current stable of imaging and cell surface determinants. These data streams will require adaption of existing decision support systems and comparative effectiveness paradigms. Lastly, scientific evidence supporting the diagnosis and management with the field of behavioral medicine will change the entire clinical spectrum

and approach to evaluation and care. As we emerge from the dark ages of behavioral medicine, we will certainly require new systems for recognizing, diagnosing, naming and intervening on behalf of our patients.

In some sense, the development of standards is just beginning. The immediate future years will be important to create effective organizations that include the right experts in the right setting to produce standards that are in themselves interoperable. That goal still remains in the future.

### ? Questions for Discussion

1. Who should be interested in interoperability and health data standards?
2. What are the five possible approaches to accelerating the creation of standards?
3. Define five health care standards, not mentioned in the chapter, which might also be needed?
4. What role should the government play in the creation of standards?
5. At what level might a standard interfere with a vendor's ability to produce a unique product?
6. Define a hypothetical standard for one of the areas mentioned in the text for which no current standard exists. Include the conceptualization and discussion points. Specifically state the scope of the standard.

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What are the potential uses for NLP in the biomedical, clinical, and health domains?
- What are the principal computational tasks of NLP for health-related texts?
- What are the different knowledge resources and linguistic representations that can support the development of NLP techniques?
- What are the near-future directions for health-related NLP research and applications?

## 8.1 Motivation

---

Language is the primary means of human communication, and it is no surprise clinicians, biomedical researchers, patients, and health consumers alike rely on language extensively. Clinicians document the care of their patients in the electronic health record and use patient record notes to determine next steps of care. Biomedical scientists write and read articles to keep abreast of research progress from their peers. Patients rely on online platforms to learn from and exchange informational and emotional support from their peers, and health consumers view health content online as a primary source of information to manage their health and increase their health literacy. In fact, there are continuously growing, unprecedented amounts of these biomedical and health-related texts available.

The field of health and biomedical natural language processing is concerned with the theories, principles, and computational approaches to building tools that exploit these textual data and support these stakeholders – patients and health consumers, clinicians, and biomedical researchers – in their information needs.

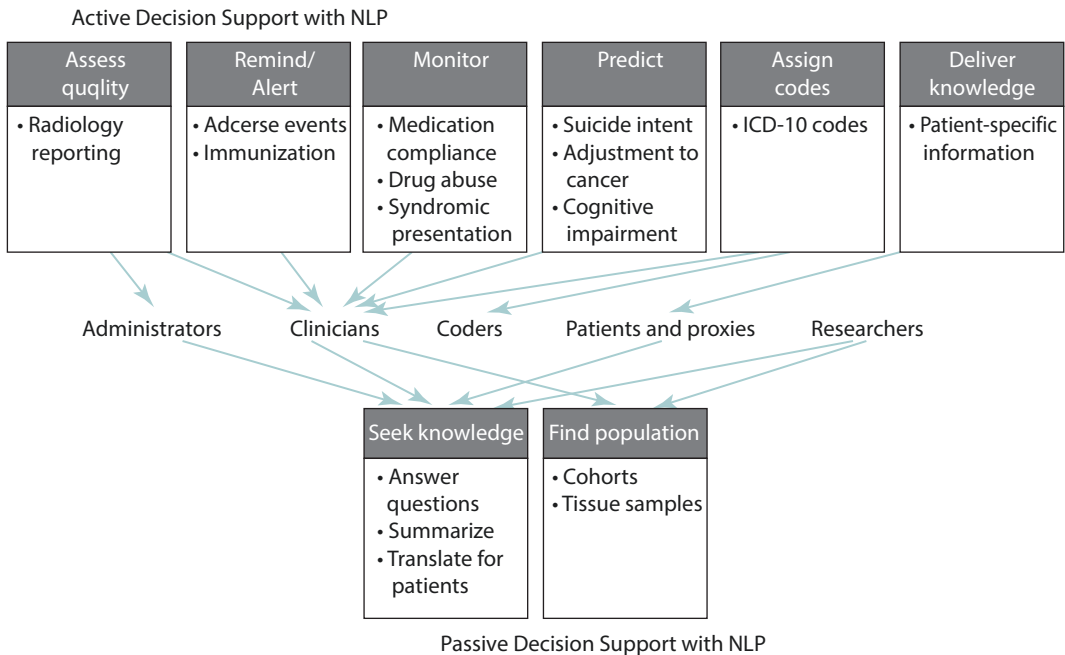

While there is valuable information conveyed in biomedical, clinical, and health texts, it is not in a format directly amenable to further processing. These texts are difficult to process reliably because of the inherent characteris-

tics and variability of language. While in most automated applications, structured, standardized data are readily available for processing, there is a significant amount of manual work currently devoted to mapping textual information to coded representations in biomedicine and health care: Professional coders assign billing codes corresponding to diagnoses and procedures to hospital admissions based on discharge summaries and admission information; indexers at the National Library of Medicine assign MeSH (Medical Subject Headings) terms to represent the main topics of scientific articles; and database curators extract genomic and phenotypic information on organisms from the literature. Because of the overwhelmingly large amount of textual information in health domains, manual work is costly, time-consuming, and impossible to keep up to date. One aim of Natural Language Processing (NLP) is to facilitate these tasks by enabling use of automated methods with high validity and reliability.

Another aim of NLP is to help advance many of the fundamental aims of biomedical informatics, which are the discovery and validation of scientific knowledge, improvement in the quality and cost of health care, and support to patients and health consumers. The considerable amounts of texts amassed through clinical care, published in the scientific biomedical literature, and discussed by patients and caregivers online can help acquire new knowledge and promote discovery of new phenomena. For instance, the information in patient notes, while not originally entered for discovery purposes, but rather for the care of individual patients, can be processed, aggregated and mined to discover patterns across patients. This process of leveraging observational health data has shown much success stories when applied to health data that are highly structured (**OHDSIPNAS**), and there is promise that incorporating learned representations of language can help as well (Ghassemi et al. 2014).

For clinicians interacting with an electronic health record and treating a particular patient, NLP can support several points in a clinician workflow: when reviewing the patient

**Fig. 8.1** Active (initiated by the application) and passive (initiated by the users) decision support applications to which NLP tools have contributed and have potential to contribute in the future

chart, NLP can be leveraged to aggregate and consolidate information spread across many notes and reports, and to highlight relevant facts about the patient. During the decision-making and actual care phase, information extracted through NLP from the notes can contribute to the decision support systems in the EHR as shown in [Fig. 8.1](#) (Demner-Fushman et al. 2009). Finally, when health care professionals are documenting patient information, higher quality notes can be generated with the help of NLP-based methods.

For quality and administrative purposes, NLP can signal potential errors, conflicting information, or missing documentation in the chart. For public health administrators, EHR patient information can be monitored for syndromic surveillance through the analysis of ambulatory notes or chief complaints in the emergency room (Hripcsak et al. 2009).

The expectations and requirements for NLP support evolve and grow due to successes and demonstrated potential, such as a tool to identify tests for EGFR (epidermal growth factor receptor) mutations deployed

in VA EHR clinical notes (Lynch et al. 2019) or Medical Text Indexer that supports indexers in assigning MeSH terms at the National Library of Medicine (Mork et al. 2017). New requirements arise in the domain of consumer language, due to the changes in consumers' behavior, which in turn, are changing the dynamics of healthcare interaction ([Chap. 11](#)). NLP is crucial in enabling consumers to get to the right information, whether through access to clinical information or to information generated by their peers. NLP can support health consumers and patients looking for information about a particular disease or treatment, by providing better access to relevant information, targeted to their information needs, and to their health literacy levels through the analysis of the topics conveyed in a document as well as the vocabulary used in the document.

When approaching the above health-related tasks or use cases for NLP, it is beneficial to align the human tasks and end-goals with the tasks that NLP has to perform. For example, giving a clinician a full

and concise description of a patient's course relevant to the patient's current state is the task of summarization. The high-level NLP tasks or applications described later in this chapter include, but are not limited to, question answering (QA), summarization, text labeling and text generation. These tasks are bringing the field closer to the ultimate goal of text understanding, which encompasses not only direct understanding of textual information, but also the author's attitude, such as sentiment polarity and modality at the document level, and temporal reasoning at a document and document sequence levels (► Chap. 23).

Across all these use cases of health NLP (hNLP), the techniques of natural language processing provide a means to bridge the gap between unstructured text and data by transforming the text to data in a computable format, allowing humans to interact using familiar natural language, while enabling computer applications to process data effectively and to provide users with easy access and synthesis of the raw textual information.

This chapter is organized with two types of readers in mind: students and researchers looking for a broad introduction to health NLP prior to delving into this active field of research, and informatics practitioners looking to use hNLP technology for specific tasks or types of text. ► Section 8.2 presents a more in-depth description of hNLP applications and emphasizes the critical role that the context in which these applications are deployed plays when developing hNLP solutions. In ► Sect. 8.3 we establish the basic computational tasks involved in most hNLP applications. ► Section 8.4 is concerned with the different linguistic knowledge resources and types of linguistic representations that can enable and facilitate these basic NLP tasks. ► Section 8.5 provides further practical considerations for users of hNLP technology, while ► Sect. 8.6 provides further research considerations for hNLP research, including evaluation methodology. Finally, ► Section 8.7 briefly outlines future directions of hNLP.

## 8.2 NLP Applications and Their Context

---

In this section, we describe specific hNLP applications that have been and continue to prove being useful to biomedical, clinical, and health stakeholders in their information needs (► Sect. 8.2.1). We then abstract away from them and emphasize the essential role that context in which these applications exist play (► Sect. 8.2.2).

### 8.2.1 NLP Applications

---

Natural language processing has a wide range of potential applications in the biomedical and health domains. The following are important applications of NLP technology for biomedicine and health:

- Information extraction locates and structures specific information in text, sometimes by performing a complete linguistic analysis of the text, but more frequently, by looking for patterns in the text. This is the most common application in biomedicine. It is also one of the earliest: In the 1970s, the Linguistic String Project (LSP) under the leadership of Dr. Naomi Sager, a pioneer in NLP, developed a comprehensive computer grammar and parser of English (Grishman et al. 1973; Sager 1981), and also began work in NLP of clinical reports (Sager 1972, 1978; Sager et al. 1987) that continued into the 1990s. Other clinical and biomedical NLP systems followed, e.g., MedLee (Medical Language Extraction and Encoding System) has been used successfully primarily for clinical information extraction, but also adapted to literature processing (Friedman et al. 1994; Hripcsak et al. 1995; Friedman 2000). Other systems that have been successfully used for extraction of information from clinical notes and the literature include MetaMap (Aronson and Lang 2010), MetaMap Lite (Demner-Fushman et al. 2017) and SemRep (Kilicoglu et al. 2012). The latter three sys-

tems developed at the National Library of Medicine rely on the Unified Medical Language system (UMLS) (Lindberg et al. 1993a) described in ► Sect. 8.4. Other systems that rely on the UMLS include cTAKES (clinical Text Analysis and Knowledge Extraction System) (Savova et al. 2010) and CLAMP (Clinical Language Annotation, Modeling, and Processing) (Soysal et al. 2017). cTAKES combines machine learning and rule-based methods to perform clinical information extraction tasks, whereas CLAMP provides a graphic user interface to build customized NLP pipelines for clinical applications.

Once textual information is extracted and structured, it can be used for a number of different tasks. In inferring social determinants of health, for instance, one can extract social risk factors from clinical notes (Conway et al. 2019) or from social media (De Choudhury et al. 2013). The extracted data, when collected across many patients, can help understand the prevalence as well as the progression of a particular disease at the community level (Eichstaedt et al. 2015). Notably, the above system for detection of social determinants of health in clinical notes continues the lineage of clinical NLP systems at the University of Utah, which started with SPRUS (which evolved into Symtext and then MPLUS, ONYX, and TOPAZ) (Haug et al. 1990, 1994; Christensen et al. 2002; Dublin et al. 2013; Ye et al. 2014). In biology, biomolecular interactions extracted from one article or from different articles can be merged to construct biomolecular pathways. ■ Figure 8.2 shows a pathway in the form of a graph, which was created by extracting interactions from one article published in the journal *Cell* (Maroto et al. 1997). The DARPA Big Mechanism program that aimed to assemble automatically the causal fragments found in individual scientific papers, such as in ■ Fig. 8.2, into pathways, demonstrated the successes and the remaining challenges in the first step of

■ Fig. 8.2 A graph showing interactions that were extracted from an article. A vertex represents a gene or protein, and an edge represents the interaction. The arrow represents the direction of the interaction so that the agent is represented by the outgoing end of the arrow and the target by the incoming end

the process: machine reading of the literature (Cohen 2015).

The techniques for information extraction may be limited to the identification of names of people or places, dates, and numerical expressions, or to certain types of terms in text (e.g. mentions of medications or proteins), which can then be mapped to canonical or standardized forms. This is referred as named-entity recognition and named-entity normalization, respectively. More sophisticated techniques identify and represent the modifiers attached to a named entity. Such advanced methods are necessary for reliable retrieval of information because the correct interpretation of a biomedical term typically depends on its relation with other terms in a given sentence. For example, the term *fever* has different interpretations in *no fever*, *high fever*, *fever lasted 2 days*, and *check for fever*. Defining the types of modifiers of interest (e.g. *no* is a negation modifier, while *lasted 2 days* is a temporal modifier), as well as techniques to recognize them in text, is an active topic of research that was in part stimulated by public release of tools and algorithms, such as NegEx (Chapman et al. 2001). Identifying relations among named entities is another important information extraction method. For example, when extracting adverse events associated with a medication, the sentences “the patient

developed a rash from amoxicillin” and “the patient came in with a rash and was given benadryl” must be distinguished. In both sentences, there is a relation between a rash and a drug, but the first sentence conveys a potential adverse drug event whereas the second sentence conveys a treatment for an adverse event. As entities are extracted within one document or across documents, one important step consists of reference resolution, that is, recognizing that two mentions in two different textual locations refer to the same entity (Kilicoglu and Demner-Fushman 2016). In some cases, resolving the references is very challenging. For instance, mentions of stroke in two different notes associated with the same patient can refer to the same stroke or two different strokes; additional contextual information and domain knowledge is often needed to resolve this problem.

- Information retrieval (IR) and NLP overlap in some of the methods that are used. IR is discussed in ► Chap. 23, but here we discuss the basic differences between IR and NLP. IR methods are generally geared to help users access documents in large collections, such as electronic health records, the scientific literature, or the Web. This is a crucial application in biomedicine and health, due to the explosion of information available in electronic form. The essential goal of information retrieval is to match a user’s query against a document collection (usually using an index) and return a ranked list of relevant documents or the best matching snippets of text. The most basic form of indexing isolates simple words and terms, and therefore, uses minimal linguistic knowledge. More advanced approaches use NLP-based methods similar to those employed in information extraction, identifying complex named entities and determining their relationships in order to improve the accuracy of retrieval. For instance, one can search for *hypertension* and have the search operate at the concept level, returning documents that mention the phrase *high blood pressure* in addition to the ones mentioning *hypertension* only. In addition, one can search for *hypertension* in a specific context, such as in the context of *treatment* or context of *etiology*.
- Question answering (QA) involves a process whereby a user submits a natural language question, which is then automatically answered by a QA system. The availability of information in journal articles and on the Web makes this type of application increasingly important as health care consumers, health care professionals, and biomedical researchers frequently search the Web to obtain information about a disease, a medication, or a medical procedure. A QA system can be very useful for obtaining the answers to clinical questions, like “In children with an acute febrile illness, what is the efficacy of single-medication therapy with acetaminophen or ibuprofen in reducing fever?” (Demner-Fushman and Lin 2007). QA systems provide additional functionalities to an IR system. In an IR system, the user has to translate a question into a list of keywords and generate a query, but this step is carried out automatically by a QA system. Furthermore, a QA system presents the user with an actual answer (often one or several passages extracted from the source documents), rather than a list of relevant source documents. QA has focused for the most part on the literature (Demner-Fushman and Lin 2007; Cao et al. 2011), however, research on answering clinician’s questions asked of EHR (Roberts and Patra 2018) and answering consumer health questions (Demner-Fushman et al. 2020; Ben Abacha et al. 2019) is burgeoning.
- Text summarization takes one or several documents as input and produces a single, coherent text, which synthesizes the main points of the input documents. Summarization helps users make sense of a large amount of data, by identifying and presenting the salient points in texts automatically. Summarization can be generic or query-focused (i.e. taking a particular information need into account when selecting important content of input documents). Query-focused summarization can

be viewed as a post-processing of IR and QA: the relevant passages corresponding to an input question are further processed into a single, coherent text. Several steps are involved in the summarization process: content selection (identifying salient pieces of information in the input document(s)), content organization (identifying redundancy and contradictions among the selected pieces of information, and ordering them so the resulting summary is coherent), and content re-generation (producing a text output from the organized pieces of information). Text summarization in the biomedical domain has focused on the literature (Elhadad et al. 2005; Zhang et al. 2011), with some forays into summarization of clinical text and Web resources (Pivovarov and Elhadad 2015; Mane et al. 2015).

— Other tasks:

Text classification (labeling) involves categorizing text into known types. Sentences in scientific articles can be classified as key sentences indicative of the article's content (Ruch et al. 2007). Sections of a clinical note can be labeled, as, e.g., social or family history (Denny et al. 2008). At the document level, texts can be classified into different genres, etc. Related to classification is clustering, which involves grouping texts based on some intrinsic similarity without knowing a priori what these similar properties are.

Text generation formulates natural language sentences from a given source of information, which is not directly readable by humans. Generation can be used to create a text from a structured database, such as summarizing trends and patterns in laboratory data (Hüske-Kraus 2003).

Machine translation converts text in one language (e.g. English) into another (e.g. Spanish). These applications are important in multilingual environments in which human translation is too expensive or time consuming (Deléger et al. 2009a).

Text readability assessment and simplification is becoming relevant to the health domain, as patients and health consumers access more and more medical informa-

tion on the Web, but need support because their health literacy levels do not match the ones of the documents they read (Elhadad 2006; Keselman et al. 2007).

Finally, sentiment analysis and emotion detection belong to the general task of automated content analysis (Zunic et al. 2020).

## 8.2.2 Context for NLP Applications

Understanding the context and intent of the speaker on meaning (pragmatics) is crucial to performing many NLP tasks correctly. Although the context of health-related NLP applications is broad and varied, it is bounded by specific tasks and environments that can be relatively easily enumerated and therefore taken into account during processing. It is defined by those who produce the text, by the purposes for which the text is produced, and by the intended readers. For example, clinicians can write a patient status report for their colleagues, or a simplified summary for the patient. Clinical researchers can describe the arms of a clinical trial in a scientific publication or describe the inclusion criteria of the same trial in a simpler language for recruitment and patient education purposes. The style of communication is often determined by cultural conventions and ecosystems in which these texts are written and read, and inference is needed for correct interpretation and generation of language. Powerful context models are missing in the open domain (Bunt 2017) but can be approximated through the semantic lexicon and rules about the discourse of a text in the biomedical domain. Biomedical sublanguages are easier to interpret than general languages because they exhibit more restrictive semantic patterns that can be represented more easily (Harris et al. 1989; Harris 1991; Sager et al. 1987). Sublanguages tend to have a relatively small number of well-defined semantic types (e.g. medication, gene, disease, body part, or organism) and a small number of semantic patterns (e.g. medication-treats-disease, gene-interacts-with-gene).

The fact that texts belong to a particular domain, be it clinical, biological or related

to health-consumers, allows us to capture domain-specific characteristics in the lexicon, the grammar, and the discourse structure. Thus, the more specific the domain of a text, the more knowledge can be encoded to help its processing, but then the NLP system would be extremely limited and specialized. For instance, in the domain of online patient discourse, patients discussing breast cancer among their peers online rely on a very different set of terms than caregivers of children on the autism spectrum. One can develop a lexicon for each subdomain, online breast cancer patients and online autism caregivers. But maintaining separate lexicons can be inefficient and error prone, since there can be a significant amount of overlap among terms across subdomains. Conversely, if a single lexicon is developed for all subdomains, ambiguity can increase as terms can have different meanings in different subdomains. For example, in the emergency medicine domain shock will more likely refer to a procedure used for resuscitating a patient, or to a critical condition brought about by a drop in blood flow, whereas in psychiatry notes it will more likely denote an emotional condition or occasionally electric shock therapy. Deciding on whether to model a domain as a whole or to focus on its subdomains independently of each other is a tradeoff. Careful determination of the use cases of a system can help determine the best choice for the system.

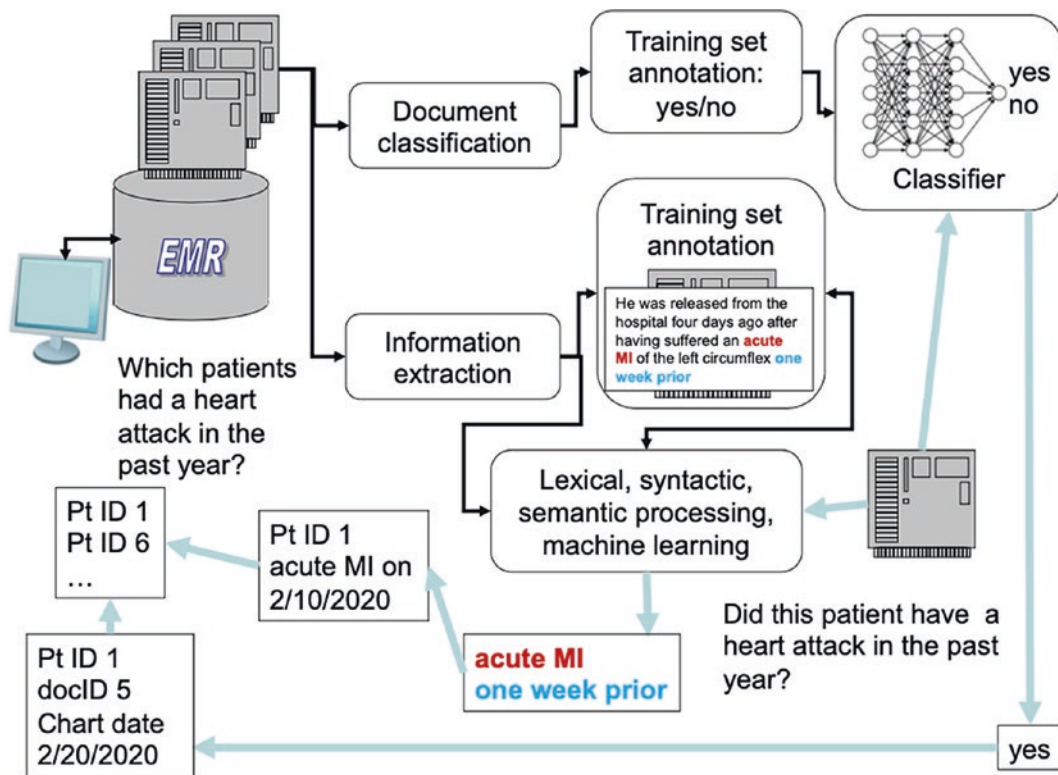

### 8.3 Basic Computational NLP Tasks

---

The different applications we reviewed in the previous sections have in common the need to process text, but they differ widely in the types of input and output they produce. Tasked with an application that entails text processing, one can think in these terms: is the goal to cluster, label, extract, generate or a combination of these? And what is my input: a corpus, a document, a fragment of text, or a sequence of words? The step of casting an application into one or a set of NLP tasks is important in determining the choice and design of the

approaches. An evaluation of the application then helps determine which design was the more appropriate. There is not always a single solution to the application casting step. For instance, take the task of identifying within a large pool of patient records the notes with documented heart attack in the past year. We can cast this application as a note labeling task: given a note, label it according to a binary label: documentation present or absent. In this case, the application will retrieve notes of patients that are labeled as a whole as likely to contain documentation of heart attack within the past year or not. To achieve the task, we will then need to compile a training set of notes and their gold-standard labels and train a document-level classifier. An alternative approach is to cast the same application as an information extraction or template filling task. There, the template would contain for instance the location in the note that mentions the condition heart attack, along with the temporal expression documenting the time at which the heart attacks occurred in the patient. In this case, all heart attacks and temporal aspects will be extracted in our pool of patient notes, and only the ones that satisfy our temporal constraint will be kept. Both tasks will achieve the same goal (identify the patients who have a documented heart attack in the past year), but will do so in different ways and with slightly different outputs: the labeling approach will not be able to provide data provenance, but might be more feasible because it is easier to label a document as a whole than it is to annotate templates and extract information as shown in  Fig. 8.3.

In this section, we review the basic tasks that are most common when processing health-related texts and in biomedical and health applications. These tasks do not constitute a pipeline, but rather a portfolio of the tasks one can rely on depending on their application and goals. They each take specific inputs (sometimes a collection of documents as in topic modeling, or a sequence of words as in sequence labeling) and produce specific outputs (groups of words in topic modeling, one label in document labeling, triples in relation extraction, or complex frames in event extraction, as shown in  Fig. 8.3).

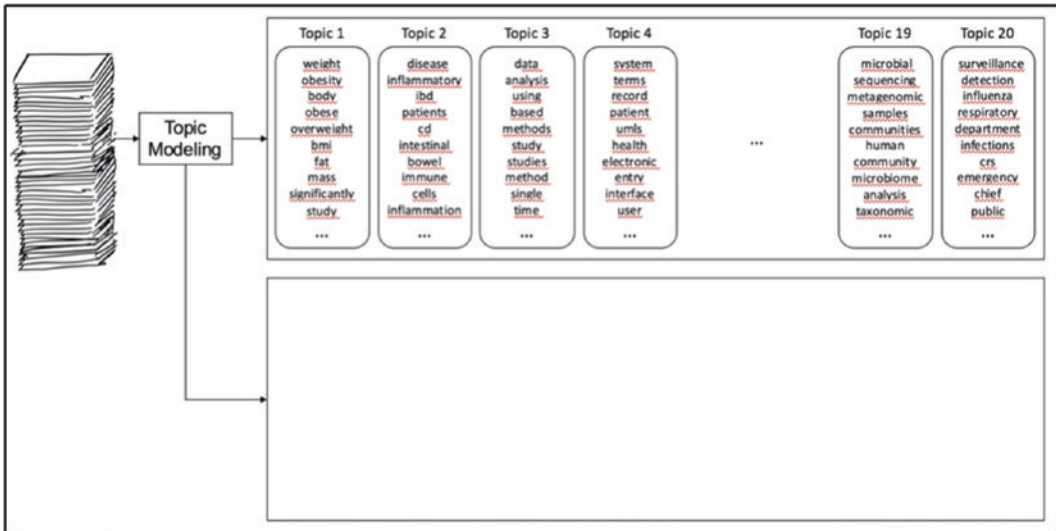

■ Fig. 8.3 Two different approaches to identifying patients who suffered a heart attack in the past year. The document labeling/classification approach and the template filling/information extraction approach

### 8.3.1 Topic Modeling

Topic modeling takes as input a collection of texts and identifies the topics discussed in the documents that comprise the collection. It is unsupervised in nature; that is, it does not require any guidance, document labels, or dictionary to identify topics. The discovered topics are expressed as clusters of words. As such, topic modeling is a particularly useful task for exploratory data analysis. A variety of methods have been proposed for the task of topic modeling, including latent semantic analysis (Deerwester et al. 1990), probabilistic latent semantic analysis (Hofmann 1999), and Latent Dirichlet Allocation (LDA) (Blei et al. 2003). All topic modeling methods take a simple representation of the documents, namely a “bag of words” approach. That is, the text is split into words using a tokenizer, and the order between the words is not taken into account during processing.

LDA belongs to the family of probabilistic generative models, and several extensions to LDA, also in the family of probabilistic generative models, were proposed in the literature and can facilitate exploratory analysis of large corpora further (Blei 2012). The generative process of LDA and its variant is what enables topic modeling to go further than a simple exploratory device within a corpus. In addition to discovering the clusters of words that determine the topics of a corpus, it is able to infer for any new document the topics which best represent it.

For instance, ■ Fig. 8.4 depicts the result of applying LDA for 20 topics on a corpus of 1700 documents. Each document in the corpus contains the title and abstract of a scientific publication from PubMed Central. Each topic consists of a ranked list of words, where the ten most likely words are presented. Through examining the topics, one can get a quick overview of the content of the corpus.

**Fig. 8.4** Topic modeling is an unsupervised basic computational tasks in hNLP. Given a corpus, two types of output are generated: topics defined as distributions

In our example, we see that our documents are a mixture of articles in the fields of clinical, public health, informatics, and biological domains. Themes that emerge from the analysis include obesity (topic 1), microbiology (topic 19), and electronic health records (topic 4). Because the topic modeling task is unsupervised, the discovered topics do not always depict actual themes, but can sometimes elicit groups of words representative of the genre of texts analyzed. Topic 3 in our example is such a topic, where the most highly ranked words are common to the genre of biomedical studies.

Beyond utility of topic modeling as exploratory technique for large corpora, it is a clustering technique which can be found useful in many other applications. For instance, in a machine learning application that leverages both text and other types of data.

### 8.3.2 Text Labeling

In Text Labeling tasks, the input is text, either in its entirety or a fragment, and the output is a label or a set of labels. Examples of applications in healthcare, consumer health, and biomedicine that use text labeling abound and

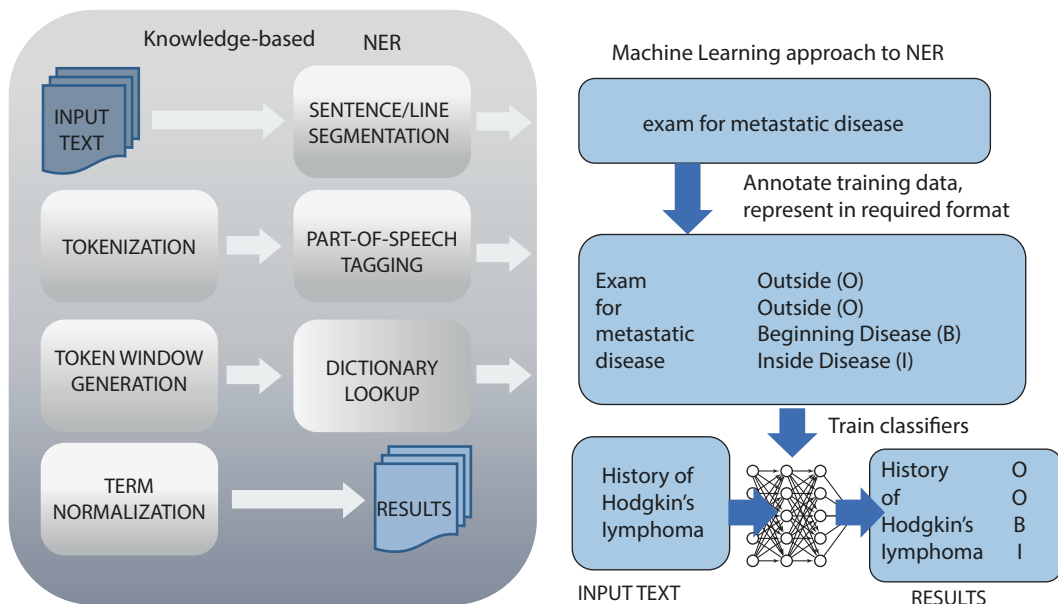

over words in the corpus, and an inference mechanism to assign topic assignments to any new document

some are already discussed in ▶ Sect. 8.2, but we list here a few examples:

- Automated coding of discharge summary according to diagnostic codes. This is an example of text labeling task where the input is an entire document – a discharge summary, the clinical note authored at the end of a hospital admission by a physician – and the output is a set of diagnostic codes, where the codes are chosen from a taxonomy, e.g., ICD-10. This task is typically carried out in hospital for billing and administrative goals, and the tasks are done in a semi-automated fashion with coders, professionals trained to select the appropriate codes (Resnik et al. 2006).
- Sentiment analysis of hospital reviews written by health consumers is another example of text labeling task (Greaves et al. 2013). There, a short text written in lay language is labeled according to a single label – its polarity or sentiment. In fact, it might even be a fragment of the text at a time that gets labeled according to its sentiment.

Most approaches to this task use classification techniques from the field of machine learning and thus require a training set of text inputs

**Fig. 8.5** Two approaches to named entity recognition. The approach on the left is a schematic representation of MetaMap – a knowledge-based tool for NER. The right side depicts an abstraction of a machine learning approach to NER. Provided with the following note as input: “Indication: Ca history, exam for metastatic disease, Impression: 1.5 cm nodule in the left midlung zone may contain calcium.” MetaMap will output the following:

- C0582103: exam: Medical Examination : [hlca]: 0 : 4 : 0.0
- C0027627: metastatic disease: Neoplasm Metastasis : [neop]: 9 : 18 : 0.0
- C4284036: exam: Exam : [fctn]: 0 : 4 : 0.0
- C2939420: metastatic disease: Metastatic Neoplasm : [neop]: 9 : 18 : 0.0

and their associated labels, although rule-based approaches are also a possibility, e.g., in labeling sections of clinical notes (Denny et al. 2008). Which features to include and how to represent them depends on the task at hand. For instance, in automated diagnosis coding, word-level representations described in ► Sect. 8.4 have been found helpful, as well as simple bag-of-words approaches.

### 8.3.3 Sequence Labeling

The task of sequence labeling is a specific case of text labeling. In sequence labeling, we are keeping track of the order in which textual units occur (be it words or text fragments), and the approaches work better at labeling the entire sequence jointly. Here are two examples of sequence labeling tasks in health-related texts.

We focus on a traditional example for sequence labeling, namely, **named entity recognition** (NER). NER is a classic task of general NLP and in the health domain. The task consists of identifying within a text the different mentions of different types of entities as shown in ► Fig. 8.5. The task is difficult because we don’t know in advance how many words comprise the entity, e.g., *lymphoma* is a single word, *Hodgkin’s lymphoma* is a two-word phrase, but many other terms include these entities:

- non-Hodgkin’s lymphoma of lung,
- Hodgkin’s lymphoma of lung (without the non), and
- non-Hodgkin’s lymphoma.

Each one of these phrases is a different term, and sometimes nested recognition might be needed, e.g., if a clinician is looking for all patients with lymphoma grouped by the type and location of the lesion, we will need to identify the full names, as well as the nested mentions of lymphoma. Sequence labeling is

also difficult because terms are often ambiguous with respect to the type of entity they instantiate. The context in which the term occurs might help identify the correct entity type and link the entity to its class or an appropriate identifier in a terminology. For instance, the term “ca” in itself in the clinical text is ambiguous towards two frequent entity types: (as in calcium) measurement or the neoplasm UMLS semantic type (as in cancer).

The output provides UMLS identifiers, positional information of the terms in the text, and their semantic types. Note that in addition to ambiguity of **Ca** that will not be easy to disambiguate to cancer because the note also contains the term calcium, **Exam** is also ambiguous due to the different semantic types assigned to physical exam. Also note the fine-grained differences in normalizing metastatic disease. The output of the machine learning model trained to label disease name sequences will identify Hodgkin’s lymphoma as disease.

Like in text labeling, sequence labeling rely on supervised approaches. Training data with sequences fully annotated are required as training examples, see ■ Fig. 8.5. While probabilistic approaches like Hidden Markov Models and Conditional Random Fields were historically used for this task, neural architectures have shown impressive results in sequence learning. Recurrent neural networks (LSTM, bi-LSTM, GRUs) in particular encode in their architecture the ability to handle almost arbitrarily long sequences and keep track of the relevant words within them (whether long-term dependency or short-term dependency) (Habibi et al. 2017).

### 8.3.4 Relation Extraction

Similarly to NER, relation extraction can be decomposed into relation detection and determination of the relation type. Until recently, research in biomedical relation extraction was limited to protein-protein interactions and gene binding, primarily due to availability of

resources created for BioCreative evaluations (Krallinger et al. 2008). In the clinical domain, relations of interest are those between medical problems and treatments, problems and tests, problems and genes, and genes and treatments (the latter two becoming increasingly important due to interest in translational research and precision medicine). The resources for extraction of some of these relations are available due to the i2b2 relation extraction challenge (Uzuner et al. 2011). Another source of literature partially annotated for entities and relations is the pharmacogenomics knowledge base (PharmGKB) (Barbarino et al. 2018). Among other activities, PharmGKB provides literature annotated for genetic variants and gene-drug-disease relationships and annotates associations between genetic variants and drugs, and drug pathways.

Initially, the existence of relations between entities was assumed if the entities co-occurred more frequently than by chance in a unit of text, such as a MEDLINE abstract or a sentence. Mutual information, chi-square and log-likelihood ratio were often used to extract co-occurrence-based relations (Hakenberg et al. 2012). This approach has two drawbacks: (1) the results are often noisy and (2) the nature of the relations is undefined.

Both the knowledge-based and statistical approaches are used to extract specific relations. Knowledge-based approaches often involve lexical-semantic or syntactic-semantic patterns. For example, to extract a relationship between a complication of a patient’s health condition and its cause, we can define a “Complications of” relation. The expressions: “status post”, “secondary to”, and others indicate the presence of the “Complications of” relation. These expressions can be combined with semantic categories to form patterns for a rule-based system. For example, the “[concept Problem][s/p][concept any|word noun]” pattern, in which “s/p” represent the set of the indicator expressions. A rule-based system that extracts “treats” relations can include the following rule:

If dependency path contains a treatment indicator, Procedure and Problem  $\Rightarrow$  (treats, Procedure, Problem)

where treatment indicators are stored in a **gazetteer** and Procedure and Problem are identified by one of the NER tools presented above. As common for the rule-based methods, this approach has relatively low recall and is potentially brittle. The currently better-performing systems use supervised machine learning. Most supervised machine learning methods assume that the entities are identified by a NER tool and require positive examples in which the relations and entities are annotated and negative examples in which there are no relations between annotated entities. Given these examples, classifiers (Support Vector Machines in the near past, and currently Deep Learning frameworks (Peng et al. 2018)) are trained to determine if a specific relationship between the candidate entities exists. If several relations are possible between the two entities, for example, drug causing a problem or drug treating a problem, a two-step approach can be applied: first determining if a relation exists; and then determining the type of the relation. As with other classification tasks, feature selection is one of the factors determining the success of the method. In addition to the standard “bag of words” in the windows preceding, following, and between the two concepts, features often used in relation extraction are: the semantic types of the concepts; the distance between the concepts, parts of speech, paths to the root of the parse tree and dependency relations between the concepts.

### 8.3.5 Template Filling

Often, n-ary relations, e.g., the size, the location and the borders of a lesion, are of interest. Capturing such information requires event (frame) extraction and is viewed as template filling task.

Biomedical events involve a change in the state of biomedical objects. Examples of the events are gene expression, protein binding and regulation in the biological domain and medication or phenotype events in the clinical domain. Events usually involve multiple entities and relations between the entities and can be nested. Medication events, as shown in

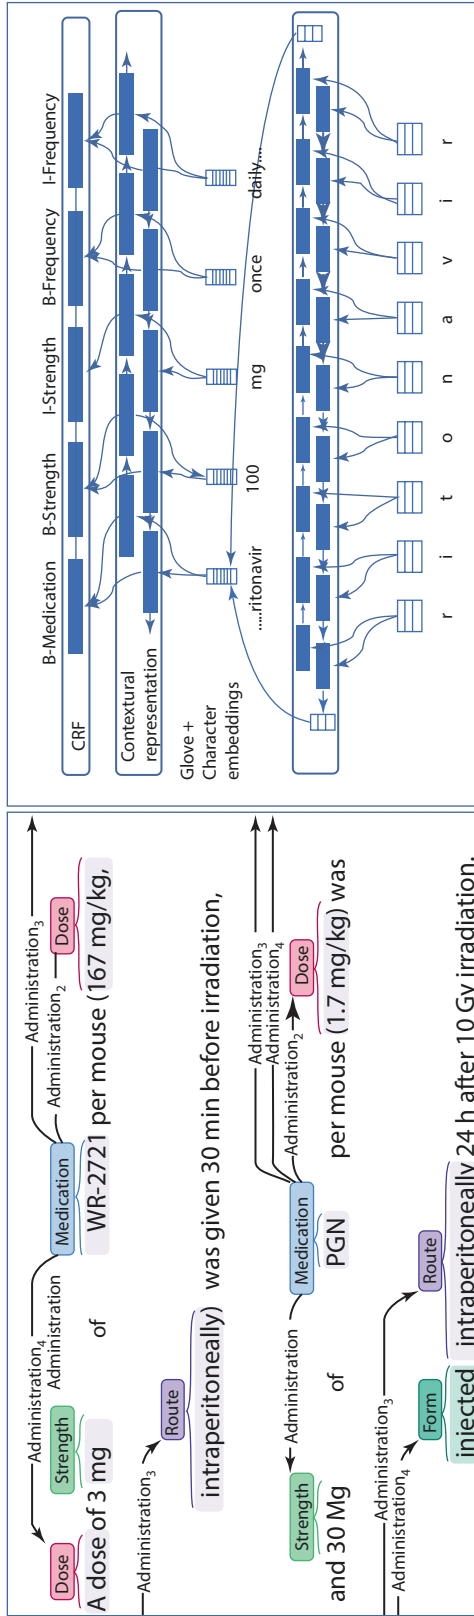

■ Fig. 8.6, exemplify relatively simple events: a medication event involves a drug, its form, dosage, administration route, duration, and indications.

The complex biomolecular events are usually more involved. For example, consider the phrase “SYK-TLR4 binding increases upon TLR4 dimerization and phosphorylation” (PMID: 22776094) that introduces a complex positive regulation event in which binding of spleen tyrosine kinase (SYK) to the toll-like receptor-4 (TLR4) is regulated by two simple events: TLR4 dimerization and phosphorylation. Secondary arguments of the events may provide additional information about the event, such as the specific domain or region of the theme of the event. For example, in “binding of SYK to the cytoplasmic domain of toll-like receptor-4 (TLR4)”, cytoplasmic domain is the secondary argument associated with the TLR4 theme of the binding event.

Many systems for event recognition are built as pipelines that start with recognizing protein names. For example, one approach to extracting biomedical events on PubMed scale (Björne et al. 2010) is to use publicly available NER tools as the first step in extraction of protein events from PubMed abstracts. In the subsequent steps, the extraction pipelines rely on the graph representations of sentence syntax and semantics, which we will present in the next section. The syntactic graph generated by a dependency parser and the identified named entities are used to generate a semantic graph for each sentence independently. The system uses the graphs as the source of features to supervised machine learning for event trigger and edge detection, which are followed by the rule-based event construction step.

## 8.4 Linguistic Knowledge and Representations

It is important to know the principles of linguistics and computational linguistics that, when incorporated in computational tasks, help achieve better results. Processing of language is not as simple as applying a pipeline of independent modules: one to determine

• **Fig. 8.6** Annotation of a medication event on the left using brat annotation tool (Stenetorp et al. 2012) and on the right, a Long Short-Term Memory (LSTM) neural network with a Conditional Random Field (CRF) layer using character embeddings trained to extract medication frames. Character level word representations are extracted using Bi-directional LSTM and concatenated with word embeddings. These word representations feed into another Bi-LSTM layer to extract contextual representations of the words. The contextual representations are fed to the CRF layer to decode the best label sequence

• **Fig. 8.6** Annotation of a medication event on the left using brat annotation tool (Stenetorp et al. 2012) and on the right, a Long Short-Term Memory (LSTM) neural network with a Conditional Random Field (CRF) layer using character embeddings trained to extract medication frames. Character level word representations are extracted

tokens, one to assign part-of-speech tags to tokens and to parse the syntax, one to interpret the meaning of a sentence, and one to resolve the discourse-level characteristics of the text. In reality, all linguistic levels influence each other. Low-level decisions about how to tokenize a string impact named-entity recognition; determining which sense to attribute to a named entity depends on its place in the syntactic tree, the pragmatics of the text, and its place in the discourse structure. How to model these interactions is one of the primary open research questions of natural language processing, which is currently addressed by modeling the tasks jointly, e.g., using deep learning approaches (James et al. 2013). Although language processing is not a simple pipeline, the practical applications still often approximate the process as one, and linguistic knowledge contributes to performing the basic tasks and modeling the interactions.

Linguistic levels consist of word-level representations (tokens and morphology; sentence-level representations (syntax and semantics); and document-level representations (pragmatics and discourse). Linguistic knowledge is captured in lexicons, domain knowledge, e.g., lists of diseases and drugs can be found in terminologies, and domain semantics, such as relations among diseases and drugs comprises ontologies.

### 8.4.1 Terminological and Ontological Knowledge

In the biomedical and clinical domains, interpreting text might require extensive background knowledge, as many facts are implied, e.g., inferring that a patient is likely hypertensive or has an edema if loop diuretics are prescribed, even though there are no explicit mentions of either high blood pressure or swelling in the text. Ontologies contain some of the background knowledge, and some can be learned from text.

The Unified Medical Language System (UMLS), including the Metathesaurus, Semantic Network, and the Specialist

Lexicon) – can be used as a knowledge base and resource for NLP tasks. MedDRA and RxNorm, two of the over 130 sources contributing to the UMLS, are examples of terminologies specific to adverse events and medications, respectively. They are particularly helpful in the clinical domain, in biosurveillance, pharmacovigilance and in pharmacogenomics. The UMLS Metathesaurus is organized by concept. It preserves the meaning and structure of the contributing sources and links alternative surface representations of a concept in many languages. It also establishes relationships between concepts. All concepts in the Metathesaurus are assigned to at least one Semantic Type from the Semantic Network. Most English strings in the Metathesaurus also appear in the SPECIALIST Lexicon. The Specialist lexicon provides detailed syntactic knowledge for words and phrases and includes a comprehensive medical vocabulary. It also provides a set of tools to assist in NLP, e.g., a lexical variant generator.

Although ontologies and lexicons are maintained and regularly updated, the language changes, new concepts enter the language, and terms fall out of use and become obsolete (although data represented with the terms may persist). The biomedical and health domains are highly dynamic in the influx of new terms (e.g. new drug names, but also sometimes new disease names, like COVID-19, SARS and H1N1). Modern corpus-based approaches compensate for that lag leveraging the existing knowledge. For example, all diseases in the UMLS can be marked in PubMed and the representation of disease can be learned as described in the section on word embeddings. A new disease such as COVID-19 can then be recognized as such using its context and the learned representation of *Disease*.

### 8.4.2 Word-Level Representations

#### ■ Tokens

**Tokens** are basic language units defined based on their utility for solving a specific language

processing task. The units include morphemes, words (often morpheme sequences), numbers, symbols (e.g. mathematical operators), and punctuation. The notion of what constitutes a token is far from trivial. The primary indication of a token in general English is the occurrence of white space before and after it; however there are many exceptions: a token may be followed by certain punctuation marks without an intervening space, such as by a period, comma, semicolon, or question mark, or may have a “-” in the middle, as shown in ► Example 8.1:

► Example 8.1

... a decoy receptor for IL-2 in the T cell ...  
 ... IL 2-regulated genes ...  
 ... Il2 and Csf2 are increased as T-cells ... ◀

The three snippets in ► Example 8.1 contain three different spellings for IL2. Ideally, we would like to link all three surface forms to interleukin-2. To achieve this normalization, we need a tokenizer that will treat the dash and the white space equally and segment IL2 into IL and 2 (or merge IL and 2 in the first two example snippets.)

In biomedicine, periods and other punctuation marks can be part of words (e.g., *p.o.* means *per os* (*by mouth; orally*) in the clinical domain, and *M03F4.2A*, is a gene name that includes a period.) Moreover, punctuation marks are used inconsistently, thereby complicating the tokenization process: In clinical text, it is common to abbreviate “discontinue” as *d/c*, without as *w/o*, but it is also common to write *s/p* for status post, and, finally, use slashes in measurements and units. In addition, chemical and biological names often include parentheses, commas and hyphens, for example (*w*)*adh-2*, which also complicate the tokenization process. For example, replacing non-alphanumeric characters with spaces will prevent us from correctly identifying entities in the following sentence: “PBMC of HLA-DR3(+) but not HLA-DR3(-) cured TB patients.” For agglutinative languages, tokenization needs to be augmented by segmentation as shown in ► Example 8.2.

► Example 8.2 *Rückschmerzen nach Brustwirbelbruch*

Ich habe oft Schmerzen im Rücken und in der Schulter. [Back pain after thoracic fracture: I often have pain in the back and in the shoulder]. ◀

In this example blog post, *Rückschmerzen* in the title needs to be split into *Rück[en]* (back) and *Schmerzen* (pains). In addition, to identify the reason for back pain, information about the fracture (*bruch*) has to be separated from its location (thoracic spine – *Brust – wirbel*.)

Some thought should be given to upper and lower case in the original text. In some situations, it makes sense to keep all tokens in lowercase, as it reduces variations in vocabulary. But in others, it might hinder further NLP: in both the biology and clinical domains, there are many acronyms, which when lowercased, might be confused with regular words, such as *CAT* (*computerized axial tomography*) and *cat* or *FISH* (*fluorescent in situ hybridization*) and *fish*.

**Morphology** concerns the combination of morphemes (roots, prefixes, suffixes) to produce words or lexemes, where a lexeme generally constitutes several forms of the same word (e.g. activate, activates, activating, activated, activation). There has been little work concerning morphology in the field of NLP in the biomedicine and health domains, especially for the English language. In other languages that are morphologically rich (e.g., Turkish, German, and Hebrew), encoding morphological knowledge is necessary. For example, morphological proximity can identify important terminological relations (Claveau and L’Homme 2005) or generate definitions of medical terms (Deléger et al. 2009b).

■ Word Embeddings

**Word embedding** is a feature learning techniques in NLP in which words or phrases from the vocabulary are numeric vectors such that similar words will have similar vectors. Word embeddings have two functions: they capture the meaning of a word using its context and, at the same time, condense the representation

of the word into a vector, e.g., a vocabulary of thousands of words can be compressed into a 300-dimensional vector. The idea of “recognizing a word by the company it keeps” originated from Firth (1957). One of the earliest corpus-based implementations, Brown clustering, aggregated words into classes using hierarchical clustering (Turian et al. 2010), and now deep learning provides more robust approaches to pre-computing representations of words using large corpora, e.g., 2.5 billion Wiki words. The growing family of text embeddings and pre-trained language models started with Word2Vec (Mikolov et al. 2013), and now includes GloVe (Pennington et al. 2014), fastText (Bojanowski et al. 2016), ELMo (Peters et al. 2018), BERT (Devlin et al. 2018), GPT (Radford et al. 2019), and BART (Lewis et al. 2019), to name a few. The language models, such as BERT, have been shown to be open to fine-tuning for specific NLP tasks. Domain-specific embeddings and models trained on PubMed and clinical text also exist, and have been shown superior to those pre-trained on the open-domain text. BioBERT, for example, significantly advanced the state-of-the-art for biomedical named entity recognition, relation extraction, and question answering (Lee et al. 2019).

#### ■ Spelling Variants and Errors

In addition to common American English and British **spelling variants**, such as -or/-our (e.g., color/colour), e/ae, e/oe, er/-re (e.g., liter/litre), and -ize/-ise, generic drug names may also differ (e.g., adrenaline (British) vs. epinephrine). The complex origins and spelling of the biomedical terms often lead to **misspellings**. Misspellings in the published literature are relatively rare, but the queries submitted to the search engines are often misspelled. Clinical notes and informal communications also often contain misspelled terms. Clinicians, when typing free text in the EHR, do so under time pressure and generally do not have the time to proofread their notes carefully. In addition, they frequently use abbreviations (e.g. *HF* for *Hispanic female* or *heart failure*, *2/2* for *secondary to* or a date), many of which are non-standard and ambiguous. For patients and health consumers, when

posting content online, misspellings, typos, and non-standard abbreviations are pervasive like in the rest of the social Web. Ignoring these variations may cause an NLP system to lose or misinterpret information. At the same time, errors can be introduced when correcting the typos automatically. For instance, it is not trivial to correct *hypetension* automatically without additional knowledge because it may refer to *hypertension* or *hypotension*. This type of error is troublesome not only for automated systems, but also for clinicians when reading a note, as this phenomenon is aggravated by the large amount of short, misspelled words in notes. In the clinical domain, misspellings can be found even in the definitions of clinical variables.

### 8.4.3 Sentence-Level Representations

#### ■ Sentence Boundary Detection

Detecting the beginning and end of a sentence may seem like an easy task, but it is highly domain dependent. Not all sentences end with a punctuation mark (this is especially true in texts with minimal editing, such as online patient posts and clinical notes entered by physicians). Sentences in scientific publications are usually well-formed and delimited by final punctuation, primarily a period. Some care has to be taken to avoid breaking up sentences on periods used in abbreviations (e.g., vs.) and in honorifics, chemical names, and decimal numbers (as discussed in tokenization). In most cases an off-the-shelf sentence tokenizer is expected to be highly accurate.

The informal biomedical text is much harder to split into meaningful utterances. Clinical notes often contain table-like structures and lists. Moreover, some electronic health records might enforce a certain line length, which could be violated by, for example, a de-identification tool. Therefore, custom solutions might be needed to detect end of sentences in these texts.

**Syntax** concerns the categorization of the words in the language, and the structure of the phrases and sentences. Each word belongs to

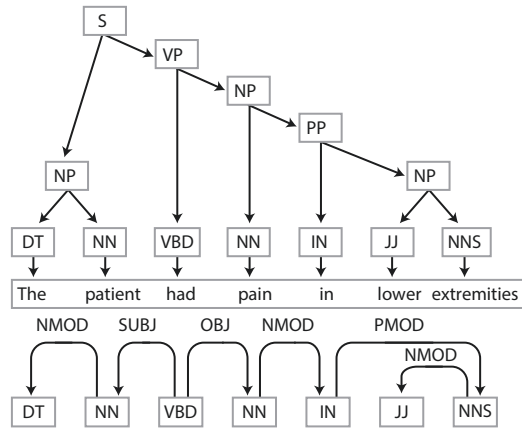

one or more parts of speech in the language, such as noun (e.g. chest), adjective (e.g. mild), or tensed verb (e.g. improves). Lexemes can consist of more than one word as in foreign phrases (ad hoc), prepositions (along with), and idioms (follow up, on and off). Lexemes combine in well-defined ways and according to their parts of speech, to form sequences of words or phrases, such as noun phrases (e.g. severe chest pain), adjectival phrases (e.g. painful to touch), or verb phrases (e.g. has increased). Each phrase generally consists of a main part of speech and modifiers, e.g. nouns are frequently modified by adjectives, while verbs are frequently modified by adverbs. The phrases then combine in well-defined ways to form sentences (e.g. “he complained of severe chest pain” is a well-formed sentence, but “pneumococcal vaccine how often?” is not).

General English imposes many restrictions on the formation of sentences, e.g. every sentence requires a verb, and count nouns (like cough) require an article (e.g., a or the). Clinical language, in contrast, is often telegraphic, relaxing many of these restrictions of the general language to achieve a highly compact form. For example, clinical language allows all of the following as sentences: *the cough worsened*, *cough worsening*, and *cough*. Because the community widely uses and accepts these alternate forms, they are not considered ungrammatical, but constitute a sublanguage (Friedman et al. 2004).

### ■ Representation of Syntactic Knowledge

Phrases and sentences can be represented as a sequence where each word is coupled with its corresponding part of speech as shown in Fig. 8.7. For example, *Severe joint pain* can be represented as *Severe/adjective joint/noun pain/noun*. Formalisms that can be used to represent syntactic linguistic knowledge include probabilistic context free grammars (Jurafsky and Martin 2019), which, along with dependency formalisms are widely used in language processing.

Dependency is a binary asymmetrical relation between a head and its dependents or modifiers. The head of a sentence is usually a tensed verb. Thus dependency structures are

■ **Fig. 8.7** A syntactic parse tree for the sentence “The patient had pain in lower extremities” according to the context-free grammar is shown above the sentence. Notice that the terminal nodes in the tree correspond to the syntactic categories of the words in the sentence. The parse tree below the sentence, is in a dependency grammar framework

basically directed relations between words. For example, in the sentence, “The patient had pain in lower extremities”, the head of the sentence is the verb “had”, which has two arguments, a subject noun “patient” and an object noun “extremities”, that modifies or is dependent on “patient”, while “in” is dependent on “pain”, “extremities” is dependent on “in”, and “lower” is dependent on “extremities”. As such, in a dependency grammar, the relations among words and the concept of head in particular (e.g. “extremities” is the head of “lower”) is closer to the semantics of a sentence.

### ■ Semantics

Semantics concerns the meaning or interpretation of words, phrases and sentences, generally associated with real-world applications. There are many different theories for representation of meaning, such as logic-based (e.g., first order logic and lambda calculus), frame-based, conceptual graph formalisms, and distributional semantics, i.e., vector representations learned from data (Jurafsky and Martin 2019).

Each word has one or more meanings – word senses (e.g. resistance, as in psychological resistance, social resistance, multidrug

resistance, and capillary resistance), and other terms may modify the senses (e.g. no, as in no fever, or last week as in fever last week). Recognizing polysemy or ambiguity of the word is important. Complementary to the phenomenon of polysemy, there are often terms that are different variations of the same concepts (synonymy). For instance, the term blood sugar is often used by health consumers to refer to a glucose measurement, but it is used rarely if ever in the clinical literature or in clinical notes.

Additionally, the meanings of the words combine to form a meaningful sentence, as in “there was thickening in the renal capsule”). Representation of the semantics of general language is extremely important, but the underlying concepts are not as clear or uniform as those concerning syntax. Interpreting the meaning of words and text in general is very challenging. In biomedical informatics, interpreting the meaning of text focuses, largely, on entity linking (i.e., representing a word or group of words with a unique semantic concept from a relatively small number of well-defined semantic types, e.g. medication, gene, disease, body part, or organism.) The semantics of phrases and sentences is also restricted to a smaller set of patterns than in general language (e.g. medication-treats-disease, gene-interacts-with-gene).

There are often several ways to express a particular medical concept as well as numerous ways to express modifiers for that concept. For example, ways to express severity include faint, mild, borderline, 1+, 3rd degree, severe, extensive, and moderate. Often, to complicate matters, modifiers can be composed or nested. For instance, in the phrase “no improvement in pneumonia,” improvement is a change modifier that modifies the concept pneumonia, and no is a negation marker that modifies improvement (not pneumonia). Complex semantic structures containing nesting can be represented using a semantic grammar, which is a context free grammar based on semantic categories. An alternative representation would facilitate processing by flattening the nesting. In this case, some information may be lost but ideally only information that is

not critical. For example, *slightly improved* may not be clinically different from *improved*. Since this type of information is fuzzy and imprecise, the loss of information may not be significant. However, the loss of a negation modifier would be significant. Another such example concerns hedging, which frequently occurs in radiology reports as well as in the scientific articles. Implementing a semantic grammar would require a large corpus that has been annotated with both syntactic and semantic information. Since a semantic grammar is domain and/or application specific, annotation involving the phrase structure would be costly and not portable, and therefore is not generally done.

#### 8.4.4 Document-Level Representations

As is the case for text in general, documents within the biomedical domain are expected to have a certain structure. Text or discourse structure refers to the way in which authors organize information within documents. The organization of biomedical text is reflective of both the type of information being conveyed as well as its intended audience. The structure of biomedical text aids in its comprehension by the reader, and can be utilized in performing various natural language processing tasks. The structure of biomedical text can be examined at a local or global level. The local level primarily concerns coherence and cohesion, aspects of structure that connect text and give it meaning, whereas the global level concerns aspects of the overall organization and rhetorical structure of a document, such as its sectioning.

The cohesive devices responsible for the local structure of text play an important role in comprehension of biomedical documents. The recognition of phenomena such as coordinating constructions, anaphora, as well as ellipsis is needed to represent biomedical text at the document level. In this section, we exemplify discourse processing with automated resolution of referential expressions and then discuss pragmatics, which concerns everything

extraneous to the text that contributes to its meaning and context. In clinical and health-consumers language processing, the context is sometimes readily accessible and sometimes easily extractable from datasets, e.g., medication orders, who wrote the text, at what time, etc. Interaction patterns can be inferred from the datasets as well.

#### 8.4.4.1 Automated Resolution of Referential Expressions

Determining which words or phrases in a text referring to the same entity, called **coreference resolution** can draw on both syntactic and semantic information in the text.

Syntactic information for resolving referential expressions includes:

- Agreement of syntactic features between the referential phrase and potential referents
- Recency of potential referents (nearness to referential phrase)
- Syntactic position of potential referents (e.g. subject, direct object, object of preposition)
- The pattern of transitions of topics across the sentences

Syntactic features that aid the resolution include such distinctions as singular/plural, animate/inanimate, and subjective/objective/possessive. For instance, the inanimate pronoun “it” usually refers to things, but sometimes does not refer to anything when it occurs in *cleftconstructions*, such as “it was noted”, “it was decided to” and “it seemed likely that”.

Referential expressions are usually very close to their referents in the text. The syntactic position of a potential referent is an important factor. For example, a referent in the subject position is a more likely candidate than the direct object, which in turn is more likely than an object of a preposition. Centering theory accounts for reference by noting how the center (focus of attention) of each sentence changes across the discourse (Grosz et al. 1995). In this approach, resolution rules attempt to minimize the number

of changes in centers. Semantic information for resolving referential expressions involves consideration of the semantic type of the expression and the way it relates to potential referents (Hahn et al. 1999; Kilicoglu 2016).

#### 8.4.5 Pragmatics

Pragmatics concerns how the intent of the author of the text, or, more generally, the context in which the text is written, influences the meaning of a sentence or a text. For example, in a mammography report “mass” generally denotes breast mass, whereas a radiological report of the chest denotes mass in lung. In yet a different genre of texts, like a religious journal, it is likely to denote a ceremony. Similarly, in a health care setting “he drinks heavily” is assumed to be referring to alcohol and not water. In these two examples, pragmatics influences the meaning of individual words. It can also influence the meaning of larger linguistic units. For instance, when physicians document the chief-complaint section of a note, they list symptoms and signs, as reported by the patient. The presence of a particular symptom, however, does not imply that the patient actually has the symptom. Rather, it is understood implicitly by both the author of the note and its reader that this is the patient’s impression rather than the truth. Thus, the meaning of the chief-complaint section of a note is quite different from the assessment and plan, for instance.

Another pragmatic consideration is the interpretation of pronouns and other referential expressions (there, tomorrow). For example, in the two following sentences “An infiltrate was noted in right upper lobe. It was patchy”, the pronoun “it” refers to “infiltrate” and not “lobe”. In a sentence containing the term “tomorrow”, it would be necessary to know when the note was written in order to interpret the actual date denoted by “tomorrow”. As mentioned above, in the biomedical domain, pragmatics can be encoded through the semantic lexicon and rules about the discourse of a text.

## 8.5 Practical Considerations

The recent years see a steadily growing demand for biomedical language processing. The traditionally manual tasks, such as assigning medical billing codes for reimbursement, indexing biomedical literature, populating biological knowledge bases, and providing evidence for clinical decision support are assisted by information extraction and classification tools. With few exceptions, such tools are not yet widely used, and the need for them exceeds their supply.

When embarking on adding natural language processing to the workflow, practitioners and users often ask where to start and if there are any tools, corpora, and resources available. These excellent questions should be asked, but with the exception of few well-established resources, we refrain from pointing to specific collections because the field is extremely active and fast moving. The questions, therefore, should be answered at the time of need using a literature search, including searching PubMed, a widely used and growing collection of citations in biomedical literature and PubmedCentral, a growing collection of open access full text biomedical articles.

Independently of the specific task, corpora and tools, any NLP endeavor starts with dealing with raw data, which entails dealing with file formats, character sets and machine settings. Bird et al. (2019) discuss the practical considerations of working with unstructured text in Python.

Specific biomedical software toolkits for many tasks, such as named entity recognition, introduced in ► Sect. 8.2.1, or modality detection, are freely available and widely used. Many of the existing approaches are built using the open domain tools, such as NLTK (Bird et al.), OpenNLP (openNLP) and UIMA (UIMA). Many solutions to specific problems leverage the existing tools to build pipelines that include the existing tools, e.g. MetaMap for NER, combined with the local implementation of the task-specific algorithms.

### 8.5.1 Patient Privacy and Ethical Concerns

As an NLP system deals with patient information, its designers must remain cognizant of the privacy and ethical concerns entailed in handling protected health information. In the clinical domain for instance, the Health Insurance Portability and Accountability Act (HIPAA) regulates the protection of patient-sensitive information (see ► Chap. 12 for a detailed description of privacy matters in the clinical domain). Online, patients provide much information about their own health in blogs and online communities. While there are no regulations in place concerning online patient-provided information, researchers have established guidelines for the ethical study and processing of patient-generated speech (Eysenbach and Till 2001).

The somewhat opposing needs for large amounts of data for NLP processing and protecting patients' privacy, led to development of de-identification and anonymization tools (Meystre et al. 2010). Many researchers are exploring transfer learning (Ruder 2019), where the tools are trained on openly available data, e.g., general domain or veterinary, or synthetically generated life-like data and then fine-tuned on the small amounts of task and domain specific data (Wu et al. 2019).

### 8.5.2 Good System Performance

If the output of an NLP system is to be used to help manage and improve the quality of healthcare and to facilitate research, it must have high enough performance for the intended application. Evidently, different applications require varying levels of performance, and the desired level of performance needs to be discussed with the intended users of the system. While discussing a system's performance, it is important to make sure the users understand the benefits and the limitations of the approach and have reasonable expectations with respect to the results, prob-

ability and nature of errors, and potential requirements for curation. An example application is finding and ranking patients with respect to eligibility for a cohort. Depending on the nature of the cohort, the users might want to see only the patients for which information was extracted with high accuracy, e.g., for a retrospective study on a large dataset, or all patients that might fit the criteria, e.g., identifying patients at risk for disease exacerbation. These pragmatic questions are external to NLP processing, but still need to be answered to optimize the models and approaches as needed.

### 8.5.3 System Interoperability

---

NLP-based systems are often part of larger applications. There must be seamless integration of the NLP component into its parent application. This is equally important in the clinical domain, where the system must follow standards for interoperability among different health information technology systems, such as Health Level 7 (HL7) and the Clinical Document Architecture (CDA; see ► Chap. 7), and in processing biomedical literature and social media, where the system should be able to communicate with the downstream applications. For example, information extracted automatically to support database curation, e.g., model organism databases, should be provided to curators within their workflow, along with an easy access to the context that suggested these terms.

## 8.6 Research Considerations

---

Biomedical natural language processing has a wide range of practical applications. It facilitates clinical and biomedical research, quality assurance of clinical care and delivery of information to patients. This wide range of tasks stimulates an ongoing and constantly growing research of foundational principles of biomedical language processing. Due to the growing interest in literature-based dis-

covery, management of big data, secondary use of clinical data, clinical decision support, and population studies through social media, the demand for biomedical language processing has increased significantly and will continue growing.

Being primarily motivated by the needs of the domain, biomedical and clinical NLP always was data driven. All NLP research starts with exploratory data analysis that takes into account the context in which the text was created and the context in which it is used. Some of the text always needs to be annotated to create gold standards for evaluation, and, depending on the approach that is researched, e.g. supervised machine learning, large amounts of annotated text might be needed to train the models. Annotation takes time, effort and money, so leveraging the existing annotated collections and approaches that allow adding minimal amounts of task-specific annotations to improve the results is growing in popularity.

Before an NLP-based system can be used for a practical task, it must be evaluated carefully, both **intrinsically** and **extrinsically**, in a setting where the system will be used. A variety of techniques exists for the evaluation and testing of natural language processing programs. They vary with respect to cost, repeatability, and the kind of information that is obtainable from them. In this section, we first discuss data annotation and annotation guidelines, and then present evaluation principles and approaches.

### 8.6.1 Data Annotation

---

During the initial task definition and data exploration for gold standard construction, an annotation schema is established to capture the minimal amount of annotations sufficient to perform the task. At the same time, annotation guidelines are created to describe the task, the schema and the annotation rules. There are ongoing community efforts, starting with The Canon group (Evans et al. 1994), to create established representations for certain

■ Fig. 8.8 Document annotation process for detection of Adverse Drug Reactions

aspects of information, such as the different modifiers of concepts and the relations among concepts that can occur in texts. Although in most cases the specific datasets are still using local representations, the de-facto standard is standoff annotation that provides offsets of the strings and meta-description to represent concepts. More variety exists in representing relations and events.

Once the initial schema is established, a small number of documents is annotated by a group of annotators to determine if the schema allows annotating all required entities and relations and if the guidelines are clear. The next step is to finalize and freeze the guidelines, and then annotate the required number of documents, ensuring some overlap to measure inter-annotator agreement. The guidelines can be modified during annotation for one purpose only: to add information about a new case that was not covered by the existing rules. ■ Figure 8.8 illustrates the process of creating a specific corpus of drug labels annotated with Adverse Drug Reactions and all steps of this annotation effort (Demner-Fushman et al. 2018).

## 8.6.2 Evaluation

Evaluating the performance of an NLP system is crucial whether the NLP system targets the end-users directly or as a part of a larger application. In the biomedical NLP domain, evaluation brings together two traditions: evaluation in biology and clinical research and evaluation of software, both with respect to its output and usability in the eyes of the intended end-users.

Biomedical and clinical researchers expect health technology assessment to include “properties of a medical technology used in health care, such as safety, efficacy, feasibility, and indications for use, cost, and cost effectiveness, as well as social, economic, and ethical consequences, whether intended or unintended” (IOM 1985). Measuring the social, economic, and ethical consequences of NLP systems in biomedical domain has not been systematically researched. Several studies looked into social consequences of delivering information to clinicians. For example, over 500 clinicians interviewed by Lindberg et al. used MEDLINE searches to choose the most

appropriate test, make the diagnosis, develop and implement a treatment plan, maintain an effective physician-patient relationship, and modify patients' health behaviors. In 8 cases, MEDLINE was credited with saving a patient's life, and in another 17 with increasing the length of life (Lindberg et al. 1993b).

The efficacy, feasibility and cost of NLP systems and tools, on the other hand, are relatively easy to measure and these evaluations follow the principles of the software evaluation tradition. The metrics described below were developed to evaluate the software performance using sets of benchmarks independent of the tasks for which the tools might be used. These intrinsic evaluations measure changes in the system's output caused by changes in the system's parameters, as well as the differences between systems that implement different algorithms. For example, we can compare different parsers against an established reference standard, such as the Penn Treebank (Taylor et al. 2003). Alternatively, in an extrinsic evaluation that measures a method's performance in a given task, we can ask what parser will improve the overall performance in a relation extraction task. Most of the large-scale evaluations (shared tasks) provide venues and generate collections that allow evaluating systems' performance in a specific task, e.g., the adverse drug reaction collection in Fig. 8.8 was used in a Text Analysis Conference evaluation (Roberts et al. 2017).

### 8.6.2.1 Evaluation Metrics

The most commonly used metrics for evaluations conducted by computational linguists are precision, recall, and F-measure. The clinical informatics community prefers referring to recall as sensitivity, and pairs it with specificity and the area under the ROC (Receiver Operating Characteristic) curve, if the task allows applying these metrics. The above metrics are based on the **confusion matrix** (or error matrix) and are often defined in terms of the four cells of the matrix:

- true positive (tp) – outputs correctly labeled as having the characteristics of interest, for example, tagging a string as gene name

- false positive (fp) – outputs incorrectly labeled as having the characteristics of interest, for example, tagging a string that is not a gene name as gene name
- true negative (tn) – outputs correctly labeled as not having the characteristics of interest, for example, tagging a string that is not a gene name as such
- false negative (fn) – outputs incorrectly labeled as not having the characteristics of interest, for example, failing to tag a string that is a gene name as gene name

In many NLP tasks, using metrics based on the true negative values is problematic because the number of true negatives is not countable. Even if we arbitrarily specify what constitutes a true negative for this task, the annotation effort for the reference set will become even more daunting and expensive than the efforts described above, and our solution will not solve the problem in general. Another reason to avoid measures based on true negatives, is the prevalence of negative results, for example, gene names will constitute a small percentage of an article, even in an article describing major pathways.

The three basic quantitative measures used to assess performance in an extrinsic or intrinsic evaluation are calculated as follows: Recall is the percentage of results that should have been obtained according to the test set that actually were obtained by the system:

**Recall** = Number of correct results obtained by system (TP) / Number of results specified in gold standard (TP + FN)

Precision is the percent of results that the system obtained that were actually correct according to the test set:

**Precision** = Number of correct results obtained by system (TP) / Total number of results obtained by system (TP + FP)

There is usually a tradeoff between recall and precision, with higher precision usually being attainable at the expense of recall, and

vice versa. The F-measure is a combination of both measures and can be used to weigh the importance of one measure over the other by giving more weight to one. If both measures are equally important, the F measure is the harmonic mean of the two measures. When reporting the results, an error analysis provides insights into ways to improve a system. This process involves determining reasons for errors in recall and in precision. In an extrinsic evaluation, some errors can be due to the NLP system and other errors can be due to the subsequent application component. Some NLP errors in recall (i.e. false negatives) can be due to failure of the NLP system to tokenize the text correctly, to recognize a word, to detect a relevant pattern, or to interpret the meaning of a word or a structure correctly. Some errors in precision can be due to errors in interpreting the meaning of a word or structure or to loss of important information. Errors caused by the application component can be due to failure to access the extracted information properly or failure of the reasoning component.

Understanding the errors is the first step in bringing the NLP applications closer to being incorporated in a wider range of biomedical and clinical text processing tasks.

## 8.7 Recapitulation and Future Directions

This chapter targets both the students and researchers looking for a broad introduction to health NLP prior to delving into this active field of research, and the informatics practitioners looking to use NLP for specific tasks or types of text. The chapter introduced NLP applications and emphasized the critical role that the context in which these applications are deployed plays when developing NLP solutions. It presented the basic computational tasks involved in most NLP applications and the different linguistic knowledge resources and types of linguistic representations that can enable and facilitate these basic NLP tasks. The chapter listed the practical considerations for users of NLP technology

and the research considerations for moving the field forward.

Although NLP continues to advance towards practical applications and more NLP methods are used in large-scale real-life health information applications, more needs to be done to make NLP use in biomedical and clinical applications a routine widespread reality. Some of the applications described in this chapter, are already used in practice, e.g., named entity recognition and text labeling are used to support MEDLINE indexers. Some research approaches are already outperforming humans on research datasets that approximate real-life tasks, for example, on reading comprehension tests (SQUAD). This does not mean, however, that NLP in general and health NLP are solved. In addition to improvements in the existing applications, new areas are emerging, and some of the well-known impediments still need to be addressed. The impediments include the data access challenges, which are partially addressed by synthetic data and transfer learning; the lack of interoperability and standards, particularly in the evaluation of tools included in the clinical workflows. The emerging areas and areas of active research include, but are not limited to: multi-modal data integration, interpretability of machine learning results, understanding machine learning models bias, and distributed large-scale computational models.

### Suggested Reading

NLP is a very active field of research in the open domain. Many of the applications and techniques described in this chapter are investigated in other domains. For a review of NLP methods in the general domain, we refer the reader to the following textbooks:

Jurafsky, D., & Martin, J. H. (2019). *Speech and language processing. An introduction to natural language processing, computational linguistics and speech recognition*. Upper Saddle River: Prentice Hall. See a draft of the 3-rd edition at <https://web.stanford.edu/~jurafsky/slp3/>.

Manning, C., & Schütze, H. (1999). *Foundations of statistical natural language processing*. Cambridge, MA: MIT Press.

This chapter provides a comprehensive and concise overview of health NLP. For additional details and examples see

Cohen, K. B., & Demner-Fushman, D. (2014). *Biomedical natural language processing*. Amsterdam: John Benjamins Publishing.

### ? Questions for Discussion

1. Develop a regular expression to regularize the tokens in lines four to nine of the following cardiac catheterization report (Complications through Heart Rate):

Procedures performed: Right Heart Catheterization Pericardiocentesis  
 Complications: None  
 Medications given during procedure: None  
 Hemodynamic data  
 Height (cm): 180  
 Weight (kg): 74.0  
 Body surface area (sq. m): 1.93  
 Heart rate: 102  
 Pressure (mmHg)  
 Sys Dias Mean Sat  
 RA 14 13 8  
 RV 36 9 12  
 PA 44 23 33 62% PCW253021  
 Hemoglobin (g/dL):  
 Conclusions: Post Operative Cardiac Transplant Abnormal Hemodynamics Pericardial Effusion Successful Pericardiocentesis  
 General Comments:  
 1600 cc of serosanguinous fluid were drained from the pericardial sac with improvement in hemodynamics.

2. Create a lexicon for the last seven lines of the cardiac catheterization report above (Conclusions through the last sentence). For each word, determine all the parts of speech that apply. Which words have more than one part of speech? Choose eight clinically relevant words in that section of the report, and suggest appropriate semantic categories for them that would be consistent with the

SNOMED-CT terminology and with the UMLS semantic network.

3. Draw a parse tree for the last sentence of cardiac catheterization report above.
4. Draw parse trees for the following sentences: no increase in temperature; low grade fever; marked improvement in pain; not breathing. (Hint: some lexemes have more than one word.)
5. Identify all the referential expressions in the text below and determine the correct referent for each. Assume that the compute attempts to identify referents by finding the most recent noun phrase. How well does this resolution rule work? Suggest a more effective rule.

The patient went to receive the AV fistula on December 4. However, he refuses transfusion. In the operating room it was determined upon initial incision that there was too much edema to successfully complete the operation and the incision was closed with staples. It was well tolerated by the patient.

6. In the two following scenarios, an off-the-shelf NLP system that identifies terms and normalizes them against UMLS concepts is applied to a large corpus of texts. In the first scenario, the corpus consists of patient notes. Looking at the frequency of different concepts, you notice that there is a large number of patients with the concept C0019682 (HIV) present, much larger than the regular incidence of HIV in the population reported in the literature. In the second scenario, the corpus consists of full-text biology articles. Looking at the frequency of different concepts, you notice that the failed axon connection (fax) gene is one of the most frequently mentioned genes in your corpus. Describe how you would check the validity of these results. For both cases, discuss what can explain the high frequency counts.

7. The following is an excerpt from a de-identified clinical discharge summary (as shown in Uzuner et al. (2008)).

**HISTORY OF PRESENT ILLNESS:**

The patient is a 77-year-old woman with long standing hypertension who presented as a Walk-in to me at the [REMOVED] Health Center on [REMOVED]. Recently had been started q.o.d. on Clonidine since [REMOVED] to taper off of the drug. Was told to start Zestril 20 mg. q.d. again. The patient was sent to the [REMOVED] Unit for direct admission for cardioversion and anticoagulation, with the Cardiologist, Dr. [REMOVED] to follow. **SOCIAL HISTORY:** Lives alone, has one daughter living in [REMOVED]. Is a non-smoker, and does not drink alcohol. **HOSPITAL COURSE AND TREATMENT:** During admission, the patient was seen by Cardiology, Dr. [REMOVED], was started on IV Heparin, Sotalol 40 mg PO b.i.d. increased to 80 mg b.i.d., and had an echocardiogram. By [REMOVED] the patient had better rate control and blood pressure control but remained in atrial fibrillation. On [REMOVED], the patient was felt to be medically stable.

- (a) Annotate all elliptical constructions and anaphoric references.
- (b) Develop an algorithm to identify section headings.

8. The following is the abstract of the article entitled “Tissue-specific distributions of alternatively spliced human PECAM-1 isoforms” by Wang et al. (as cited by Agarwal and Yu (2009)). Annotate each sentence according to the four categories: Introduction, Methods, Results, and Discussion.

PECAM-1 plays an important role in endothelial cell-cell and cell-matrix

interactions, which are essential during vasculogenesis and/or angiogenesis. Here, we examined expression of PECAM-1 mRNA in vascular beds of various human tissues and compared it with expression of PECAM-1 in human endothelial and hematopoietic cells. A short exposure of the blot probed with GAPDH is shown, because poly(A)+ RNA from the cell lines gives a strong signal within several hours compared with the total RNA from human tissue. Therefore, total RNA from various tissues required a much longer exposure to reveal GAPDH mRNA. Human tissue and cell lines expressed multiple RNA bands for PECAM-1, which may represent alternatively spliced PECAM-1 isoforms, the identity of which required further analysis.

9. Develop a regular expression that is capable of differentiating in-text parenthetical citations of the form “(Author, Year)” from other parentheticals.
10. Manually or programmatically, repeat Swansonian literature-based discovery ((Swanson 1986), see some implementation details in (Ganiz et al. 2005)):
  - (a) Pick a topic of interest (Raynaud’s Disease)
  - (b) Search to find literature  $C = \{\text{Raynaud’s}\}$
  - (c) Guess that B (e.g., blood factors) should be studied in relation to Raynaud’s
  - (d) Search literature  $C, = C \cap \text{blood}$
  - (e) Notice two common descriptors: blood viscosity, red blood cell rigidity
  - (f) Search literature  $A = \{\text{blood viscosity}\} \cup \{\text{red blood cell rigidity}\}$
  - (g) Notice the term “Fish Oil”
  - (h) Search literature  $A = \{\text{Fish Oil}\}$
  - (i) Show  $\{\text{Fish Oil}\} \cap \{\text{Raynaud’s}\} = \emptyset$
  - (j) Show plausible connection between Raynaud’s and Fish Oil

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- Why are sequence, structure, and biological pathway information relevant to medicine?
- Where on the Internet should you look for a DNA sequence, a protein sequence, or a protein structure?
- What are two problems encountered in analyzing biological sequence, structure, and function?
- How has the age of genomics changed the landscape of bioinformatics?
- What are two computational challenges in bioinformatics for the future?

## 9.1 The Problem of Handling Biological Information

**Bioinformatics** is the study of how information is represented and analyzed in biological systems, especially information derived at the molecular level. Whereas clinical informatics deals with the management of information related to the delivery of health care, bioinformatics focuses on the management of information related to the underlying basic biological sciences. As such, the two disciplines are closely related—more so than generally appreciated (see ► Chap. 1). Bioinformatics and clinical informatics share a concentration on systems that are inherently uncertain, difficult to measure, and the result of complicated interactions among multiple complex components. Both deal with living systems that generally lack straight edges and right angles. Although **reductionist approaches** to studying these systems can provide valuable lessons, it is often necessary to analyze those systems using **integrative models** that are not based solely on first principles. Nonetheless, the two disciplines approach the patient from opposite directions. Whereas applications within clinical informatics usually are concerned with the social systems of medicine, the cognitive processes of medicine, and the technologies required to understand human physiology, bioinformatics is concerned with understand-

ing how basic biological systems conspire to create molecules, organelles, living cells, organs, and entire organisms. Remarkably, however, the two disciplines share significant methodological elements, so an understanding of the issues in bioinformatics can be valuable for the student of clinical informatics and vice versa.

The discipline of bioinformatics continues to be in a period of rapid growth, because the needs for information storage, retrieval, and analysis in biology—particularly in molecular biology and **genomics**—have increased dramatically over the past two decades. History has shown that scientific developments within the basic sciences tend to have a delayed effect on clinical care and there is typically a lag of a decade before the influence of basic research on clinical medicine is realized. It cannot be understated the impact that genomics and bioinformatic approaches are having in the clinic and the point of care. Indeed, chapters focusing on “Translational Bioinformatics” and “Precision Medicine and Informatics” (► Chaps. 28 and 30) describe how these foundational advances are leading toward impacts on human health and improved approaches to clinical care.

### 9.1.1 Many Sources of Biological Data

There are many sources of information that are revolutionizing our understanding of human biology and that are creating significant challenges for computational processing. New technologies are enabling the miniaturization of laboratory experiments, increased automation of experiments and through advanced computer processing, and the interpretation of data quickly. These technologies are producing data at a staggering rate. The data produced can interrogate different views into the **Central Dogma of Biology**, the **metabolome**, the **metagenome** and ancillary molecular processes.

The most dominant new type of information is the **sequence information** produced by genetic studies. This was enabled by the **Human**

**Genome Project**, an international undertaking intended to determine the complete sequence of human DNA as it is encoded in each of the 23 human chromosomes. The first draft of the sequence was published in 2001 (Lander et al. 2001) and a final version was announced in 2003 coincident with the 50th anniversary of the solving of the Watson and Crick structure of the DNA double helix. The sequence continues to be revised and refined and now the sequence the genomes of many different individuals have been realized. Initially, the 1000 genomes consortium provided >1000 genomes of healthy individuals (1000 Genomes Consortium, 2010), and now datasets exist with >100,000 genomes of individuals with a variety of conditions.<sup>1</sup> Essentially, the entire set of genetically driven events from conception through embryonic development, childhood, adulthood, and aging are encoded by the DNA blueprints within most human cells. Given a complete knowledge of these DNA sequences, we are in a position to understand these processes at a fundamental level and to consider the possible use of DNA sequences for diagnosing and treating disease. This has led to the application of bioinformatics (and other foundational domains) as Translational Bioinformatics and Precision Medicine Informatics (► Chaps. 28 and 30).

Additionally, large-scale experimental methodologies are used to collect data on thousands or millions or more molecules simultaneously. Scientists apply these methodologies longitudinally over time and across a wide variety of organisms or within an organism to observe the development of various physiological phenomena. Technologies give us the ability to follow the production and degradation of molecules, such as the expression (transcription) of large numbers of genes simultaneously, the presence of proteins or metabolites in a biosample, or the populations of microorganisms in a sample.

The first high throughput experiments measured the expression of genes on **gene expression microarrays** (Lashkari et al. 1997).

This enabled the study of the expression of large numbers of genes with one another (Bai and Elledge 1997) and to study multiple variations on a genome to explore the implications of changes in genome function on human disease. This work has led to the field of **genomics**, the study of the molecular state of a cell, tissue or organism through the state and activity of its genome. With technology advancements, gene expression can now be measured by directly sequencing messenger RNA molecules in a cell and counting the number of copies of that RNA molecule that is observed.

While some scientists are studying the human genome, other researchers are studying the functions of the genomes of numerous other biological organisms, including important model organisms (such as mouse, rat, fruit fly and yeast) as well as important human pathogens (such as *Mycobacterium tuberculosis* or *Haemophilus influenzae*). The genomes of these organisms have been determined, and efforts are underway to characterize them. These allow two important types of analysis: the analysis of mechanisms of pathogenicity and the analysis of animal models for human disease. In both cases, the functions encoded by genomes can be studied, classified, and categorized, allowing us to decipher how genomes affect human health and disease.

These ambitious scientific projects are not only proceeding at a furious pace, but also are often accompanied by another approach to biology, which produces another source of biomedical information: **proteomics**, the study of the protein gene products of the genome—the proteome. Proteomics enables researchers to discover the state (quantity and configuration) of proteins within an organism. These protein states can be correlated with different physiological conditions, including disease states. Some of these protein states can be used as identifying markers of human disease. Similar approaches are being applied to understanding the diversity, concentration levels and functions of non-DNA, RNA or protein molecules such as metabolites through the study of the small molecules in the **metabolome**.

Using these technologies together, we can now study the **epigenome**, the non-genetic

1 ► <https://www.nhlbiwgs.org/> (accessed December 1, 2018).

effects that influence genome function. These include molecules that directly alter the structure of DNA but not its sequence (such as **DNA methylation**) or proteins that bind to DNA and affect how that DNA expresses genes. Epigenomics gives us a more complete picture of how biology functions and what its implications are for human health.

All these technologies, along with the genome-sequencing projects, are conspiring to produce a volume of biological information that at once contains secrets to age-old questions about health and disease and threatens to overwhelm our current capabilities of data analysis. Thus, bioinformatics is becoming critical for medicine in the twenty-first century.

### 9.1.2 Implications for Clinical Informatics

The effects of this new biological information on clinical medicine and clinical informatics are still evolving. It is already clear, however, that some major changes to medicine will have to be accommodated. These efforts have emerged as important areas of biomedical informatics that have become their own domains, Translational Bioinformatics (► Chap. 26) and Precision Medicine and Informatics (► Chap. 28) and use of biotechnology data is now common in Clinical Research Informatics (► Chap. 27).

1. *Genetic information in the medical record.* With the first set of human genomes now available and prices for gene sequencing rapidly decreasing, it is now cost-effective to consider sequencing every patient genome or at least genotyping key sections of the genomes and integrating that with the medical record.
2. *New diagnostic and prognostic information sources.* One of the main contributions of the genome-sequencing projects (and of the associated biological innovations) is that we are likely to have unprecedented access to new diagnostic and prognostic tools. Diagnostically, the genetic markers from a patient with an autoimmune disease, or of an infectious pathogen within a patient, will

be highly specific and sensitive indicators of the subtype of disease and of that subtype's probable responsiveness to different therapeutic agents. Several **genotype**-based databases have been developed to identify markers that are associated with specific **phenotypes** and identify how genotype affects a patient's response to therapeutics. ClinVar<sup>2</sup> and The Human Gene Mutation Database (HGMD)<sup>3</sup> both annotate mutations with disease phenotype. This resource has become invaluable for genetic counselors, basic researchers, and clinicians. Additionally, the Pharmacogenomics Knowledge Base (PharmGKB) collects genetic information that is known to affect a patient's response to a drug (more on PharmGKB is described in Translational Bioinformatics, ► Chap. 26).<sup>4</sup>

3. *Ethical considerations.* One of the critical questions facing the genome-sequencing and other related projects is "Can genetic or other molecular information be misused?" The answer is certainly yes. With knowledge of a complete genome for an individual, it may be possible in the future to predict the types of disease for which that individual is at risk years before the disease actually develops. If this information fell into the hands of unscrupulous employers or insurance companies, the individual might be denied employment or coverage due to the likelihood of future disease, however distant. There is even debate about whether such information should be released to a patient even if it could be kept confidential. Should a patient be informed that he or she is likely to get a disease for which there is no treatment? What about that patient's relatives, who share genetic information with the patient? This is a matter of intense debate, and such questions have significant implications for what information is collected and for how and to whom that information

is disclosed (Durfy 1993). Passage of the Genetic Information Nondiscrimination Act in 2008 set initial federal guidelines on use of genetic information.<sup>5</sup> Additionally, the Personal Genome Project (PGP) has been working to define **open consent models** for releasing genetic information.<sup>6</sup> The Clinical Sequencing and Exploratory Research Consortium (CSER) has been tackling the difficult issues in translation of genomic data to the clinic broadly.<sup>7</sup>

## 9.2 The Rise of Bioinformatics

A brief review of the biological basis of medicine will bring into focus the magnitude of the revolution in molecular biology and the tasks that are created for the discipline of bioinformatics. The genetic material that we inherit from our parents, that we use for the structures and processes of life, and that we pass to our children is contained in a sequence of chemicals known as **deoxyribonucleic acid (DNA)**.<sup>8</sup> The total collection of DNA for a single person or organism is referred to as the **genome**. DNA is a long polymer chemical made of four basic subunits. The sequence in which these subunits occur in the polymer distinguishes one DNA molecule from another and directs a cell's production of proteins and all other basic cellular processes. **Genes** are discreet units encoded in DNA and they are transcribed into **ribonucleic acid (RNA)**, which has a composition very similar to DNA. Genes are transcribed into messenger RNA (mRNA) and a majority of mRNA sequences are translated by complex macromolecular machines, called ribosomes, into protein. Not all RNAs are messengers

for the translation of proteins. Ribosomal RNA, for example, is used in the construction of the ribosome, the huge molecular engine that translates mRNA sequences into protein sequences. Additionally, mRNAs can be modified through alternative splicing, degradation, and formation of secondary structures that influence transcriptions. Once expressed, proteins are frequently modified (e.g. phosphorylated), and these modifications can change the function of the protein. This process of DNA being transcribed to RNA and RNA being translated to protein is commonly referred to as the **Central Dogma of Biology**.

Understanding the basic building blocks of life requires understanding the function of genomic sequences, genes, and proteins. When are genes expressed? Once genes are transcribed and translated into proteins, into what cellular compartment are the proteins directed? How do the proteins function once there? Do the proteins need to be modified in order for them to become active? How are the proteins turned off? Experimentation and bioinformatics have divided the research into several areas, and the largest are: (1) DNA and protein sequence analysis, (2) macromolecular structure–function analysis, (3) gene expression analysis, (4) proteomics, (5) metabolomics, (6) metagenomics, and (5) systems biology.

### 9.2.1 Roots of Modern Bioinformatics

Practitioners of bioinformatics have come from many backgrounds, including medicine, molecular biology, chemistry, physics, statistics, mathematics, engineering, and computer science. It is difficult to define precisely the ways in which this discipline emerged. There are, however, two main developments that have created opportunities for the use of information technologies in biology. The first is the progress in our understanding of how biological molecules are constructed and how they perform their functions. This dates back as far as the 1930s with the invention of electrophoresis, and then in the 1950s with the elucidation of the structure of DNA and the subsequent sequence of discoveries in the relationships

8 If you are not familiar with the basic terminology of molecular biology and genetics, reference to an introductory textbook in the area would be helpful before you read the rest of this chapter.

among DNA, RNA, and protein structure. The second development has been the parallel increase in the availability of computing power. Starting with mainframe computer applications in the 1950s and moving to modern workstations, and ‘the Cloud’, there have been hosts of biological problems addressed with computational methods.

### 9.2.2 The Genomics Explosion

---

The benefit of the human genome sequence to medicine is both in the short and in the long term. The short-term benefits lie principally in diagnosis; the availability of sequences of normal and variant human genes will allow for the rapid identification of these genes in any patient (e.g., Babor and Matzner 1997). The long-term benefits will include a greater understanding of the proteins produced from the genome: how the proteins interact with drugs; how they malfunction in disease states; and how they participate in the control of development, aging, and responses to disease.

The effects of genomics on biology and medicine cannot be overstated. We now have the ability to measure the activity and function of genes within living cells. Genomics data and experiments have changed the way biologists think about questions fundamental to life. Whereas in the past, reductionist experiments probed the detailed workings of specific genes, we can now assemble those data together to build an accurate understanding of how cells work.

### 9.3 Biology Is Now Data-Driven

---

Nearly 30 years ago, the use of computers was proving to be useful to the laboratory researcher. Today, computers are an essential component of modern research. This has led to a change in thinking about the role of computers in biology. Before, they were optional tools that could help provide insight to experienced and dedicated enthusiasts. Today, they are required by most investigators, and experimental approaches rely on them as

critical elements. This is because advances in research methods such as **genetic sequencing, experimental robotics and microfluidics, X-ray crystallography, nuclear magnetic resonance spectroscopy, cryoelectron microscopy, proteomic mass spectrometry** and other high throughput experiments have resulted in experiments that generate massive amounts of data. These data pose new problems for basic researchers on how the data are properly stored, analyzed, and disseminated.

The volume of data being produced by genomics projects is staggering. There are now more than 211 million sequences in **GenBank** comprising more than 285 billion digits. Since 2008, sequencing has bested Moore’s law (see ► Chap. 1).<sup>9</sup> But these data do not stop with sequence data: PubMed contains over 28 million literature citations, the **Protein Data Bank (PDB)** contains three-dimensional structural data for over 45,538 distinct protein structures, and the **Gene Expression Omnibus (GEO)** contains over 2.8 million arrayed samples. These data are of incredible importance to biology, and in the following sections we introduce and summarize the importance of sequences, structures, gene expression experiments, systems biology, and their computational components to medicine.

#### 9.3.1 Sequences in Biology

---

Sequence information (including DNA sequences, RNA sequences, and protein sequences) is critical in biology: DNA, RNA, and protein can be represented as a set of sequences of basic building blocks (bases for DNA and RNA, amino acids for proteins). Computer systems within bioinformatics thus must be able to handle biological sequence information effectively and efficiently. To that end, the bioinformatics community has developed central databases to store sequence information, data models to represent that information and software analysis tools to process sequence data.

---

9 ► <http://www.genome.gov/sequencingcosts/> (accessed November 1, 2018).

### 9.3.2 Structures in Biology

The sequence information mentioned in ► Sect. 9.3.1 is rapidly becoming inexpensive to obtain and easy to store. On the other hand, the **three-dimensional structure information** about the proteins, DNA, and RNA is much more difficult and expensive to obtain, and presents a separate set of analysis challenges. Currently, only about 45,000 distinct three-dimensional structures of biological macromolecules are known.<sup>10</sup> These models are incredibly valuable resources, however, because an understanding of structure often yields detailed insights about biological function. As an example, the structure of the ribosome has been determined for several species and contains more atoms than any other structure to date. This structure, because of its size, took two decades to solve, and presents a formidable challenge for functional annotation (Cech 2000). Yet, the functional information for a single structure is dwarfed by the potential for comparative genomics analysis between the structures from several organisms and from varied forms of the functional complex. Since the ribosome is ubiquitously required for all forms of life these types of comparisons are possible. Thus, a wealth of information comes from relatively few structures. To address the problem of limited structure information, the publicly funded structural genomics initiative aims to identify all of the common structural scaffolds found in nature and to increase the number of known structures considerably. In the end, it is the physical interactions between molecules that determine what happens within a cell; thus the more complete the picture, the better the functional understanding. In particular, understanding the physical properties of therapeutic agents is the key to understanding how agents interact with their targets within the cell (or within an invading organism). These are the key questions for structural biology within bioinformatics:

1. How can we analyze the structures of molecules to learn their associated function?

Approaches range from detailed molecular simulations (Levitt 1983) to statistical analyses of the structural features that may be important for function (Wei and Altman 1998).

2. How can we extend the limited structural data by using information in the sequence databases about closely related proteins from different organisms (or within the same organism, but performing a slightly different function)? There are significant unanswered questions about how to extract maximal value from a relatively small set of examples.
3. How should structures be grouped for the purposes of classification? The choices range from purely functional criteria (“these proteins all digest proteins”) to purely structural criteria (“these proteins all have a toroidal shape”), with mixed criteria in between. One interesting resource available today is the Structural Classification of Proteins (SCOP),<sup>11</sup> which classifies proteins based on shape and function.

### 9.3.3 Genome Sequencing Data in Biology

Advances in sequencing technology are pivotal in enabling the practice of genomic medicine. Whereas the first human genome sequence was carried out over approximately 13 years at a cost of \$2.7 billion (Davies 2010), whole human genomes can now be sequenced in a matter of days at a cost that is growing ever-closer to the magic, if somewhat arbitrary, \$1000 price tag. This amount is commonly seen as the price at which it becomes feasible to sequence a patient in the course of clinical care, justifiable both clinically and financially. In 2004, and again in 2011, the National Human Genome Research Institute (part of the National Institutes of Health) funded a number of efforts specifically aimed

10 For more information see ► <http://www.rcsb.org/> (accessed November 1, 2018).

11 ► <http://scop2.mrc-lmb.cam.ac.uk/> (accessed December 1, 2018).

at increasing speed and decreasing the cost of genome scale sequencing.

Traditional sequencing involves a method referred to as Sanger sequencing. This method typically is applied to sequences ranging from 300 to 1000 nucleotides in a non-high throughput manner.<sup>12</sup> In the early to mid 2000s, several technologies were introduced to sequence large amounts of DNA in parallel. These **high throughput sequencing methods** (of which there are many including sequencing by synthesis, single molecule sequencing, combinatorial probe anchor synthesis, and others) typically involve shorter sequences than Sanger based approaches, but can generate gigabases of sequence in short fragments at low cost (<\$0.05 per megabase sequenced). These methods are being used for many applications, including identification of genetic variants in clinical studies, characterizing genome function with specific experiments and sequencing novel species genomes. These studies have already discovered the genetic basis of rare genetic disorders by sequencing entire families (Ng et al. 2010), and we have seen a glimpse of the future of genome sequencing for routine health care in the analysis of a single genome of a healthy man (Ashley et al. 2010). As will be described in detail in the Translational Bioinformatics chapter (► Chap. 26), these sequencing approaches have been put to practice clinically. One emergent area of research is **metagenomics**, the study of microorganism ecosystems using DNA sequencing, including the association of human gut flora populations to disease phenotypes in humans (Qin et al. 2010).

### 9.3.4 Expression Data in Biology

The development of DNA microarrays led to a wealth of data and unprecedented insight into the fundamental biological machine. The traditional premise is relatively simple; tens of thousands of gene sequences derived from genomic data are fixed onto a glass slide or

filter. The sequences for each spot are derived from a single gene sequence and the sequences are attached at only one end, creating a forest of sequences in each spot that are all identical. An experiment is performed where two samples (e.g. groups of cells that are grown in different conditions or for comparisons of normal and cancer tissue), one group is a control group and the other is the experimental group. The control group is grown normally, while the experimental group is grown under experimental conditions. For example, a researcher may be trying to understand how a cell compensates for a lack of sugar. The experimental cells will be grown with limited amounts of sugar. As the sugar depletes, some of the cells are removed at specific intervals of time. When the cells are removed, all of the mRNA from the cells is separated from the cells and converted back to DNA, using reverse transcriptase (a special enzyme that can create a DNA copy from an RNA template). This leaves a pool of cDNA molecules (DNA derived from mRNA is called complementary DNA or cDNA) that represent the genes that were expressed (turned on) in that group of cells. In the development of genomics experimentation, these cDNA molecules would be tagged with fluorescence and hybridized to slides containing single stranded DNA “probes” that are arrayed in a grid. These microarray “chips” can then be analyzed for color differences between grid points that correspond to specific gene regions. Today, with the advent of high throughput sequencing the RNA/cDNA can be sequenced directly to measure expression levels and using DNA barcoding technology and microfluidics, individual cells can be sequenced alone instead of in pooled samples where all cells’ contributions to mRNA is in the same analysis. High throughput single cell sequencing is an exciting advancement which adds orders of complexity to the required computational analysis (Shapiro et al. 2013).

Computers become critical for analyzing these data because it is impossible for a researcher to measure and analyze all of the datasets by hand. Currently scientists are using gene expression experiments to study how cells from different organisms compen-

12 ► [http://en.wikipedia.org/wiki/DNA\\_sequencing](http://en.wikipedia.org/wiki/DNA_sequencing) (accessed November 1, 2018).

sate for environmental changes, how pathogens fight antibiotics, and how cells grow uncontrollably (as is found in cancer). A challenge for biological computing is to develop methods to analyze these data, tools to store these data, and computer systems to collect the data automatically.

### 9.3.5 Metabolomics Data in Biology

Genomics and proteomics study the function of the genome and the proteome, while **metabolomics** studies the diversity and function of small molecules in a biosample. These include metabolites such as lipids, carbohydrates, metal ions, hormones, signaling molecules, etc. Interest in the metabolome has increased significantly with the development of separation and mass spectrometry technologies that can identify small molecule molecular mass and identities in a high throughput fashion. Bioinformatics is a key component of both the identification of specific molecules by matching mass spectrometry “fingerprints” with a database of known molecules as well as in the analysis the resulting data. For example, researchers have characterized the metabolome of human colorectal cancers and stool and identified disease enriched metabolites as a possible detectable markers of disease or treatment outcomes (Brown et al. 2016).

### 9.3.6 Epigenetics Data in Biology

**Epigenetics** consists of heritable changes that are not encoded in the primary DNA sequence. Several types of epigenetic effects can now be studied in the laboratory, and they have been associated to disease and risks of disease (Goldberg et al. 2007). First, the regional structure of chromosomes affects which regions of the genome can be transcribed, i.e. which regions can be *expressed*. Large proteins, called histones, coordinate the structure of chromosomes and their structure and positions are regulated with protein posttranslational modifications to the histones bound to the DNA. These

changes have been associated with spontaneous mutations in cancer, complex genetic diseases, and Mendelian inherited genetic diseases. Second, cytosine bases in the DNA can be methylated and this can affect gene expression. DNA methylation patterns can be passed on when DNA is replicated. Like chromosome structure, these modifications have been associated with human disease (Bird 2002).

### 9.3.7 Systems Biology

Recent advances in high throughput technologies have enabled a new, dynamic approach to studying biology, that of **systems biology**. In contrast to the historically reductionist approach to biology, studying one molecule at a time, systems biology looks at the entirety of a system including dynamic relationships between the different components. With that said, systems biology is still maturing. As an analogy, consider an airplane. Having a “parts list” for a Boeing 747 does not enable us to understand how those parts work together to make the airplane operate. If the airplane breaks, the parts list alone does not tell us how to remedy the situation. Rather, we need to understand how the parts interact, how one affects another, and how perturbations to one part of the system affect the rest of the system. Similarly, systems biology involves understanding not only the “parts list”, i.e. the list of all genes, proteins, metabolites, etc., but also the dynamic networks of interactions among these parts. An integrated simulation of an entire bacterial cell has shown the feasibility of accurate computational simulations of cell physiology (Karr et al. 2012).

Current research in **-omics technologies** have both enabled and catalyzed the advancement of systems biology. However, a systems biology approach goes beyond simply performing these high bandwidth methods for the purpose of biological discovery. Rather, systems biology implies a systematic, hypothesis-driven approach based on omic-scale (very large) hypotheses. Once the interactions in a biological network are understood, one can model that network to make predictions

regarding the system's behavior, particularly in light of specific perturbations. Understanding how the system has evolved to work can also help us understand what goes wrong when the system breaks down, and how to intervene in order to restore the system to normal.

## 9.4 Key Bioinformatics Algorithms

There are a number of common computations that are performed in many contexts within bioinformatics. In general, these computations can be classified as sequence alignment, structure alignment, pattern analysis of sequence/structure, gene expression analysis, and pattern analysis of biochemical function.

### 9.4.1 Early Work in Sequence and Structure Analysis

As it became clear that the information from DNA and protein sequences would be voluminous and difficult to analyze manually, algorithms began to appear for automating the analysis of sequence information. The first requirement was to have a reliable way to align sequences so that their detailed similarities and distances could be examined directly. Needleman and Wunsch (1970) published an elegant method for using **dynamic programming** techniques to align sequences in time related to the cube of the number of elements in the sequences. Smith and Waterman (1981) published refinements of these algorithms that allowed for searching both the best global alignment of two sequences (aligning all the elements of the two sequences) and the best local alignment (searching for areas in which there are segments of high similarity surrounded by regions of low similarity). A key input for these algorithms is a matrix that encodes the similarity or substitutability of sequence elements: When there is an inexact match between two elements in an alignment of sequences, it specifies how much "partial credit" we should give to the overall alignment based on the similarity of the elements, even though they may not be identical. Looking at a set of evolutionarily related proteins, Dayhoff (1974) published

one of the first matrices derived from a detailed analysis of which amino acids (elements) tend to substitute for others.

Within structural biology, the vast computational requirements of the experimental methods (such as X-ray crystallography and nuclear magnetic resonance) for determining the structure of biological molecules drove the development of powerful structural analysis tools. In addition to software for analyzing experimental data, graphical display algorithms allowed biologists to visualize these molecules in great detail and facilitated the manual analysis of structural principles (Langridge 1974; Richardson 1981). At the same time, methods were developed for simulating the forces within these molecules as they rotate and vibrate (Gibson and Scheraga 1967; Karplus and Weaver 1976; Levitt 1983).

The most important development to support the emergence of bioinformatics, however, has been the creation of databases with biological information. In the 1970s, structural biologists, using the techniques of X-ray crystallography, set up the Protein Data Bank (PDB) specifying the Cartesian coordinates of the structures that they elucidated (as well as associated experimental details) and made PDB publicly available. The first release, in 1977, contained 77 structures. The growth of the database is chronicled on the Web: the PDB now has over 75,000 detailed atomic structures and is the primary source of information about the relationship between protein sequence and protein structure.<sup>13</sup> Similarly, as the ability to obtain the sequence of DNA molecules became widespread, the need for a database of these sequences arose. In the mid-1980s, the GENBANK database was formed as a repository of sequence information. Starting with 606 sequences and 680,000 bases in 1982, the GENBANK has grown by much more than 135 million sequences and 125 billion bases.<sup>14</sup> The GENBANK database of DNA sequence information supports the experimental reconstruction of genomes and acts as a focal point

<sup>13</sup> See ► <http://www.rcsb.org/> (accessed December 1, 2018).

<sup>14</sup> ► <http://www.ncbi.nlm.nih.gov/genbank/> (accessed December 1, 2018).

for experimental groups. Numerous other databases store the sequences of protein molecules<sup>15</sup> and information about human genetic diseases.<sup>16</sup>

Included among the databases that have accelerated the development of bioinformatics is the Medline database of the biomedical literature and its paper-based companion Index Medicus (see ► Chap. 23).<sup>17</sup> Including articles as far back as 1809 and brought online free on the Web in 1997, Medline provides the glue that relates many high-level biomedical concepts to the low-level molecule, disease, and experimental methods. In fact, this “glue” role was the basis for creating the NCBI suite of databases and software and PubMed systems (see ► Sect. 9.5) for integrating access to literature references and the associated databases.

### 9.4.2 Sequence Alignment and Genome Analysis

Perhaps the most basic activity in computational biology is comparing two biological sequences to determine (1) whether they are similar and (2) how to align them. The problem of alignment is not trivial but is based on a simple idea. Sequences that perform a similar function should, in general, be descendants of a common ancestral sequence, with mutations over time. These mutations can be replacements of one amino acid with another, deletions of amino acids, or insertions of amino acids. The goal of **sequence alignment** is to align two sequences so that the evolutionary relationship between the sequences becomes clear. If two sequences are descended from the same ancestor and have not mutated too much, then it is often possible to find corresponding locations in each sequence that play the same role in the evolved proteins. The problem of solving correct biological alignments is difficult because it requires knowl-

edge about the evolution of the molecules that we typically do not have. There are now, however, well-established algorithms for finding the mathematically optimal alignment of two sequences. These algorithms require the two sequences and a scoring system based on (1) exact matches between amino acids that have not mutated in the two sequences and can be aligned perfectly; (2) partial matches between amino acids that have mutated in ways that have preserved their overall biophysical properties; and (3) gaps in the alignment signifying places where one sequence or the other has undergone a deletion or insertion of amino acids. The algorithms for determining optimal sequence alignments are based on a technique in computer science known as **dynamic programming** and are at the heart of many computational biology applications (Gusfield 1997). ■ Figure 9.1 shows an example of a Smith-Waterman matrix, the first described local alignment algorithm that utilizes a dynamic programming approach. The algorithm works by calculating a similarity matrix between two sequences, then finding optimal paths through the matrix that maximize a similarity score between the two sequences.

Unfortunately, the dynamic programming algorithms are too computationally expensive to apply to large numbers of sequences, so a number of faster, more heuristic methods have been developed. The most popular algorithm is the **Basic Local Alignment Search Tool (BLAST)** (Altschul et al. 1990). BLAST is based on the observation that sections of proteins are often conserved without gaps (so the gaps can be ignored—a critical simplification for speed) and that there are statistical analyses of the occurrence of small subsequences within larger sequences that can be used to prune the search for matching sequences in a large database. These tools work well for both protein and nucleic acid sequences. Other tools have been developed that are better suited for nucleic acid sequence assembly and mapping of short read high throughput sequencing data including BLAT (Kent 2003), SOAP (Li et al. 2008), and others.

Protein 3D structures can be aligned, visualized and compared in a similar way to linear protein sequences (■ Fig. 9.2). Tools such

as PyMol<sup>18</sup> and UCSF Chimera<sup>19</sup> provide sophisticated and extensible applications for relatively easy visualization of 3D structures. Tools for 3D alignment of the structures are provided with these applications.

### 9.4.3 Prediction of Structure and Function from Sequence

One of the primary challenges in bioinformatics is taking a newly determined DNA sequence (as well as its translation into a protein sequence) and predicting the structure of the associated molecules, as well as their function. Both problems are difficult, being fraught with all the dangers associated with making predictions without hard experimental data. Nonetheless, the available sequence data are starting to be sufficient to allow good predictions in a few cases. For example, there is a Web site devoted to the assessment of biological macromolecular structure prediction methods.<sup>20</sup> Results suggest that when two protein molecules have a high degree (more than 40%)

of sequence identity and one of the structures is known, a reliable model of the other can be built by analogy. In the case that sequence similarity is less than 25%, however, performance of these methods is much less reliable.

With the advent of deep learning, there has been an acceleration of progress in many machine learning tasks, including structure prediction. Recently, the use of convolutional neural networks by DeepMind Inc. called AlphaFold (Senior, et al. 2020) has led to a quantum leap in the quality of predicted structures—so much so that some experts in protein structure prediction have said that parts of this challenge can now be considered “solved<sup>21</sup>.” They make this claim because on multiple prediction tasks, the accuracy of the predicted structure is similar to those determined experimentally. Of course, it is likely that there are classes of proteins that may not perform as well, but for a large fraction of protein sequences, the structure seems to be predictable by these methods. An important caveat is that these methods must be carefully reviewed by the community, reproduced and made generally available before they will have their full impact

When scientists investigate biological structure, they commonly perform a task analogous to sequence alignment, called **structural alignment**. Given two sets of three-dimensional coordinates for a set of atoms, what is the best way to superimpose them so that the similarities and differences between the two structures are clear? Such computations are useful for determining whether two structures share a common ancestry and for understanding how the structures’ functions have subsequently been refined during evolution. There are numerous published algorithms for finding good structural alignments. We can apply these algorithms in an automated fashion whenever a new structure is determined, thereby classifying the new structure into one of the protein families.

There are also algorithms for using the structure of a large biomolecule and the structure of a small organic molecule (such as a

21 ► <https://www.nature.com/articles/d41586-020-03348-4>.

drug or cofactor) to try to predict the ways in which the molecules will interact. An understanding of the structural interaction between a drug and its target molecule often provides critical insight into the drug's mechanism of action. The most reliable way to assess this interaction is to use experimental methods to solve the structure of a drug–target complex. Once again, these experimental approaches are expensive, so computational methods play an important role. Typically, we can assess the physical and chemical features of the drug molecule and can use them to find complementary regions of the target. For example, a highly electronegative drug molecule will be most likely to bind in a pocket of the target that has electropositive features.

Prediction of function often relies on use of sequential or structural similarity metrics and subsequent assignment of function based on similarities to molecules of known function. These methods can guess at general function for roughly 60–80% of all genes, but leave considerable uncertainty about the precise functional details even for those genes for which there are predictions, and have little to say about the remaining genes.

#### 9.4.4 Clustering of Gene Expression Data

---

Analysis of gene expression data often begins by clustering the expression data. A typical experiment is represented as a large table, where the rows are the genes on each chip and the columns represent the different experiments, whether they be time points or different experimental conditions. Each row is then a vector of values that represent the results of the experiment with respect to a specific gene. Clustering can then be performed to determine which genes are being expressed similarly. Genes that are associated with similar expression profiles are often functionally associated. For example, when a cell is subjected to starvation (fasting), ribosomal genes are often downregulated in anticipation of lower protein production by the cell. It has similarly been shown that genes associated with neoplastic progression could be identified relatively

easily with this method, making gene expression experiments a powerful assay in cancer research (see Yan and Gu 2009, for a review). In order to cluster expression data, a distance metric must be determined to compare a gene's profile with another gene's profile. If the vector data are a list of values, Euclidian distance or correlation distances can be used. If the data are more complicated, more sophisticated distance metrics may be employed. These methods fall into two categories: supervised and unsupervised. Supervised learning methods require some preconceived knowledge of the data at hand (discussed below). Usually, the method begins by selecting profiles that represent the different groups of data, e.g., genes that represent certain pathways, and then the clustering method associates each of the genes with the representative profile to which they are most similar. Unsupervised methods are more commonly applied because these methods require no knowledge of the data, and can be performed automatically.

Two such unsupervised learning methods are the hierarchical and K-means clustering methods. Hierarchical methods build a dendrogram, or a tree, of the genes based on their expression profiles. These methods are agglomerative and work by iteratively joining close neighbors into a cluster. The first step often involves connecting the closest profiles, building an average profile of the joined profiles, and repeating until the entire tree is built. K-means clustering builds  $k$  clusters or groups automatically. The algorithm begins by picking  $k$  representative profiles randomly. Then each gene is associated with the representative to which it is closest, as defined by the distance metric being employed. Then the center of mass of each cluster is determined using all of the member gene's profiles. Depending on the implementation, either the center of mass or the nearest member to it becomes the new representative for that cluster. The algorithm then iterates until the new center of mass and the previous center of mass are within some threshold. The result is  $k$  groups of genes that are regulated similarly. One drawback of K-means is that one must choose the value for  $k$ . If  $k$  is too large, logical "true" clusters may be split into pieces and if  $k$  is too small, there

will be clusters that are merged. One way to determine whether the chosen  $k$  is correct is to estimate the average distance from any member profile to the center of mass. By varying  $k$ , it is best to choose the lowest  $k$  where this average is minimized for each cluster. Another drawback of K-means is that different initial conditions can give different results, therefore it is often prudent to test the robustness of the results by running multiple runs with different starting configurations (■ Fig. 9.3).

The future clinical usefulness of these algorithms cannot be overstated. In 2002, van't Veer et al. (2002) found that a gene expression profile could predict the clinical outcome of breast cancer. The global analysis of gene expression showed that some cancers were associated with different prognosis, not detectable using traditional means. Another exciting advancement in this field is the potential use of microarray expression data to profile the molecular effects of known and potential therapeutic agents. This molecular understanding of a disease and its treatment will soon help clinicians make more informed and accurate treatment choices (for more, see ► Chap. 26).

■ Fig. 9.3 The exponential growth of GENBANK. This plot shows that since 1982 the number of bases in GENBANK has grown by five full orders of magnitude and continues to grow by a factor of 10 every 4 years

#### 9.4.4.1 Classification and Prediction

A high level description of some common approaches to classification or supervised learning are described below, but note that entire courses could be, and are, taught on each of these methods. For further details we refer readers to the suggested texts at the end of this chapter.

One of the simplest methods for classification is that of  $k$ -nearest-neighbor, or KNN. Essentially, KNN uses the classification of the  $k$  closest instances to a given input as a set of votes regarding how that instance should be classified. Unfortunately, KNN tends not to be useful for omics-based classification because it tends to break down in high-dimensional space. For high-dimensional data, KNN has difficulty in finding enough neighbors to make prediction, which will lead to large variation in the classification. This breakdown is one aspect of the “curse of dimensionality,” described in more detail below (Hastie et al. 2009).

A more general statistical approach to supervised learning, and one which encompasses a number of popular methods, is that of function approximation. In this approach, one attempts to find a useful approximation of the function  $f(x)$  that underlies the actual relation between the inputs and outputs. In this case, one chooses a metric by which to judge the accuracy of the approximation, for example the residual sum of squares, and uses this metric to optimize the model to fit the training data. Bayesian modeling, logistic regression, and Support Vector Machines all use variations on this approach.

Finally, there is the class of rule-based classifiers. This type of classifier may be thought of as a series of rules, each of which splits the set of instances based on a given characteristic. Details such as what criteria are used to choose the feature on which to base a rule, and whether the algorithm uses enhancements such as ensemble learning (i.e., multiple models together) determine the specifics of the classifier type, for example decision trees, random forests, or covering rules.

Which approach to use depends both on the nature of the data and the question being

asked. The question might prioritize sensitivity over specificity or vice versa. For example, for a test to detect a life-threatening infection that is easily treatable by readily available antibiotics, one might want to err on the side of sensitivity. In addition, data may be numeric or categorical or have differing degrees of noise, missing values, correlated features or non-linear interactions among features. These different qualities are better handled by different methods. In many cases the best approach is actually to try a number of different methods and to compare the results. Such comparative analysis is facilitated through freely available software packages such as R/Bioconductor<sup>22</sup> and Weka.<sup>23</sup>

### 9.4.5 The Curse of Dimensionality

In the post-genomic era, there is no shortage of data to analyze. Rather, many researchers have more data than they know what to do with. However this overabundance tends to be a factor of the dimensionality of the data, rather than the number of subjects. This mismatch can lead to challenges for experimental design and statistical analysis. Type 1 error, or the tendency to incorrectly reject the null hypothesis and say that indeed there is statistical significance to a pattern (see ► Chap. 13), is amplified by looking at high-dimensional data. This is one aspect of what is known as the “curse of dimensionality” (Hastie et al. 2009). Consider analysis of gene expression data for 20,000 genes, trying to detect a pattern that can predict outcome. In a sample of, say, 30 subjects—a reasonable number when testing a single hypothesis—by random chance, some number of genes will correlate with outcome. Essentially one is testing not one but 20,000 hypotheses simultaneously. One must therefore correct for multiple hypothesis testing. The Bonferroni method is a common and straightforward approach to correct

for multiple hypothesis testing.<sup>24</sup> It entails dividing the threshold  $p$ -value one would use, traditionally 0.05, by the number of hypotheses. So, for a test of 20,000 genes, one would require a  $p$ -value of  $2.5 \times 10^{-6}$  to call a gene significant. Typically, analyses using high dimensional data such as gene expression are not sufficiently powered to pass this stringent test. One would need thousands of samples to be sufficiently powered. Another approach is to use  $q$ -value, or false discovery rate (Storey and Tibshirani 2003), rather than  $p$ -value. This approach relies on empirical permutation to determine the expected number of false positives if indeed the null hypothesis is correct, which enables approximation of the proportion of false positives among all reported positives. Consider again the microarray experiment above in which each array includes 20,000 genes. We want to know whether gene X was differentially expressed in cases versus controls. Choosing a threshold  $p$ -value, or false *positive* rate, of 0.05 means that 1 time in 20 we will erroneously reject the null hypothesis and predict a false positive. If a statistical test returns 2000 positives, i.e. 2000 genes appear to be significantly differentially expressed, we expect 1 in 20 of the genes being analyzed ( $20,000 \times (1/20) = 1000$ ) or approximately half of them to be false positives. A false *discovery* rate of 0.05, on the other hand, would mean that 5% of those called *positive*, in this case 100 out of 2000, are false positives.  $Q$ -value is thus less stringent than  $p$ -value, but may be of greater utility in a high-dimensional omics context than a traditional  $p$ -value or correction for multiple hypotheses.

Another approach to analysis of high dimensional data sets is to use dimensionality reduction methods such as feature selection or feature extraction. Feature selection entails extracting only a subset of the features at hand, in this case genes. This may be done in a number of ways, based on which genes vary the most, or on which genes seem to best predict the categorization at hand. In contrast,

22 ► <http://bioconductor.org/> (accessed December 1, 2018).

23 ► <http://www.cs.waikato.ac.nz/ml/weka/> (accessed December 1, 2018).

24 ► [http://en.wikipedia.org/wiki/Bonferroni\\_correction](http://en.wikipedia.org/wiki/Bonferroni_correction) (accessed December 1, 2018).

feature extraction creates a new smaller set of features that captures the essence of the original variation. As an example, imagine a plane flight from Seattle, WA to Key West, FL. One could use a 3-dimensional vector consisting of latitude and longitude to describe the plane's position at any given point along the way. In this case, one value would describe how far the plane had gone in the north/south direction, and one would indicate how far the plane had gone in the east/west direction. However, if we change the axis along which we are measuring to instead be the direct route along which the plane is flying, then we only need 1 dimension to describe where the plane is located. The distance flown tells us where the plane is located at any given time. This approach of changing the axes is the basis for principle components analysis (PCA), a common method for feature extraction. Instead of going from two dimensions to one, PCA on gene expression data typically goes from tens of thousands of features to just a few. Both for feature selection and feature extraction, it is important to replicate the findings in an independently generated data set in order to be sure the model is not over fitting the data on which it was trained.

## 9.5 Current Application Successes from Bioinformatics

Biologists have embraced the Internet in a remarkable way and have made access to data a normal and expected mode for doing business. Hundreds of databases curated by individual biologists create a valuable resource for the developers of computational methods who can use these data to test and refine their analysis algorithms. With standard Internet search engines, most biological databases can be found and accessed within moments. The large number of databases has led to the development of meta-databases that combine information from individual databases to shield the user from the complex array that exists. There are various approaches to this task.

The National Center for Biotechnology Information (NCBI) suite of databases and software (previously known as the 'Entrez'

gives integrated access to the biomedical literature, protein, and nucleic acid sequences, macromolecular and small molecular structures, and genome project links (including both the Human Genome Project and sequencing projects that are attempting to determine the genome sequences for organisms that are either human pathogens or important experimental model organisms) in a manner that takes advantages of either explicit or computed links between these data resources.<sup>25</sup> Newer technologies are being developed that will allow multiple heterogeneous databases to be accessed by search engines that can combine information automatically, thereby processing even more intricate queries requiring knowledge from numerous data sources. One example is the Bioconductor project, a toolbox for bioinformatics in the R programming language.<sup>26</sup>

### 9.5.1 Data Sharing

In 1996, the First International Strategy Meeting on Human Genome Sequencing was held in Bermuda. In this meeting, a set of principles was agreed upon regarding sharing of human genome sequencing data. These principles came to be known as the Bermuda principles. They stipulated that (1) all sequence assemblies larger than 1 kb should be released as soon as possible, ideally within 24 h; (2) finished annotated sequences should be published immediately to public databases; and (3) that all human sequence data generated in large-scale sequencing centers should be made available in the public domain.<sup>27</sup>

Increasingly, journals and funders require that researchers deposit all types of research data in publicly available repositories (Fischer and Zigmond 2010). In 2009, President Obama announced an Open Government

25 ► <https://www.ncbi.nlm.nih.gov/search/> (accessed December 7th, 2020).

26 ► <http://bioconductor.org/> (accessed December 1, 2018).

27 ► [http://www.ornl.gov/sci/techresources/Human\\_Genome/research/bermuda.shtml](http://www.ornl.gov/sci/techresources/Human_Genome/research/bermuda.shtml) (accessed December 1, 2018).

Directive that included plans to make federally funded research data available to the public.<sup>28</sup> This announcement describes the NIH's policy regarding published manuscripts in particular, but also notes that the results of vgovernment-funded research can take many forms, including data sets. Currently the NIH requires that proposals for funding of over \$500,000 include a data sharing plan.<sup>29</sup>

To that end, a significant advancement in bioinformatics is in making research datasets more available and reusable. From the community of researchers who are enabling this effort the concept of FAIR data has emerged. FAIR datasets are Findable, Accessible, Interoperable and Reusable. FAIR data principles lay out a framework to encourage increased sharing and use of scientific datasets. Findable data includes the use of global persistent identifiers and metadata standards. Accessible data is available on the Internet and searchable through metadata usage. Interoperable data use a “formal, accessible, shared and broadly applicable language for knowledge representation”. Finally, reusable data have clear attribution and license that enables reuse. The webportal FAIRsharing provides curated resources on datasets, standards and collections that are more FAIR.<sup>30</sup> Resources such as BioCaddie DataMed enable discovery of datasets through a Data Discovery Index.<sup>31</sup>

## 9.5.2 Data Standards, Metadata and Biomedical Ontologies

► Chapter 7 on standards in biomedical informatics addresses standardized terminologies as well as standards for data exchange, and terminologies for translational research are discussed in ► Chap. 27. The develop-

ment of such schemes necessitates the creation of terminology standards, just as in clinical informatics. There are now many controlled vocabularies (or ontologies) and metadata standards for annotation of genomic or proteomic data. Metadata standards help define information which should be collected and annotated upon various types of datasets. Furthermore, a great many tools have been developed to help researchers access and analyze this data. For example, the previously mentioned Bioconductor project provides bioinformatic tools in the R language for solving common problems. Other commonly used tools include BioPerl, BioPython and MATLAB.<sup>32</sup>

Biomedical ontologies have become a key component in the development of metadata standards for the management and exchange of bioinformatic datasets and in making data more FAIR (see ► Sect. 9.5.1). The open biomedical ontologies consortium (OBO) has developed a number of reference ontologies that are in wide use in bioinformatics including Gene Ontology, Human Phenotype Ontology and the UBERON anatomy ontology (Smith et al. 2007). For example, **Gene Ontology (GO)** is an ontology used for annotation of gene function, and arguably the most widely used ontology in basic research. Ontologies enable indexing, exchange and computing with biomedical datasets and metadata.

Metadata standards for bioinformatics datasets are an intellectual challenge for researchers to enable the sharing and interoperability of data and to make data more FAIR. There are a number of tools and web portals such as the Center for Expanded Data Annotation and Retrieval (CEDAR) provide tools for creation and sharing of metadata about datasets.<sup>33</sup> Metadata can include information about an experiment such as the protocol, the time the experiment was performed, who performed the experiment and technology used to generate or analyze the experiment, but

**Lineage** Eukaryota; Metazoa; Chordata; Craniata; Vertebrata; Euteleostomi; Mammalia; Eutheria; Euarchontoglires; Primates; Haplorhini; Catarrhini; Hominoidea; Homo

**Also known as** CBPP; ELA3B

**Summary** Elastases form a subfamily of serine proteases that hydrolyze many proteins in addition to elastin. Humans have six elastase genes which encode the structurally similar proteins elastase 1, 2, 2A, 2B, 3A, and 3B. Unlike other elastases, elastase 3B has little elastolytic activity. Like most of the human elastases, elastase 3B is secreted from the pancreas as a zymogen and, like other serine proteases such as trypsin, chymotrypsin and kallikrein, it has a digestive function in the intestine. Elastase 3B preferentially cleaves proteins after alanine residues. Elastase 3B may also function in the intestinal transport and metabolism of cholesterol. Both elastase 3A and elastase 3B have been referred to as protease E and as elastase 1, and excretion of this protein in fecal material is frequently used as a measure of pancreatic function in clinical assays. can also include information such as organism, disease model, tissue, conditions, etc.

### 9.5.2.1 Sequence and Genome Databases

The main types of sequence information that must be stored are DNA and protein. One of the largest DNA **sequence databases** is GENBANK, which is managed by the NCBI.<sup>23</sup> GENBANK is growing rapidly as genome-sequencing projects feed their data (often in an automated procedure) directly into the database. **Figure 9.3** shows the logarithmic growth of data in GENBANK since 1982. NCBI Gene curates some of the many genes within GENBANK and presents the data in a way that is easy for the researcher to use (**Fig. 9.4**).

In addition to GENBANK, there are numerous special-purpose DNA databases for which the curators have taken special care to clean, validate, and annotate the data. The work required of such curators indicates the degree to which raw sequence data must be

of the key regions in the sequence and the complete sequence of DNA bases (a, g, t, and c) is provided as a link. (Courtesy of NCBI)

interpreted cautiously. GENBANK can be searched efficiently with a number of algorithms and is usually the first stop for a scientist with a new sequence who wonders “Has a sequence like this ever been observed before? If one has, what is known about it?” There are increasing numbers of stories about scientists using GENBANK to discover unanticipated relationships between DNA sequences, allowing their research programs to leap ahead while taking advantage of information collected on similar sequences.

A database that has become very useful recently is the University of California Santa Cruz Genome Browser<sup>34</sup> (**Fig. 9.5**). This data set allows users to search for specific sequences in the UCSC version of the human genome. Powered by the similarity search tool BLAT, users can quickly find annotations on the human genome that contain their sequence of interest. These annotations include known

34 <http://genome.ucsc.edu/> (accessed December 1, 2018).

**Fig. 9.5** Screen from the UC Santa Cruz genome browser showing the chymotrypsin C gene. The rows in the browser show annotations on the gene sequence. The browser window here shows a small segment of human chromosome 15, as if the sequence of a, g, c and

t are represented from left to right (5–3). The annotations include gene predictions and annotations as well as an alignment of the similarity of this region of the genome when compared with the mouse genome

variations (mutations and SNPs), genes, comparative maps with other organisms, and many other important data.

### 9.5.3 Structure Databases

Although sequence information is obtained relatively easily, structural information remains expensive on a per-entry basis. The experimental protocols used to determine precise molecular structural coordinates are expensive in time, materials, and human power. Therefore, we have only a small number of structures for all the molecules characterized in the sequence databases. The two main sources of structural information are the Cambridge Structural Database<sup>35</sup> for small

molecules (usually less than 100 atoms) and the PDB<sup>36</sup> for macromolecules (see ▶ Sect. 9.3.2), including proteins and nucleic acids, and combinations of these macromolecules with small molecules (such as drugs, cofactors, and vitamins). The PDB has approximately 75,000 high-resolution structures, but this number is misleading because many of them are small variants on the same structural architecture. There are approximately 100,000 proteins in humans; therefore, many structures remain unsolved (e.g., Burley and Bonanno 2002). In the PDB, each structure is reported with its biological source, reference information, manual annotations of interesting features, and the Cartesian coordinates of each atom within the molecule. Given knowledge of the three-dimensional structure of

35 ▶ <https://www.ccdc.cam.ac.uk/solutions/csd-system/components/csd/> (accessed December 15, 2018).

36 ▶ <https://www.rcsb.org/> (accessed December 18, 2018).

molecules, the function sometimes becomes clear. For example, the ways in which the medication methotrexate interacts with its biological target have been studied in detail for two decades. Methotrexate is used to treat cancer and rheumatologic diseases, and it is an inhibitor of the protein dihydrofolate reductase, an important molecule for cellular reproduction. The three-dimensional structure of dihydrofolate reductase has been known for many years and has thus allowed detailed studies of the ways in which small molecules, such as methotrexate, interact at an atomic level. As the PDB increases in size, it becomes important to have organizing principles for thinking about biological structure. SCOP2<sup>37</sup> provides a classification based on the overall structural features of proteins. It is a useful method for accessing the entries of the PDB.

#### 9.5.4 Analysis of Biological Pathways and Understanding of Disease Processes

The ECOCYC project is an example of a computational resource that has comprehensive information about biochemical pathways. ECOCYC is a knowledge base of the metabolic capabilities of *E. coli*; it has a representation of all the enzymes in the *E. coli* genome and of the chemical compounds those enzymes transform.<sup>38</sup> It also links these enzymes to their genes, and genes are mapped to the genome sequence.

EcoCyc also encodes the genetic regulatory network of *E. coli*, describing all protein and RNA regulators of *E. coli* genes. The network of pathways within ECOCYC provides an excellent substrate on which useful applications can be built. For example, they provide: (1) the ability to guess the function of a new protein by assessing its similarity to *E. coli* genes with a similar sequence, (2) the ability to ask what the effect on an organism would be if a critical component of a path-

way were removed (would other pathways be used to create the desired function, or would the organism lose a vital function and die?), and (3) the ability to provide a rich user interface to the literature on *E. coli* metabolism. Similarly, the Kyoto Encyclopedia of Genes and Genomes (KEGG) provides pathway datasets for organism genomes.<sup>39</sup>

#### 9.5.5 Integrative Databases

A **integrative database** is a postgenomic database that bridges the gap between molecular biological databases with those of clinical importance. One excellent example of a postgenomic database is the Online Mendelian Inheritance in Man (OMIM) database, which is a compilation of known human genes and genetic diseases, along with manual annotations describing the state of our understanding of individual genetic disorders.<sup>40</sup> Each entry contains links to special-purpose databases and thus provides links between clinical syndromes and basic molecular mechanisms (■ Fig. 9.6).

### 9.6 Future Challenges as Bioinformatics and Clinical Informatics Converge

Bioinformatics didn't solve all of its problems with the sequencing of the human genome. There is a series of challenges for which the completion of the first human genome sequence is only the beginning.

#### 9.6.1 Linkage of Molecular Information with Symptoms, Signs, and Patients

There is currently a gap in our understanding of disease processes. Although we have a good understanding of the principles by

Clinical Synopsis

▼ TEXT

Townes (1969) reported a 3.5-year-old female with generalized anasarca, hypoproteinemia, and congestive heart failure. A combined proteolytic and lipolytic defect was found. Activities of trypsin, chymotrypsin, carboxypeptidase, and lipase were completely absent. Activation studies proved negative. Striking improvement accompanied feeding of protein hydrolysate (Townes, 1972). The child also had an imperforate anus, a point of interest because a patient with trypsinogen deficiency also had imperforate anus.

which small groups of molecules interact, we are not able to explain fully how thousands of molecules interact within a cell to create both normal and abnormal physiological states. As the databases continue to accumulate information ranging from patient-specific data to fundamental genetic information, a major challenge is creating the conceptual links among these databases to create an audit trail from molecular-level information to macroscopic phenomena, as manifested in disease. The availability of these links will facilitate the identification of important targets for future research and will provide a scaffold for biomedical knowledge, ensuring that important literature is not lost within the increasing volume of published data.

## 9.6.2 Computational Representations of the Biomedical Literature

An important opportunity within bioinformatics is the linkage of biological experimental data with the published papers that report them. Electronic publication of the biologi-

cal literature provides exciting opportunities for making data easily available to scientists. Already, certain types of simple data that are produced in large volumes are expected to be included in manuscripts submitted for publication, including new sequences that are required to be deposited in GENBANK and new structure coordinates that are deposited in the PDB. However, there are many other experimental data sources that are currently difficult to provide in a standardized way, either because the data are more intricate than those stored in GENBANK or PDB or they are not produced in a volume sufficient to fill a database devoted entirely to the relevant area. Knowledge base technology can be used, however, to represent multiple types of highly interrelated data.

Knowledge bases can be defined in many ways (see ▶ Chap. 24); for our purposes, we can think of them as databases in which (1) the ratio of the number of tables to the number of entries per table is high compared with usual databases, (2) the individual entries (or records) have unique names, and (3) the values of many fields for one record in the database are the names of other records, thus creating

in which chymotrypsin (NCBI Gene entry shown in **Fig. 9.2**) is totally absent (as are some other key digestive enzymes). (Courtesy of NCBI)

a highly interlinked network of concepts. The structure of knowledge bases often leads to unique strategies for storage and retrieval of their content. To build a knowledge base for storing information from biological experiments, there are some requirements. First, the set of experiments to be modeled must be defined. Second, the key attributes of each experiment that should be recorded in the knowledge base must be specified. Third, the set of legal values for each attribute must be specified, usually by creating a controlled terminology for basic data or by specifying the types of knowledge-based entries that can serve as values within the knowledge base.

### 9.6.3 Computational Challenges with an Increasing Deluge of Biomedical Data

An increasing challenge in biomedicine is storing, interpreting and integrating the massive amount of datasets the biomedical community is generating, largely from modern technologies in high throughput experimentation. The amount of DNA sequence data being generated over time has dwarfed Moore's Law, for example. This issue is important for all areas of biomedical informatics, and is discussed in more detail in the on Translational Bioinformatics (► Chap. 26).

## 9.7 Conclusion

Bioinformatics is closely allied to translational and clinical informatics. It differs in its emphasis on a reductionist view of biological systems, starting with sequence information and moving to structural and functional information. The emergence of the genome sequencing projects and the new technologies for measuring metabolic processes within cells is beginning to allow bioinformaticians to construct a more synthetic view of biological processes, which will complement the whole-organism, top-down approach of clinical informatics. More importantly, there are technologies that can be shared between bio-

informatics and clinical informatics because they both focus on representing, storing, and analyzing biological or biomedical data. These technologies include the creation and management of standard terminologies and data representations, the integration of heterogeneous databases, the organization and searching of the biomedical literature, the use of machine learning techniques to extract new knowledge, the simulation of biological processes, and the creation of knowledge-based systems to support advanced practitioners in the two fields.

### Suggested Readings

- Altman, R. B., Dunker, A. K., Hunter, L., & Klein, T. E. (2003). *Pacific symposium on Biocomputing'03*. Singapore: World Scientific Publishing. The proceedings of one of the principal meetings in bioinformatics, this is an excellent source for up-to-date research reports. Other important meetings include those sponsored by the International Society for Computational Biology (ISCB, <http://www.iscb.org/>), Intelligent Systems for Molecular Biology (ISMB, <http://iscb.org/conferences.shtml.35>), and the RECOMB meetings on computational biology (<http://www.ctw-congress.de/recomb/>). ISMB and PSB have their proceedings indexed in PubMed.
- Baldi, P., & Brunak, S. (2001). *Bioinformatics: The machine learning approach*. Cambridge, MA: MIT Press. This introduction to the field of bioinformatics focuses on the use of statistical and artificial intelligence techniques in machine learning.
- Baldi, P., & Hatfield, G. W. (2002). *DNA microarrays and gene expression*. Cambridge: Cambridge University Press. Introduces the different microarray technologies and how they are analyzed.
- Berg, J. M., Tymoczko, J. L., & Stryer, L. (2010). *Biochemistry*. New York: W.H. Freeman. The textbook by Stryer and colleagues is well written, and is illustrated and updated on a regular basis. It provides an excellent introduction to basic molecular biology and biochemistry.
- Durbin, R., Eddy, S. R., Krogh, A., & Mitchison, G. (1998). *Biological sequence analysis: Probabilistic models of proteins and nucleic acids*. Cambridge: Cambridge University Press.

This edited volume provides an excellent introduction to the use of probabilistic representations of sequences for the purposes of alignment, multiple alignment, and analysis.

- Gusfield, D. (1997). *Algorithms on strings, trees and sequences: Computer science and computational biology*. Cambridge: Cambridge University Press. Gusfield's text provides an excellent introduction to the algorithmics of sequence and string analysis, with special attention paid to biological sequence analysis problems.
- Malcolm, S., & Goodship, J. (Eds.). (2007). *Genotype to phenotype* (2nd ed.). Oxford: BIOS Scientific Publishers. This volume illustrates the different efforts to understand how diseases are linked to genes.
- Pevsner, P. (2009). *Bioinformatics and functional genomics*. Hoboken: Wiley. A widely used excellent introduction to bioinformatics algorithms.

### ? Questions for Discussion

1. How are DNA and protein sequence information changing the way that medical records are managed? Which types of systems are or will be most affected (laboratory, radiology, admission and discharge, financial, order entry)?
2. It has been postulated that clinical informatics and bioinformatics are working on the same problems, but in some areas one field has made more progress than the other. Identify three common themes. Describe how the issues are approached by each subdiscipline.
3. Why should an awareness of bioinformatics be expected of clinical informatics professionals? Should a chapter on bioinformatics appear in a clinical informatics textbook? Explain your answers.
4. Why should an awareness of clinical informatics be expected of bioinformatics professionals? Should a chapter on clinical informatics appear in a bioinformatics textbook? Explain your answers.
5. One major problem with introducing computers into clinical medicine is the extreme time and resource pressure placed on physicians and other health care workers. Do you think that the same problems are arising in basic biomedical research?
6. Why have biologists and bioinformaticians embraced the Web as a vehicle for disseminating data so quickly, whereas clinicians and clinical informaticians have been more hesitant to put their primary data online?
7. If a patient's entire genome were present in their medical record how would one go about interpreting it clinically? Similarly, if we had an entire electronic health record database that included human genomes, how would a researcher go about finding new or novel genetic associations?
8. With the many high throughput experiments that are used in biomedical research, how are some ways to integrate those datasets using systems biology? For example, if you had a microarray dataset that annotated gene expression levels and a proteomics dataset that identified protein interactions, how could you jointly use both datasets to identify markers for a disease?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

1. What makes images a challenging type of data to be processed by computers when compared to non-image clinical data?
2. Why are there many different imaging modalities, and by what major two characteristics do they differ?
3. How are visual and knowledge content in images represented computationally? How are these techniques similar to representation of non-image biomedical data?
4. What sort of applications can be developed to make use of the semantic image content made accessible using the Annotation and Image Markup model?
5. What are four different types of image processing methods? Why are such methods assembled into a pipeline when creating imaging applications?
6. What is an imaging modality with high spatial resolution? What is a modality that provides functional information? Why are most imaging modalities not capable of providing both?
7. What is the goal in performing segmentation in image analysis? Why is there more than one segmentation method?
8. What are the main segmentation methods and what are their limitations? Should deep learning be always used as a first choice as its performance is relatively high?
9. What are two types of quantitative information in images? What are two types of semantic information in images? How might this information be used in medical applications?
10. What is the difference between image registration and image fusion? What are examples of each?
11. Can medical image analysis methods replace physicians who interpret images, or should their role to serve as adjunct tools to assist their image interpretations?

## 10.1 Introduction

Imaging plays a central role in the healthcare process. The field is crucial not only to health care, but also to medical communication and education, as well as in research. In fact much of our recent progress, particularly in diagnosis, can be traced to the availability of increasingly sophisticated imaging techniques that not only show the structure of the body in incredible detail, but also show the function of the tissues within the body.

Although there are many types (or modalities) of imaging equipment, the images the modalities produce are nearly always acquired in or converted to digital form. The evolution of imaging from analog, film-based acquisition to digital format has been driven by the necessities of cost reduction, efficient throughput, and workflow in managing and viewing an increasing proliferation in the number of images produced per imaging procedure (currently hundreds or even thousands of images). At the same time, having images in digital format makes them amenable to image processing methodologies for enhancement, analysis, display, storage, and even enhanced interpretation.

Because of the ubiquity of images in biomedicine, the increasing availability of images in digital form, the rise of high-powered computer hardware and networks, and the commonality of image processing solutions, digital images have become a core data type that must be considered in many biomedical informatics applications. Therefore, this chapter is devoted to a basic understanding of the unique aspects of images as a core data type and the unique aspects of imaging from an informatics perspective. ► Chapter 22, on the other hand, describes the use of images and image processing in various applications, particularly those in radiology since that field places the greatest demands on imaging methods.

The topics covered by this chapter and ► Chap. 22 comprise the growing discipline of biomedical imaging informatics (Kulikowski 1997), a subfield of biomedical informatics (see ► Chap. 1) that has arisen in recognition

■ **Fig. 10.1** The major topics in biomedical imaging informatics follow a workflow of activities and tasks commencing with include image acquisition, followed

by image content representation, management/storage of images, image processing, and image interpretation/computer reasoning

of the common issues that pertain to all image modalities and applications once the images are converted to digital form.

Biomedical imaging informatics is a dynamic field, recently evolving from primarily focusing on image processing to broader informatics topics such as representing and processing the semantic contents (Rubin and Napel 2010) and integrating image data with other types of data (Scheckenbach et al. 2017; Pujara et al. 2018; Valdora et al. 2018; Weaver and Leung 2018). At the same time, imaging informatics shares common methodologies and challenges with other domains in biomedical informatics. By trying to understand these common issues, we can develop general solutions that can be applied to all images, regardless of the source.

The major topics in biomedical imaging informatics include image acquisition, image

content representation, management/storage of images, image processing, and image interpretation/computer reasoning (■ Fig. 10.1).

**Image acquisition** is the process of generating images from the modality and converting them to digital form if they are not intrinsically digital. **Image content representation** makes the information in images accessible to machines for processing. **Image management/storage** includes methods for storing, transmitting, displaying, retrieving, and organizing images. **Image processing** comprises methods to enhance, segment, visualize, fuse, or analyze the images. **Image interpretation/computer reasoning** is the process by which the individual viewing the image renders an impression of the medical significance of the results of imaging study, potentially aided by computer methods. ▶ Chapter 22 is primarily concerned with information systems for

image management and storage, whereas this chapter concentrates on these other core topics in biomedical imaging informatics.

An important concept when thinking about imaging from an informatics perspective is that images are an *unstructured data type*; though they are readily understood and interpreted by knowledgeable human experts, their contents are not readily machine understanding except at the granular pixel level. As such, while machines can readily manage the raw image data in terms of storage/retrieval, they cannot easily access image contents (recognize the type of image, annotations made on the image, or anatomy or abnormalities within the image), except for newer deep learning methods (► Sect. 10.4.5). In this regard, biomedical imaging informatics shares much in common with natural language processing (NLP; ► Chap. 8). In fact, as the methods of computationally representing and processing images is presented in this chapter, parallels to NLP should be considered, since there is synergy from an informatics perspective.

As in NLP, a major purpose of the methods of imaging informatics is to extract particular information; in biomedical informatics the goal is often to extract information about the structure of the body and to collect features that will be useful for characterizing abnormalities based on morphological alterations. In fact, imaging provides detailed and diverse information very useful for characterizing disease, providing an “imaging phenotype” useful for characterizing disease, since “a picture is worth a thousand words,<sup>1</sup>” and the informatics methods for capturing imaging phenotypes complement the informatics methods that are now being applied to electronic medical records data to capture “electronic phenotypes” of diseased patients. However, to overcome the challenges posed by the unstructured image data type, recent work is applying semantic methods from biomedical informatics to images to make their content explicit for machine processing

(Rubin and Napel 2010), as well as processing entire images to learn certain semantic image content (Hosny et al. 2018; Yamashita et al. 2018). Many of the topics in this chapter therefore involve how to represent, extract and characterize the information that is present in images, such as anatomy and abnormalities. Once that task is completed, useful applications that process the image contents can be developed, such as image search and decision support to assist with image interpretation.

While we seek generality in discussing biomedical imaging informatics, many examples in this chapter are taken from a few selected domains such as brain imaging, which is part of the growing field of **neuroinformatics** (Koslow and Huerta 1997). Though our examples are specific, we attempt to describe the topics in generic terms so that the reader can recognize parallels to other imaging domains and applications.

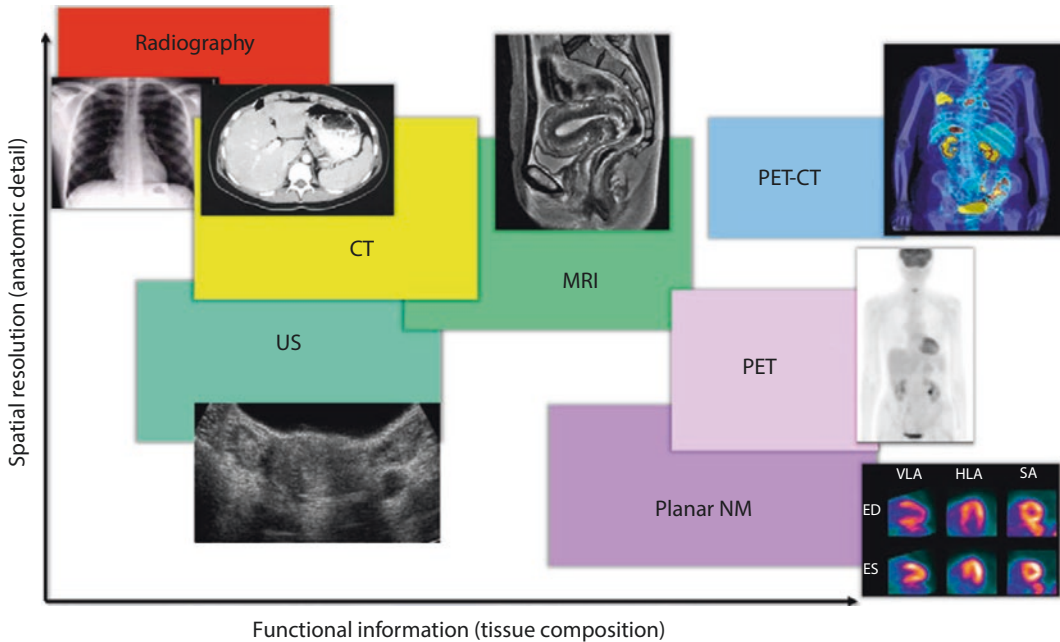

## 10.2 Image Acquisition

In general, there are two different strategies in imaging the body: (1) delineate *anatomic structure* (anatomic/structural imaging), and (2) determine *tissue composition or function* (functional imaging) (■ Fig. 10.2). In reality, one does not choose between anatomic and functional imaging; many modalities provide information about both morphology and function. However, in general, each imaging modality is characterized primarily as being able to render high-resolution images with good contrast resolution (anatomic imaging) or to render images that depict tissue function (functional imaging).

### 10.2.1 Anatomic (Structural) Imaging

Imaging the structure of the body has been and continues to be the major application of medical imaging, although, as described in ► Sect. 10.2.2, functional imaging is a very active area of research. The goal of anatomic imaging is to accurately depict the structure

1 Frederick Barnard, “One look is worth a thousand words,” Printers’ Ink, December, 1921.

**Fig. 10.2** The various radiology imaging methods differ according to two major axes of information of images, spatial resolution (anatomic detail) and func-

tional information depicted (which represents the tissue composition—e.g., normal or abnormal). A sample of the more common imaging modalities is shown

of the body—the size and shape of organs—and to visualize abnormalities clearly. Since the goal in anatomic imaging is to depict and understand the structure of anatomic entities accurately, high spatial resolution is an important requirement of the imaging method (Fig. 10.2). Conversely, in anatomic imaging, recognizing tissue function (e.g., tissue ischemia, neoplasm, inflammation, etc.) is not the goal, though this is crucial to functional imaging and to patient diagnosis. In most cases, imaging will be done using a combination of methods or modalities to derive both structural/anatomic information as well as functional information.

## 10.2.2 Functional Imaging

Many imaging techniques not only show the structure of the body, but also the function, where for imaging purposes function can be inferred by observing changes of structure over time. In recent years this ability to image function has greatly accelerated. For example, ultrasound and angiography are widely used

to show the functioning of the heart by depicting wall motion, and ultrasound doppler can image both normal and disturbed blood flow (Mehta et al. 2000). Molecular imaging (Sect. 10.2.3) is increasingly able to depict the expression of particular genes superimposed on structural images, and thus can also be seen as a form of functional imaging.

A particularly important application of functional imaging is for understanding the cognitive activity in the brain. It is now routinely possible to put a normal subject in a scanner, to give the person a cognitive task, such as counting or object recognition, and to observe which parts of the brain light up. This unprecedented ability to observe the functioning of the living brain opens up entirely new avenues for exploring how the brain works.

Functional brain imaging modalities can be classified as *image-based* or *non-image based*. In both cases it is taken as axiomatic that the functional data must be mapped to the individual subject's anatomy, where the anatomy is extracted from structural images using techniques described in the previous sections.

Once mapped to anatomy, the functional data can be integrated with other functional data from the same subject, and with functional data from other subjects whose anatomy has been related to a template or probabilistic atlas. Techniques for generating, mapping and integrating functional data are part of the field of Functional Brain Mapping, which has become very active in the past few years, with several conferences (Organization for Human Brain Mapping 2001) and journals (Fox 2001; Toga et al. 2001) devoted to the subject.

#### ■ ■ Image-Based Functional Brain Imaging

Image-based functional data generally come from scanners that generate relatively low-resolution volume arrays depicting spatially-localized activation. For example, **positron emission tomography** (PET) (Heiss and Phelps 1983; Aine 1995; Alberini et al. 2011) and **magnetic resonance spectroscopy** (MRS) (Ross and Bluml 2001) reveal the uptake of various metabolic products by the functioning brain; and **functional magnetic resonance imaging** (fMRI) reveals changes in blood oxygenation that occur following neural activity (Aine 1995). The raw intensity values generated by these techniques must be processed by sophisticated statistical algorithms to sort out how much of the observed intensity is due to cognitive activity and how much is due to background noise.

As an example, one approach to fMRI imaging is language mapping (Corina et al. 2000). The subject is placed in the **magnetic resonance imaging** (MRI) scanner and told to silently name objects shown at 3-second intervals on a head-mounted display. The actual objects (“on” state) are alternated with nonsense objects (“off” state), and the fMRI signal is measured during both the on and the off states. Essentially the **voxel** values at the off (or control) state are subtracted from those at the on state. The difference values are tested for significant difference from non-activated areas, then expressed as t-values. The voxel array of t-values can be displayed as an image.

A large number of alternative methods have been and are being developed for acquir-

ing and analyzing functional data (Frackowiak et al. 1997). The output of most of these techniques is a low-resolution 3-D image volume in which each voxel value is a measure of the amount of activation for a given task. The low-resolution volume is then mapped to anatomy guided by a high-resolution structural MR dataset, using one of registration techniques described in ► Sect. 10.4.7.

Many of these and other techniques are implemented in the SPM program (Friston et al. 1995), the AFNI program (Cox 1996), the Lyngby toolkit (Hansen et al. 1999), and several commercial programs such as Medex (Sensor Systems Inc. 2001) and BrainVoyager (Brain Innovation B.V. 2001). The FisWidgets project at the University of Pittsburgh is developing an approach that allows customized creation of graphical user interfaces in an integrated desktop environment (Cohen 2001). A similar effort (VoxBox) is underway at the University of Pennsylvania (Kimborg and Aguirre 2002).

The ultimate goal of functional neuroimaging is to observe the actual electrical activity of the neurons as they perform various cognitive tasks. fMRI, MRS and PET do not directly record electrical activity. Rather, they record the results of electrical activity, such as (in the case of fMRI) the oxygenation of blood supplying the active neurons. Thus, there is a delay from the time of activity to the measured response. In other words these techniques have relatively poor temporal resolution (► Sect. 10.2.4). **Electro-encephalography** (EEG) or **magnetoencephalography** (MEG), on the other hand, are more direct measures of electrical activity since they measure the electromagnetic fields generated by the electrical activity of the neurons. Current EEG and MEG methods involve the use of large arrays of scalp sensors, the output of which are processed in a similar way to CT in order to localize the source of the electrical activity inside the brain. In general this “source localization problem” is under-constrained, so information about brain anatomy obtained from MRI is used to provide further constraints (George et al. 1995).

### 10.2.3 Imaging Modalities

There are many different approaches that have been developed to acquire images of the body. A proliferation in imaging modalities reflects the fact that there is no single imaging technique that satisfies all the desiderata for depicting the broad variety of types of pathology. Some abnormalities are better seen on some modalities than on others. The primary difference among the imaging modalities is the type of energy source used to generate the images. In radiology, nearly every type of energy in the electromagnetic spectrum has been used, in addition to other physical phenomena such as sound and heat. We describe the more common methods according to the type of energy used to create the image.

#### ■ Light

The earliest medical images used visible light to create photographs, either of gross anatomic structures and skin lesions or, if a microscope was used, of histological specimens. Light is still an important source for creation of images, and in fact optical imaging has seen a resurgence of interest and application for areas such as molecular imaging (Weissleder and Mahmood 2001; Ray 2011) and imaging of brain activity on the exposed surface of the cerebral cortex (Pouratian et al. 2003). Visible light is the basis for dermatological imaging (Katragadda, Finnane et al. 2016), retinal imaging (Panwar et al. 2016), and a newer modality called “optical imaging” that has promising applications such as cancer imaging (Solomon et al. 2011). Visible light, however, does not allow us to see more than a short distance beneath the surface of the body; thus other modalities are used for imaging structures deep inside the body.

#### ■ Radiography

X-rays were first discovered in 1895 by Wilhelm Conrad Roentgen, who was awarded the 1901 Nobel Prize in Physics for this achievement. The discovery caused worldwide excitement, especially in the field of medicine; by 1900, there already were several medical radiological societies. Thus, the foundation was laid for

■ **Fig. 10.3** A radiograph of the chest (Chest X-ray) taken in the frontal projection. The image is shown as if the patient is facing the viewer. This patient has abnormal density in the left lower lobe

a new branch of medicine devoted to imaging the structure and function of the body (Kevles 1997).

Radiography (colloquially called “X-ray”) is still the primary modality used in radiology departments today, both to record a static image (■ Fig. 10.3) as well as to produce a real-time view of the patient (fluoroscopy) or a movie (cine). Both film and fluoroscopic analog screens were used initially for recording radiology images, but the fluoroscopic images very faint and required dark adaption (radiologists wore red goggles during the daytime to maximally sensitize their vision). By the 1940s, however, television and image-intensifier technologies were developed to produce clear real-time fluorescent images. Fluoroscopic examinations commonly combine real-time video monitoring of fluoroscopic images with the creation of selected higher resolution images.

Radiography is a projection technique; an X-ray beam—one form of ionizing radiation—is projected from an X-ray source through a patient’s body (or other object) onto an X-ray array detector (a specially coated cassette that is scanned by a computer to capture the image in digital form), or film (to produce a non-digital image). Because an X-ray beam is differentially absorbed by

the various body tissues based on the thickness and atomic number of the tissues, the X-rays produce varying degrees of brightness and darkness on the radiographic image. The differential amounts of brightness and darkness on the image are referred to as “image contrast;” differential contrast among structures on the image is the basis for recognizing anatomic structures. Since the image in radiography is a projection, radiographs show a superposition of all the structures traversed by the X-ray beam. Much of the art (and difficulty) in interpretation of radiographs is understanding the imaging patterns that result from these superimposed structures and how to differentiate pathologies from normal structures or artifacts.

Radiographic images have very high spatial resolution because a high photon flux is used to produce the images, and a high resolution detector (film or digital image array) that captures many line pairs per unit area is used. On the other hand, since the contrast in images is due to differences in tissue density and atomic number, the amount of functional information that can be derived from radiographic images is limited (■ Fig. 10.2). Radiography is also limited by relatively poor contrast resolution (compared with other modalities such as computed tomography (CT) or magnetic resonance imaging (MRI) described below), their use of ionizing radiation, the challenge of spatial localization due to projection ambiguity, and their limited ability to depict physiological function. As described below, newer imaging modalities have been developed to increase contrast resolution, to eliminate the need for X-rays, and to improve spatial localization. A benefit of radiographic images is that they can be generated in real time (fluoroscopy) and can be produced using portable devices.

**Digital radiography (DR)** is an imaging technique that directly creates digital radiographs from the imaging procedure. Storage phosphor replaces film by substituting a reusable phosphor plate in a standard film cassette. The exposed plate is processed by a reader system that scans the image into digital form, erases the plate, and packages the cassette for reuse. An important advantage of

CR systems is that the cassettes are of standard size, so they can be used in any equipment that holds film-based cassettes (Horii 1996). More recently, digital radiography uses charge-coupled device (CCD) arrays to capture the image directly. Currently, nearly all radiology departments no longer acquire radiographic images on film (analog images) and instead use digital radiography (Korner et al. 2007) to acquire digital images. This evolution was driven by the cost of film and technological advances in digital image acquisition detectors and monitors whose resolution approached that of film. At the same time, digitization of radiology drove the evolution of methods of imaging informatics we describe in this chapter.

**Computed Tomography (CT)** is an important imaging method that uses X-rays to produce cross sectional and volumetric images of the body (Lee 2006). Similar to radiography, X-rays are projected through the body onto an array of detectors; however, the beam and detectors rotate around the patient, making numerous views at different angles of rotation. Using computer reconstruction algorithms, an estimate of absolute density at each point (volume element or **voxel**) in the body is computed. Thus, the CT image is a computed image (■ Fig. 10.4); CT did not become practical for generating high quality images until the advent of powerful computers and development of computer-based reconstruction techniques, which represent one of the most

■ **Fig. 10.4** A CT image of the upper chest. CT images are slices of a body plane; in this case, a cross sectional (axial) image of the chest. Axial images are viewed from below the patient, so that the patient's left is on viewer's right. This image shows a cancer mass in the left upper lobe of the lung

spectacular applications of computers in all of medicine (Buxton 2009). The spatial resolution of images is not as high in CT as it is in radiography, due to the computed nature of the images; however, the contrast resolution and ability to derive functional information of tissues in the body are superior for CT than for radiography (■ Fig. 10.2).

### ■ Ultrasound

A common energy source used to produce images is **ultrasound**, which developed from research performed by the Navy during World War II in which sonar was used to locate objects of interest in the ocean. Ultrasonography uses pulses of high-frequency sound waves rather than ionizing radiation to image body structures (Kremkau 2006). The basis of image generation is due to a property of all objects called acoustical impedance. As sound waves encounter different types of tissues in a patient's body (particularly interfaces where there is a change in acoustical impedance), a portion of the wave is reflected and a portion of the sound beam (which is now attenuated) continues to traverse into deeper tissues. The time required for the echo to return is proportional to the distance into the body at which it is reflected; the amplitude (intensity) of a returning echo depends on the acoustical properties of the tissues encountered and is represented in the image as brightness (more echoes returning to the source is shown as image brightness). The system constructs two-dimensional images

(B-scans) by displaying the echoes from pulses of multiple adjacent one-dimensional paths (A-scans). Current ultrasound machines are essentially specialized computers with attached peripherals, with active development of three-dimensional imaging. The ultrasound transducer now often sweeps out a 3-D volume rather than a 2-D plane, and the data are written directly into a three-dimensional array memory, which is displayed using volume or surface-based rendering techniques (Ritchie et al. 1996).

Ultrasound images are acquired as digital images from the outset. They may also be recorded as frames in rapid succession (cine loops) for real-time imaging. Ultrasound imaging captures not only structural information but also functional information. Doppler methods in ultrasound are used to measure and characterize the blood flow in blood vessels in the body (■ Fig. 10.5). More recently, ultrasound techniques called elastography have been developed to measure tissue stiffness, which is improving the ability of ultrasound to diagnose a variety of pathology conditions such as liver fibrosis (Pawlus et al. 2015; Zaleska-Dorobisz et al. 2015). The low cost of ultrasound and the fact it doesn't use ionizing radiation makes it very attractive as a primary modality for imaging worldwide, particularly for obstetrical and pediatric imaging.

Since the image contrast in ultrasound is based on differences in the acoustic impedance of tissue, ultrasound provides functional information (e.g., tissue composition and

■ **Fig. 10.5** An ultrasound image of abdomen. Like CT and MRI, ultrasound images are slices of a body, but because a user creates the images by holding a probe, any arbitrary plane can be imaged (so long as the probe can be oriented to produce that plane). This image shows an axial slice through the pancreas, and flow in nearby blood vessels (in color) is seen due to Doppler effects incorporated into the imaging method

blood flow). On the other hand, the flux of sound waves is not as dense as the photon flux used to produce images in radiography; thus ultrasound images are generally lower resolution images than other imaging modalities (■ Fig. 10.2).

### ■ Magnetic Resonance Imaging (MRI)

Creation of images from the resonance phenomena of unpaired spinning charges in a magnetic field grew out of **nuclear magnetic resonance (NMR) spectroscopy**, a technique that has long been used in chemistry to characterize chemical compounds. Many atomic nuclei within the body have a net magnetic moment, so they act like tiny magnets. When a small chemical sample is placed in an intense, uniform magnetic field, these nuclei line up in the direction of the field, spinning around the axis of the field with a frequency dependent on the type of nucleus, on the surrounding environment, and on the strength of the magnetic field.

If a radio pulse of a particular frequency is then applied at right angles to the stationary magnetic field, those nuclei with rotation frequency equal to that of the radiofrequency pulse resonate with the pulse and absorb energy. The higher energy state causes the nuclei to change their orientation with respect to the fixed magnetic field. When the radiofrequency pulse is removed, the nuclei return to their original aligned state (a process called “relaxation”), emitting a detectable radiofrequency signal as they do so. Characteristic parameters of this signal—such as intensity, duration, and frequency shift away from the original pulse—are dependent on the density and environment of the nuclei. In the case of traditional NMR spectroscopy, different molecular environments cause different frequency shifts (called chemical shifts), which we can use to identify the particular compounds in a sample. In the original NMR method, however, the signal is not localized to a specific region of the sample, so it is not possible to create an image.

Creation of medical images from NMR signals, known as Magnetic Resonance Imaging (MRI), came about shortly after fast computer-based reconstruction techniques,

■ Fig. 10.6 An MRI image of the knee. Like CT, MRI images are slices of a body. This image is in the sagittal plane through the mid knee, showing in a tear in the posterior cruciate ligament (arrow)

similar to CT, were developed. The basis of image formation in MRI is based on proton relaxation (referred to as T1 and T2 relaxation); differences in T1 and T2 are inherent properties of tissue and they vary among tissues. Thus, MRI provides detailed functional information about tissue and can be valuable in clinical diagnosis (■ Fig. 10.6). At the same time, the flux of radiofrequency waves used to produce the images is high, and MRI thus has high spatial resolution (■ Fig. 10.2).

Many new modalities are being developed based on magnetic resonance. For example, magnetic resonance arteriography (MRA) and venography (MRV) are used to image blood flow (Lee 2003) and diffusion tensor imaging (DTI) is increasingly being used to image white matter fiber tracts in the brain (Le Bihan et al. 2001; Hasan et al. 2010; de Figueiredo et al. 2011; Gerstner and Sorensen 2011). More recently, a technique called MRI elastography has been developed to measure tissue stiffness (Venkatesh and Ehman 2015).

### ■ Nuclear Medicine Imaging

In **nuclear medicine imaging**, the imaging approach is a reverse of the radiographic imaging: instead of the imaging beam being outside the subject and projecting into the

subject, the imaging source is inside the subject and projects out. Specifically, a radioactive isotope is chemically attached to a biologically active compound (such as an analogue of glucose) and then is injected into the patient's peripheral circulation. The compound collects in the specific body compartments or organs (such as metabolically-active tissues), where it is stored or processed by the body. The isotope emits radiation locally, and the radiation is measured using a special detector. The resultant nuclear-medicine image depicts the level of radioactivity that was measured at each spatial location of the patient. Because the counts are inherently quantized, digital images are produced. Multiple images also can be processed to obtain temporal dynamic information, such as the rate of arrival or of disappearance of isotope at particular body sites.

Nuclear medicine images, like radiographic images, are usually acquired as projections—a large planar detector is positioned outside the patient and it collects a projected image of all the radioactivity emitted from the patient. The images are similar in appearance to radiographic projection images. However, since the photon flux is extremely low (to minimize the radiation dose to the patient), the spatial resolution of nuclear medicine images is low. On the other hand, since the only places where radioisotope accumulates will be places in the body that are targeted by the injected agent, nearly all the information in nuclear medicine images is functional information; thus nuclear imaging methods have high functional information and low spatial resolution (■ Fig. 10.2). Nuclear medicine techniques have recently attracted much attention because of an explosion in novel imaging probes and targeting mechanisms to localize the imaging agent (Drude et al. 2017).

In addition to projection images, a computed tomography-like method called **single-photon emission computed tomography** (SPECT) (Alberini et al. 2011) is often used. A camera rotates around the patient similar to CT, producing a computed volumetric image that may be viewed and navigated in multiple planes. A technique called Positron Emission Tomography (PET) uses a special

■ **Fig. 10.7** A PET image of the body in a patient with cancer in the left lung (same patient as in ■ Fig. 10.4). This is a projection image taken in the frontal plane after injection of a radioactive isotope that accumulates in cancers. A small black spot in the left upper lobe is abnormal and indicates the cancer mass in the upper lobe of the left lung

type of radioactive isotope that emits positrons, which, upon encountering an electron, produces an annihilation event that sends out two gamma rays in opposite directions that are simultaneously detected on an annular detector array and used to compute a cross sectional slice through the patient, similar to CT and SPECT (■ Fig. 10.7). These volumetric nuclear medicine imaging methods, like the projection methods, have high functional information and low spatial resolution. However, recently a newer modality called PET/CT has been developed that integrates a PET scanner and CT with image fusion (discussed below) to get the best of both worlds—functional information about lesions in the PET image plus spatial localization of the abnormality on the CT image (■ Figs. 10.2 and 10.8).

A subdomain of nuclear imaging called **molecular imaging** has emerged that embodies this work on molecularly-targeted imaging (and therapeutic) agents (Weissleder and

■ **Fig. 10.8** A PET/CT fused image. The axial slice from the PET study (■ Fig. 10.7) and the corresponding axial slice from the CT study (■ Fig. 10.4) are combined into a single image that has both good spatial resolution and functional information, showing that the lung mass has abnormal uptake of isotope, indicating it is metabolically active

Mahmood 2001; Massoud and Gambhir 2003; Biswal et al. 2007; Hoffman and Gambhir 2007; Margolis et al. 2007; Ray and Gambhir 2007; Willmann et al. 2008; Pysz et al. 2010). Molecularly-tagged molecules are increasingly being introduced into the living organism, and imaged with optical, radioactive, or magnetic energy sources, often using reconstruction techniques and often in 3-D. It is becoming possible to combine gene sequence information, gene expression array data, and molecular imaging to determine not only which genes are expressed, but where they are expressed in the organism (Kang and Chung 2008; Min and Gambhir 2008; Singh et al. 2008; Lexe et al. 2009; Smith et al. 2009; Harney and Meade 2010). These capabilities will become increasingly important in the post-genomic era for determining exactly how genes generate both the structure and function of the organism.

## 10.2.4 Image Quality

### ■ Characteristics of Image Quality

The imaging modalities described above are complex devices with many parameters that need to be specified in generating the image, and most of the parameters can have substantial impact on the following key characteristics of the final image appearance: spatial resolution, contrast resolution, and temporal resolution, all of which have substantial impact on image quality and diagnostic value

of the image. These characteristics provide an objective means for comparing images formed by digital imaging modalities.

- **Spatial resolution** is related to the sharpness of the image; it is a measure of how well the imaging modality can distinguish points on the object that are close together. For a digital image, spatial resolution is generally related to the number of pixels per image area. Spatial resolution is critical for detecting abnormalities in very small structures, such as microcalcifications on mammograms or diffuse lung diseases on chest radiographs.
- **Contrast resolution** is a measure of the ability to distinguish small differences in intensity in different regions of the image, which in turn are related to differences in measurable parameters, such as X-ray attenuation. For digital images, the number of bits per pixel is related to the contrast resolution of an image. Contrast resolution is critical to image interpretation, since differences in contrast are the basis for an object (of sufficient size) to be appreciated by the human eye or by a computerized image detection algorithm.
- **Temporal resolution** is a measure of the time needed to create an image. We consider an imaging procedure to be a real-time application if it can generate images concurrent with the physical process it is imaging. At a rate of at least 30 images per second, it is possible to produce unblurred images of the beating heart.

Other parameters that are specifically relevant to medical imaging are the degree of invasiveness, the dosage of ionizing radiation, the degree of patient discomfort, the size (portability) of the instrument, the ability to depict physiologic function as well as anatomic structure, and the availability and cost of the procedure at a specific location.

A perfect imaging modality would produce images with high spatial, contrast, and temporal resolution; it would be available, low in cost, portable, free of risk, painless, and noninvasive; it would use nonionizing radiation; and it would depict physiological function as well as anatomic structure. As seen above, the different modalities differ in these characteristics and none is uniformly strong across all the parameters (■ Fig. 10.2).

#### ■ Contrast Agents

One of the major motivators for development of new imaging modalities is the desire to increase contrast resolution. A contrast agent is a substance introduced into the body to enhance the imaging contrast of structures or fluids in medical imaging. Contrast agents can be introduced in various ways, such as by injection, inspiration, ingestion, or enema. The chemical composition of contrast agents vary with modality so as to be optimally visible based on the physical basis of image formation. For example, iodinated contrast agents are used in radiography and CT because iodine has high atomic number, greatly attenuating X-rays, and thus greatly enhancing image contrast in any tissues that accumulate the contrast agent. Contrast agents for radiography are referred to as “radiopaque” since they absorb X-rays and obscure the beam. Contrast agents in radiography are used to highlight the anatomic structures of interest (e.g., stomach, colon, urinary tract). In an imaging technique called angiography, a contrast agent is injected into the blood vessels to opacify them on the images. In pathology, histological staining agents such as haematoxylin and eosin (H&E) have been used for years to enhance contrast in tissue sections, and mag-

netic contrast agents such as gadolinium have been introduced to enhance contrast in MR images.

Recently, contrast agents have been developed for ultrasound to greatly enhance image contrast (Durot et al. 2018). Ultrasound contrast agents generally comprise microbubbles—bubbles in the blood that are too small to cause damage to tissues, but that in aggregate alter the impedance mismatch between blood and tissue to enhance image contrast.

Although contrast agents have been very successful and they are commonly used, their enhancement tends to be non-specific in that any vascularized structure will be enhanced. In recent years, advances in molecular biology have led to the ability to design contrast agents that are highly specific for individual molecules. In addition to radioactively tagged molecules used in nuclear medicine, molecules are tagged for imaging by magnetic resonance and optical energy sources. Tagged molecules are imaged in 2-D or 3-D, often by application of reconstruction techniques developed for clinical imaging (Pysz et al. 2010; Jokerst and Gambhir 2011; Weissleder et al. 2016). Tagged molecules have been used for several years *in vitro* by such techniques as immunocytochemistry (binding of tagged antibodies to antigen) (Van Noorden 2002) and *in situ* hybridization (binding of tagged nucleotide sequences to DNA or RNA) (King et al. 2000). More recently, methods have been developed to image these molecules in the living organism, thereby opening up entirely new avenues for understanding the functioning of the body at the molecular level (Biswal et al. 2007; Hoffman and Gambhir 2007; Margolis et al. 2007; Ray and Gambhir 2007; Willmann et al. 2008; Pysz et al. 2010). Recent work in altering microbubbles of ultrasound contrast agents to target them to particular tissues and types of disease raises the exciting prospects for ultrasound imaging to provide even greater functional information about tissues in a minimally invasive and cost effective manner (Deshpande et al. 2010; Abou-Elkacem et al. 2015; Zhang et al. 2017).

## 10.2.5 Imaging Methods in Other Medical Domains

Though radiology is a core domain and driver of many clinical problems and applications of medical imaging, several other medical domains are increasingly relying on imaging to provide key information for biomedical discovery and clinical insight. The methods of biomedical informatics presented in this chapter, while focusing on radiology in our examples, are generalizable and applicable to these other domains. We briefly highlight these other domains and the role of imaging in them.

### ■ ■ Microscopic/cellular imaging

At the microscopic level, there is a rapid growth in **cellular imaging** (Larabell and Nugent 2010; Toomre and Bewersdorf 2010; Wessels et al. 2010), including use of computational methods to evaluate the features in cells (Carpenter et al. 2006). The confocal microscope uses electronic focusing to move a two-dimensional slice plane through a three-dimensional tissue slice placed in a microscope. The result is a three-dimensional voxel array of a microscopic, or even submicroscopic, specimen (Wilson 1990; Paddock 1994). Confocal endomicroscopy, in which high resolution microscopic imaging technology is integrated into endoscopes, is opening up exciting opportunities for real-time histopathological evaluation in disease (Neumann et al. 2010). At the electron microscopic level electron tomography generates 3-D images from thick electron-microscopic sections using techniques similar to those used in CT (Perkins et al. 1997).

### ■ ■ Pathology/tissue imaging

The radiology department was revolutionized by the introduction of digital imaging and **Picture Archiving and Communication Systems** (PACS). Pathology has likewise begun to shift from an analog to a digital workflow (Leong and Leong 2003; Gombas et al. 2004). Pathology informatics is a rapidly emerging field (Becich 2000; Gabril and Yousef 2010), with goals and research prob-

lems similar to those in radiology, such as managing huge images, improving efficiency of workflow, learning new knowledge by mining historical cases, identifying novel imaging features through correlative quantitative imaging analysis, and decision support. A particularly promising area is deriving novel quantitative image features from pathology images to improve characterization and clinical decision making (Giger and MacMahon 1996; Nielsen et al. 2008; Armstrong 2010) or to improve detection of disease within the specimen (Nagarkar et al. 2016; Ehteshami Bejnordi et al. 2017). Given that pathology and radiology produce images that characterize phenotype of disease, there is tremendous opportunity for information integration and linkage among pathology, radiology, and molecular data for discovery (Permeth et al. 2016).

### ■ ■ Ophthalmologic imaging

Visualization of the retina is a core task of ophthalmology to diagnose disease and to monitor treatment response (Bennett and Barry 2009). Imaging modalities include retinal photography, autofluorescence, and fluorescein angiography. Recently, tomographic-based imaging has been introduced through a technique called **optical coherence tomography** (OCT; ■ Fig. 10.9) (Figurska et al. 2010). This modality is showing great progress in evaluating a variety of retinal diseases (Freton and Finger 2011; Schimmel et al. 2011; Sohrab et al. 2011; de Sisternes et al. 2014). As with radiological imaging, a number of quantitative and automated segmentation methods are being created to evaluate disease objectively (Cabrera Fernandez et al. 2005; Baumann et al. 2010; Hu et al. 2010a, b; Niu et al. 2016; de Sisternes et al. 2017a, b). Likewise, image processing methods for image visualization and fusion are being developed, similar to those used in radiology.

### ■ ■ Dermatologic imaging

Imaging is becoming an important component of dermatology in the management of patients with skin lesions. Dermatologists

■ **Fig. 10.9** An OCT image of the retina. Like ultrasound, OCT produces an image slice at any arbitrary angle (depending on how the light beam can be oriented), but it is limited to visualizing superficial structures due to poor penetration by light. In this image, the layered structure of the retina can be seen, as well as abnormalities (drusen)

frequently take photographs of patients with skin abnormalities, and while initially this was done for clinical documentation, increasingly this is done to leverage imaging informatics methods for training, to improve clinical care, for consultation, for monitoring progression or change in skin disease, and for image retrieval (Bittorf et al. 1997; Diepgen and Eysenbach 1998; Eysenbach et al. 1998; Lowe et al. 1998; Ribaric et al. 2001). Like radiology and pathology, recent work is being done to analyze the image content to enable decision support (Seidenari et al. 2003; Esteva et al. 2017).

### 10.3 Image Content Representation

The image contents comprise two components of information, the *visual content* and the *knowledge content*. The visual content is the raw values of the image itself, the information that a computer can access in a digital image directly. The knowledge content arises as the observer, who has biomedical knowledge about the image content, views the visual information in the image. For example, a radiologist viewing a CT image of the upper abdo-

men immediately recognizes that the image contains the liver, spleen, and stomach (anatomic entities), as well as image abnormalities such as a mass in the liver with rim enhancement (imaging observation entities). Unlike the visual content, the knowledge content of images is not directly accessible to computers from the image itself. However, semantic methods are being developed to make this content machine-accessible (► Sect. 10.3.2). In this section we describe imaging informatics methods for representing the visual and knowledge content of images.

#### 10.3.1 Representing Visual Content in Digital Images

The visual content of digital images typically is represented in a computer by a two-dimensional array of numbers (a bit map). Each element of the array represents the intensity of a small square area of the picture, called a picture element (or pixel). Each **pixel** element corresponds to a volume element (or **voxel**) in the imaged subject that produced the pixel. If we consider the image of a volume, then a three-dimensional array of numbers is required. Another way of thinking of a volume is that it is a stack of two-dimensional images. However, it is also important to be aware of the voxel dimensions that correspond to the pixels when doing this. In many 2-D imaging applications, the in-plane resolution (the size of the voxels in the  $x,y$  plane) is higher than the resolution in the  $z$ -axis (i.e., the slice thickness); this is often referred to as “non-isotropic voxels.” Non-isotropic voxels creates a problem when re-sampling the volume data to create other projections, such as coronal or sagittal from primary axial image data. If the dimensions of the voxels (and pixels) are uniform in all dimensions, they are referred to as “isotropic.” Fortunately, nearly all modern volumetric imaging methods (e.g., CT and MRI) currently produce images with isotropic voxels.

We can store any image in a computer as a matrix of integers (or real-valued numbers), either by converting it from an analog

to a digital representation or by generating it directly in digital form. Once an image is in digital form, it can be handled just like all other data. It can be transmitted over communications networks, stored compactly in databases on magnetic or optical media, and displayed on graphics monitors. In addition, the use of computers has created an entirely new realm of capabilities for image generation and analysis: images can be computed rather than measured directly. Furthermore, digital images can be manipulated for display or analysis in ways not possible with film-based images.

In addition to the 2D (slice) and 3D (volume) representation for image data, there can be additional dimensions to representing the visual content of images. It is often the case that multi-modality data are required for the diagnosis; this can be a combination of varying modalities, (e.g., CT and PET, CT and MRI) and can be a combination of imaging sequences *within* a modality (e.g., T1, T2, or other sequences in MRI) (■ Fig. 10.10). Pixel (or voxel) content, from each of the respective acquisition modalities, are combined in what is known as a “feature-vector” in the multi-dimensional space. For example, a 3-dimensional intensity-based feature vector, based on 3 MRI pulse sequences, can be

defined as a set of three values for each pixel in the image, where the intensity of each pixel in each of the three MRI images is extracted and recorded (e.g., [Intensity(Sequence 1), Intensity(Sequence 2), Intensity(Sequence 3)]). Any imaging performed over time (e.g., cardiac echo videos) can be represented by the set of values at each time point, thus the time is added as an additional dimension to the representation.

Finally, in addition to representing the visual content, medical images also need to represent certain information about that visual content (referred to as **image metadata**). Image metadata include such things as the name of the patient, date the image was acquired, the slice thickness, the modality that was used to acquire the image, etc. All image metadata are usually stored in the header of the image file. Given that there are many different types of equipment and software that produce and consume images, standards are crucial. For images, the Digital Imaging and Communications in Medicine (DICOM) standard is for distributing and viewing any kind of medical image regardless of the origin (Bidgood Jr. and Horii 1992). DICOM has become pervasive throughout radiology and is becoming a standard in other domains such as pathology, ophthalmology, and dermatol-

■ Fig. 10.10 Multi-modality imaging. Images of the brain from three modalities (T1 without contrast, T1 with contrast, and T2) are shown. The patient has a lesion in the left occipital lobe that has distinctive image

features on each of these modalities, and the combination of these different features on different modalities establishes characteristic patterns useful in diagnosis

ogy. In addition to specifying a standard file syntax and metadata structure, DICOM specifies a standard protocol for communicating images among imaging devices.

### 10.3.2 Representing Knowledge Content in Digital Images

As noted above, the knowledge content related to images is not directly encoded in the images, but it is recognized by the observer of the images. This knowledge includes recognition of the anatomic entities in the image, imaging observations and characteristics of the observations (sometimes called “findings”), and interpretations (probable diseases). Representing this knowledge in the imaging domain is similar to knowledge representation in other domains of biomedical informatics (see ► Chap. 24). Specifically, for representing the entities in the domain of discourse, we adopt terminologies or ontologies. To make specific statements about individuals (images), we use “information models” (described below) that reference ontological entities as necessary. As described below, different aspects of the knowledge content of images is stored in different ways (which is one of the challenges of leveraging this information).

#### ■ Knowledge Representation of Anatomy

Given segmented anatomical structures, whether at the macroscopic or microscopic level, and whether represented as 3-D surface meshes or extracted 3-D regions, it is often desirable to attach labels (names) to the structures in images. If the names are drawn from a controlled terminology or ontology, they can be used as an index into a database of segmented structures, thereby providing a qualitative means for comparing structures from multiple subjects or retrieving images containing particular structures.

If the terms in the vocabulary are organized so as to assert relationships that are true for all instances (the case in “ontologies”), they can support systems that manipulate and retrieve image contents in intelligent ways. If anatomical ontologies are linked to other

ontologies of physiology and pathology they can provide increasingly sophisticated knowledge about the meaning of the various images and other data that are increasingly becoming available in online databases. This kind of knowledge (by the computer, as opposed to the scientist) will be required in order to achieve the seamless integration of all forms of imaging and non-imaging data.

At the most fundamental level, *Nomina Anatomica* (International Anatomical Nomenclature Committee 1989) and its successor, *Terminologia Anatomica* (Federative Committee on Anatomical Terminology 1998) provide a classification of officially sanctioned terms that are associated with macroscopic and microscopic anatomical structures. This canonical term list, however, has been substantially expanded by synonyms that are current in various fields, and has also been augmented by a large number of new terms that designate structures omitted from *Terminologia Anatomica*. Many of these additions are present in various controlled terminologies (e.g., MeSH (National Library of Medicine 1999), SNOMED (Spackman et al. 1997), Read Codes (Schultz et al. 1997), GALEN (Rector et al. 1993)). Unlike *Terminologia* these vocabularies are entirely computer-based, and therefore lend themselves for incorporation in computer-based applications.

Classification and ontology projects to date have focused primarily on arranging the terms of a particular domain in hierarchies. As noted with respect to the evaluation of *Terminologia Anatomica* (Rosse 2000), insufficient attention has been paid to the relationships among these terms. These relationships are named (e.g., “*is-a*” and “*part-of*”) to indicate how the entities connected by them are related (e.g., Left Lobe of Liver *part-of* Liver). Linking entities with relations encodes knowledge and is used by computer reasoning applications in making inferences. *Terminologia*, as well as anatomy sections of the controlled medical terminologies, mix *-is a-* and *-part of-* relationships in the anatomy segments of their hierarchies. Although such heterogeneity does not interfere with using these term lists for keyword-based retrieval, these programs will

fail to support higher level knowledge (reasoning) required for knowledge-based applications. To meet this gap, the Foundational Model of Anatomy (FMA) was developed to define a comprehensive symbolic description of the structural organization of the body, including anatomical concepts, their preferred names and synonyms, definitions, attributes and relationships (Rosse et al. 1998a, b; Rosse and Mejino 2003).

In the FMA, anatomical entities are arranged in class-subclass hierarchies, with inheritance of defining attributes along the *is-a* link, and other relationships (e.g., parts, branches, spatial adjacencies) represented as additional descriptors associated with the concept. The FMA currently consists of over 75,000 concepts, represented by about 120,000 terms, and arranged in over 2.1 million links using 168 types of relationships. These concepts represent structures at all levels: macroscopic (to 1 mm resolution), cellular and macromolecular. Brain structures have been added by integrating NeuroNames with the FMA as a Foundational Model of Neuroanatomy (FMNA) (Martin et al. 2001).

The FMA can be useful for symbolically organizing and integrating biomedical information, particularly that obtained from images. But in order to answer non-trivial queries in neuroscience and other basic science areas, and to develop “smart tools” that rely on deep knowledge, additional ontologies must also be developed (e.g., for physiological functions mediated by neurotransmitters, and pathological processes and their clinical manifestations, as well for the radiological appearances with which they correlate). The relationships that exist among these concepts and anatomical parts of the body must also be explicitly modeled. Next-generation informatics efforts that link the FMA and other anatomical ontologies with separately developed functional ontologies will be needed in order to accomplish this type of integration.

#### ■ Knowledge Representation of Radiology Imaging Features

While FMA provides a comprehensive knowledge representation for anatomy, it does not

cover other portions of the radiology domain. As is discussed in ► Chap. 7, there are controlled terminologies in other domains, such as MeSH, SNOMED, and related terminologies in the UMLS (Cimino 1996; Bodenreider 2008); however, these lack terminology specific to radiology for describing the features seen in imaging. The Radiological Society of North America (RSNA) recently developed RadLex, a controlled terminology for radiology (Langlotz 2006; Rubin 2008). The primary goal of RadLex is to provide a means for radiologists to communicate clear, concise, and orderly descriptions of imaging findings in understandable, unambiguous language. Another goal is to promote an orderly thought process and logical assessments and recommendations based on observed imaging features based on terminology-based description of radiology images and to enable decision support (Baker et al. 1995; Burnside et al. 2009). Another goal of RadLex is to enable radiology research; data mining is facilitated by the use of standard terms to code large collections of reports and images (Channin et al. 2009a, b).

RadLex includes thousands of descriptors of visual observations and characteristics for describing imaging abnormalities, as well as terms for naming anatomic structures, radiology imaging procedures, and diseases (■ Fig. 10.11). Each term in RadLex contains a unique identifier as well as a variety of attributes such as definition, synonyms, and foreign language equivalents. In addition to a lexicon of standard terms, the RadLex ontology includes term relationships—links between terms to relate them in various ways to encode radiological knowledge. For example, the *is-a* relationship records subsumption. Other relationships include part-of, connectivity, and blood supply. These relationships are enabling computer-reasoning applications to process image-related data annotated with RadLex.

RadLex has been used in several imaging informatics applications, such as to improve search for radiology information. RadLex-based indexing of radiology journal figure captions achieved very high precision and recall, and significantly improved

**Fig. 10.11** RadLex controlled terminology (<http://radlex.org>). RadLex includes term hierarchies for describing anatomy (“anatomical entity”), imaging observations (“imaging observation”) and characteristics (“imaging observation characteristic”), imaging procedures and procedure steps (“procedure step”), dis-

eases (“pathophysiologic process”), treatments (“treatment”), and components of radiology reports (“report”). Each term includes definitions, preferred name, image exemplars, and other term metadata and relationships such as subsumption

image retrieval over keyword-based search (Kahn and Rubin 2009). RadLex has been used to index radiology reports (Marwede et al. 2008). Work is underway to introduce RadLex controlled terms into radiology reports to reduce radiologist variation in use of terms for describing images (Kahn Jr. et al. 2009). Tools are beginning to appear enabling radiologists to annotate and query image databases using RadLex and other controlled terminologies (Rubin et al. 2008b; Channin et al. 2009a, b).

In addition to RadLex, there are other important controlled terminologies for radiology. The Breast Imaging Reporting and Data System (BI-RADS) is a lexicon of descriptors and a reporting structure comprising assessment categories and management recommendations created by the American College of Radiology (D’Orsi and Newell 2007). Terminologies are also being created in other radiology imaging domains, including the Fleischner Society Glossary of terms for thoracic imaging (Hansell et al. 2008), the Nomenclature of Lumbar Disc Pathology (Appel 2001), terminologies for image guided tumor ablation (Goldberg

et al. 2009) and transcatheter therapy for hepatic malignancy (Brown et al. 2009), and the CT Colonography Reporting and Data System (Zalis et al. 2005).

#### ■ Knowledge Representation of Radiology Procedures

A very important type of knowledge representation for images is the type of imaging procedure that produced it. While RadLex contains atomic terms for the various modalities, such as CT and MRI, it lacks the full spectrum of types of procedures that can be performed on a patient. The RadLex Playbook (Wang et al. 2017) is a project of the Radiological Society of North America that provides a standard system for naming radiology procedures, based on atomic terms (usually from RadLex) that define an imaging procedure, such as “CT Head.” By providing standard names and codes for radiologic studies, the RadLex Playbook can facilitate a variety of operational and quality improvement efforts, including workflow optimization, chargemaster management, radiation dose tracking, enterprise integration and image exchange (Wang et al. 2017).

The RadLex Playbook grammar describes how to create the pre-coordinated Playbook terms across the defining name attributes. Each such term is comprised of several RadLex atomic terms. The unique combination of RadLex clinical terms defines a unique Playbook term, which is given a unique identifier (the RadLex Playbook ID, or RPID). Thus, for each RPID there is a corresponding set of RadLex IDs that link to the associated RadLex clinical terms. This knowledge representation can be very useful for retrieving particular types of images from systems that support Playbook, such as “retrieve all CT of the head,” which would include *CT Head w/wo* (with and without contrast agent), *CT Head Angio w/wo*, *CT Orbits wo*, *CT Temporal Bone w/wo*, etc.

The Logical Observation Identifiers, Names, and Codes (LOINC®) terminology includes radiology terms (Vreeman and McDonald 2005), and recently a unified model LOINC/Playbook model and terminology for radiology procedure names has been created that represents the attributes of term names with an extensible set of values and provides LOINC codes and display name for each procedure (Vreeman et al. 2018). There is also a single integrated governance process for managing the unified terminology.

#### ■ Semantic Representation of Image Contents

While ontologies and controlled terminologies are useful for representing knowledge related to images, they do not provide a means to directly encode assertions for recording the semantic content in images. For example, we may wish to record the fact that “there is a mass 4x5 cm in size in the right lobe of the liver.” The representation of this semantic image content certainly will use ontologies and terminologies to record the entities to which such assertions refer; however, an **information model** is required to provide the required grammar and syntax for recording such assertions. There are two approaches to recording these assertions, no formal information model (narrative text) and a formal information model.

#### ■ Narrative text

In the current workflow, nearly all semantic image content is recorded in narrative text (radiology reports). The advantage of text reports is that they are simple, quick to produce (the radiologist speaks freely into a microphone), and they can be expressive, capturing the subtle nuances (and ambiguities) that the English language provides. There are several downsides, however. First, text reports are unstructured; there is no adherence to controlled terminology and not consistent structure that would permit reliable information extraction. Second, the reports may be incomplete, vague, or contradictory. Further, free text is challenging for computers (see ► Chap. 8), which makes it difficult to leverage free text in applications. Finally, radiology images and the corresponding radiology report are currently disconnected; e.g., the report may describe a mass in an organ, and the image may contain a **region of interest** (ROI) measuring the lesion, but there is no information directly linking the description of the lesion in the report with the ROI in the image. Such linkage could enable applications such as content-based image retrieval, as described below.

**Structured reporting** of radiology results has recently become increasingly the standard process for generating reports, usually using macros and templates (Weiss and Langlotz 2008; Langlotz 2009; Schwartz et al. 2011). In structured reports, a variety of fields is provided, such as a list of organs visualized on the image and a list of radiologist observations about them. Though structured reports improve on the ability to recognize and extract particular types of information in reports, they generally do not use controlled terminologies, and their content is usually recorded in narrative free text, so this method of recording semantic information about images is not much more computer-accessible than a fully narrative radiology report.

#### ■ Information model

An information model provides an explicit specification of the types of data to be collected and the syntax by which it will be saved.

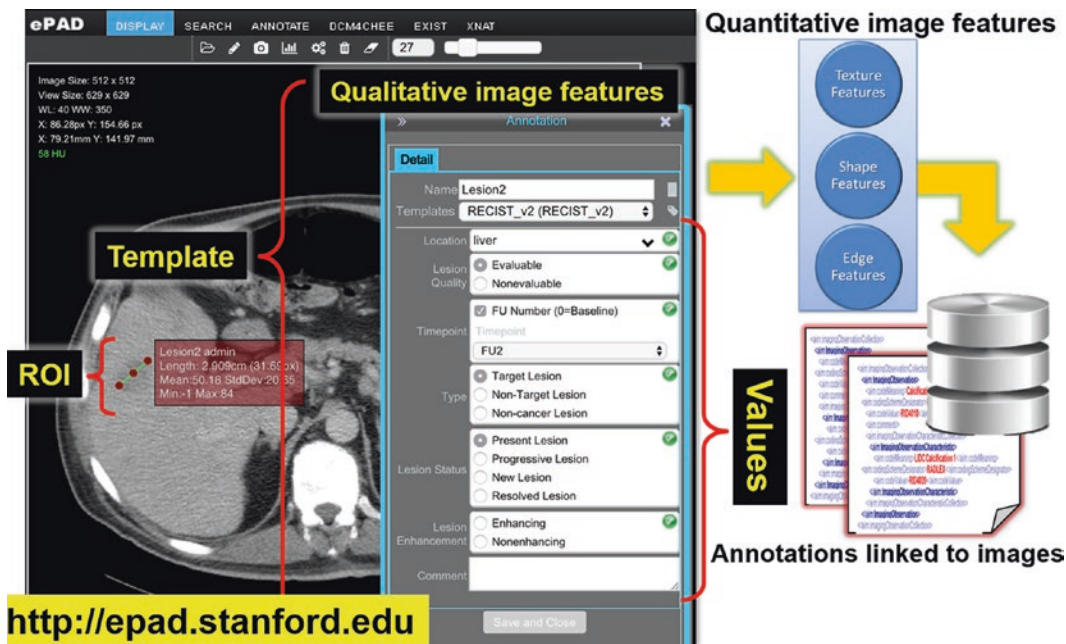

**Fig. 10.12** Semantic annotation of images. The radiologist's image annotation (left) and interpretation (middle) associated with the annotation are not represented in a form such that the detailed content is directly accessible. The same information can be put into a structured representation as a semantic annotation

(right), comprising terms from controlled terminologies (Systematized Nomenclature of Medicine (SNOMED) and RadLex) as well as numeric values (coordinates and measurements). (Figure reprinted with permission from (Rubin and Napel 2010). © Thieme)

So-called “semantic annotation” methods are being developed to adapt the semantic content about images that would have been put into narrative text so that it can instead be put in structured annotations compliant with the information model. The information model conveys the pertinent image information explicitly and in human-readable and machine accessible format. For example, a semantic annotation might record the coordinates of the tip of an arrow and indicate the organ (anatomic location) and imaging observations (e.g., mass) in that organ. These annotations can be recorded in a standard, searchable format, such as the Annotation and Image Markup (AIM) schema, developed by the National Cancer Imaging Program of NCI for storing and sharing image metadata (caBIG In-vivo Imaging Workspace 2008; Rubin et al. 2008a, 2009a). AIM captures a variety of information about image annotations, e.g., regions of interest, a lesion identification label, lesion location, measurements of image regions, method of measurement, radiologist observations, anatomic locations of abnormalities, calculations, inferences, and other qualitative and quantitative image features (Channin et al. 2009a, b). The image metadata also include information about the

image, such as the name of imaging procedure and how or when the image was acquired. AIM supports controlled terminologies, enabling semantic interoperability. AIM has recently been incorporated into the DICOM Structured Report (DICOM SR) standard (DICOM Standards Committee - Working Group 8 – Structured Reporting 2017), with specifications for saving AIM in DICOM-SR (DICOM Standards Committee 2017). Given that DICOM is the international standard for specifying image data, it is hoped that there will be widespread adoption of the AIM/DICOM-SR format to enable interoperability of image annotations across systems.

The AIM information model includes use of controlled terms as semantic descriptors of lesions (e.g., RadLex). It also provides a syntax associating an ROI in an image with the aforementioned information, enabling raw image data to be linked with semantic information, and thus bridges the current disconnect between semantic terms and the lesions in images being described. In conjunction with RadLex, the AIM information model provides a standard syntax (in XML schema) to create a structured representation of the semantic contents of images (Fig. 10.12). Once the semantic contents are recorded in

**Fig. 10.13** The electronic Imaging Physician Annotation Device (ePAD). This tool creates structured semantic annotations on images using a graphical interface to minimize impact on image viewing workflow. The user views the image in and draws a region of interest (left). ePAD incorporates ontologies so that users can specify controlled terms as values in making their

annotations (pull down panel on right). As they make their annotation, they receive feedback to ensure data entries are complete and that there are no violations of pre-specified annotation logic (panel on lower right). The ePAD tool saves image annotations in the AIM information model XML format

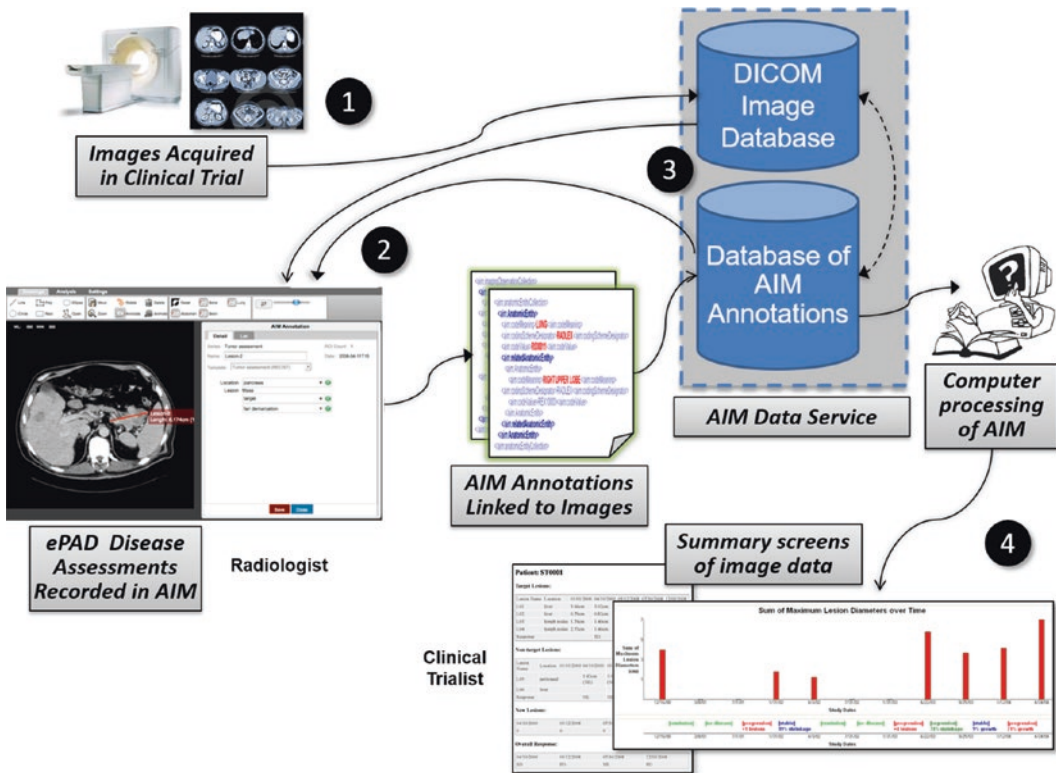

AIM (as XML instances of the AIM XML schema), applications can be developed for image query and analysis.

AIM has been gaining traction in the research community. A number of diverse research projects have embraced and have been enabled by AIM (Levy et al. 2009, Napel et al. 2010, Gevaert et al. 2011, Gimenez et al. 2011a, b, Hoang et al. 2011, Levy and Rubin 2011a, b, Napel et al. 2011, Plevritis et al. 2011, Gevaert et al. 2012a, b; Levy et al. 2012). An increasing number of tools are supporting AIM to facilitate creating semantic annotations on images as part of the image viewing workflow are being developed, including open source projects such as Osirix (Rubin and Snyder 2011), ClearCanvas (Klinger 2010; National Cancer Institute 2012), Slicer (Pieper et al. 2004; Fedorov 2012; Fedorov et al. 2012), and ePAD (Rubin and Snyder 2011). There are also several commercial applications using AIM that are in development (Rubin et al. 2010; Zimmerman et al. 2011). Automated

semantic image annotation methods are also being pursued (Carneiro et al. 2007; Mechouche et al. 2008; Yu and Ip 2008) that will ultimately make the process of generating this structured information efficient.

The electronic Imaging Physician Annotation Device (ePAD (Rubin and Snyder 2011)) is a freely available web-based image viewing and AIM-compliant annotation tool. ePAD permits the user to draw image annotations in a manner in which they are accustomed while viewing images, while simultaneously collecting semantic information about the image and the image region directly from the image itself as well as from the user using a structured reporting template (Fig. 10.13). The tool also features a panel to provide feedback so as to ensure complete and valid annotations. Image annotations are saved in the AIM XML format.

By making the semantic content of images explicit and machine-accessible, these structured annotations of images will help radiologists analyze data in large databases of images.

■ **Fig. 10.14** ePAD and AIM within the clinical/research environment. (1) Images are acquired and stored in the hospital PACS, (2) the Radiologist uses ePAD to review the images and to make measurements on cancer lesions, (3) The measurements (saved as AIM XML in ePAD) with links to the images are stored by

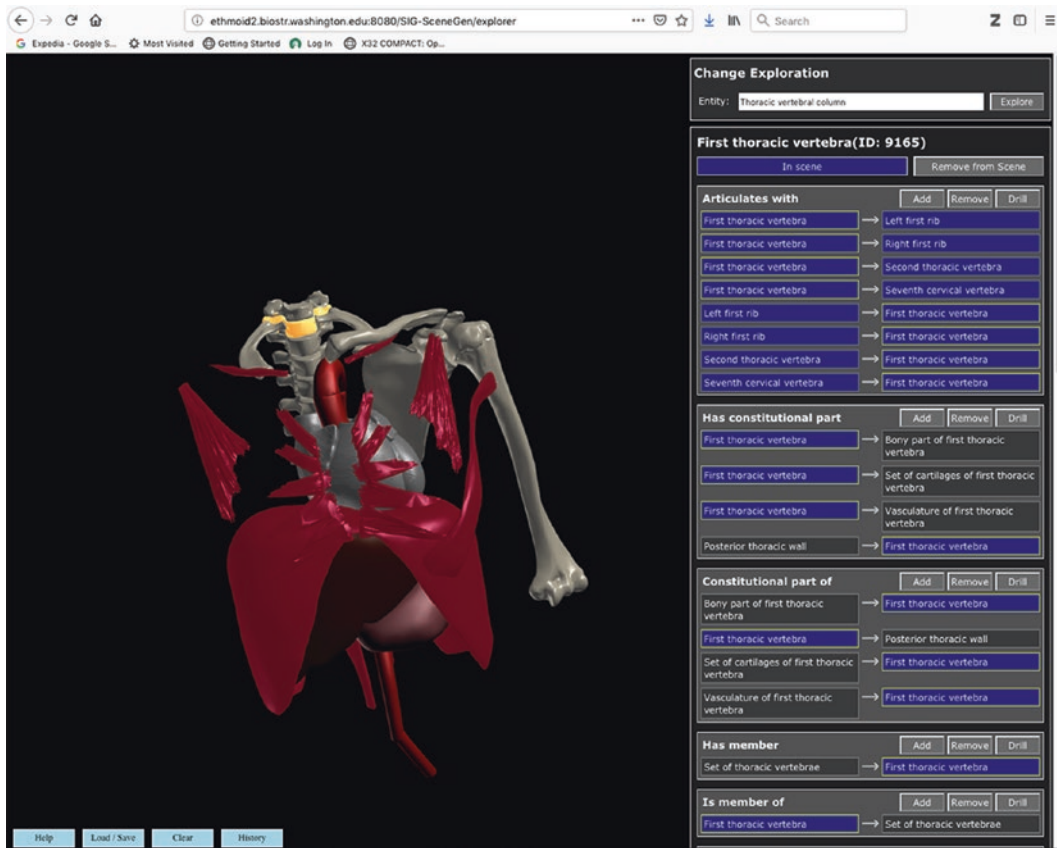

the AIM Data Service, and (4) a variety of software applications can use the AIM Data Service to access the image metadata for different purposes, such as listing the lesion measurements or generating a summary of patient response assessment

■ Figure 10.14 shows how image annotations in AIM can be integrated into routine research and clinical workflows. Images acquired from imaging devices flow into the PACS and can be viewed on an imaging workstation. If the imaging workstation supports AIM (e.g., ePAD as shown in the figure), then image annotations and radiologist observations are saved in the AIM format and stored in database of AIM annotation files (an XML database in the case of ePAD). The AIM annotations have a pointer to their corresponding images and queries and analyses can be done on the image annotations for clinical applications, such as summarizing the change in cancer lesion sizes over time for assessing response assessment to cancer (■ Fig. 10.14). Cancer patients often have many serial imaging studies in which a set of lesions is evalu-

ated at each time point. Automated tools such as ePAD can use semantic image annotations to identify the measurable lesions at each time point and produce a summary of, and automatically reason about, the total tumor burden over time, helping physicians to determine how well patients are responding to treatment (Levy and Rubin 2008).

#### ■ ■ Atlases

Spatial representations of anatomy, in the form of segmented regions on 2-D or 3-D images, or 3-D surfaces extracted from image volumes, are often combined with symbolic representations to form digital atlases. A digital atlas (which for this chapter refers to an atlas created from 3-D image data taken from real subjects, as opposed to artists' illustrations) is generally created from a single indi-

**Fig. 10.15** The Digital Anatomist Dynamic Scene Generator. The user can select a set of 3-D anatomical models, in which each model is associated with an entity from the Foundational Model of Anatomy (FMA) to select a starting structure, load relations from the FMA between that structure and related structures, and, if 3-D models are available, to add those models to the scene. The evolving scene can be manipulated in real-time on the web and can be saved as a standalone scene that can be saved locally or accessed via URL, thus permitting it to be embedded in other web apps. The scene

shown here was created by first requesting one of the muscles of the thorax, then exploring FMA to find the heart, aorta and branches, and thoracic vertebral column. In the scene on the left, the first thoracic vertebra was clicked, which caused it to be highlighted, and the relations between it and other structures are then shown in the panel on the right. The top pane of the right panel = shows the structures with which the first thoracic vertebra articulates. (Figure used with permission from Jim Brinkley)

vidual, which therefore serves as a “canonical” instance of the species. Traditionally, atlases have been primarily used for education, and most digital atlases are used the same way.

As an example in 2-D, the Digital Anatomist Interactive Atlases (Sundsten et al. 2000) were created by outlining ROIs on 2-D images (many of which are snapshots of 3-D scenes generated by reconstruction from serial sections) and labeling the regions with terminology from the FMA. The atlases, which are available on the web, permit inter-

active browsing, where the names of structures are given in response to mouse clicks; dynamic creation of “pin diagrams”, in which selected labels are attached to regions on the images; and dynamically-generated quizzes, in which the user is asked to point to structures on the image (Brinkley et al. 1997).

As an example 3-D, the Digital Anatomist Dynamic Scene Generator (DSG, **Fig. 10.15**) creates interactive 3-D atlases “on-the-fly” for viewing and manipulation over the web (Brinkley et al. 1999; Wong et al.

1999). An example of a 3-D brain atlas created from the Visible Human is Voxelman (Hohne et al. 1995), in which each voxel in the Visible Human head is labeled with the name of an anatomic structure in a “generalized voxel model” (Hohne et al. 1990), and highly-detailed 3-D scenes are dynamically generated. Several other brain atlases have also been developed, primarily for educational use (Johnson and Becker 2001; Stensaas and Millhouse 2001).

Atlases have also been developed for integrating functional data from multiple studies (Bloom and Young 1993; Toga et al. 1994, 1995; Swanson 1999; Fougousse et al. 2000; Rosen et al. 2000; Martin and Bowden 2001). In their original published form these atlases permit manual drawing of functional data, such as neurotransmitter distributions, onto hardcopy printouts of brain sections. Many of these atlases have been or are in the process of being converted to digital form. The Laboratory of Neuroimaging (LONI) at the University of California Los Angeles has been particularly active in the development and analysis of digital atlases (Toga 2001), and the California Institute of Technology Human Brain Project has released a web-accessible 3-D mouse atlas acquired with micro-MR imaging (Dhenain et al. 2001).

The most widely used human brain atlas is the Talairach atlas, based on post mortem sections from a 60-year-old woman (Talairach and Tournoux 1988). This atlas introduced a proportional coordinate system (often called “Talairach space”) which consists of 12 rectangular regions of the target brain that are piecewise affine transformed to corresponding regions in the atlas. Using these transforms (or a simplified single affine transform based on the anterior and posterior commissures) a point in the target brain can be expressed in Talairach coordinates, and thereby related to similarly transformed points from other brains. Other human brain atlases have also been developed (Schaltenbrand and Warren 1977; Hohne et al. 1992; Caviness et al. 1996; Drury and Van Essen 1997; Van Essen and Drury 1997).

## 10.4 Image Processing

**Image processing** is a form of **signal processing** in which computational methods are applied to an input image to produce an output image or a set of characteristics or parameters related to the image. Most image processing techniques involve treating the image as a two-dimensional signal and analyzing it using signal-processing techniques or a variety of other transformations or computations. There are a broad variety of image processing methods, including transformations to enhance visualization, computations to extract features, and systems to automate detection or diagnose abnormalities in the images. The latter two methods, referred to as computer-assisted detection and diagnosis (CAD) is discussed in ► Sect. 10.5.2. In this section we discuss the former methods, which are more elemental and generic processing methods.

The rapidly increasing number and types of digital images has created many opportunities for image processing, since one of the great advantages of digital images is that they can be manipulated just like any other kind of data. This advantage was evident from the early days of computers, and success in processing satellite and spacecraft images generated considerable interest in biomedical image processing, including automated image analysis to improve radiological interpretation. Beginning in the 1960s, researchers devoted a large amount of work to this end, with the hope that eventually much of radiographic image analysis could be improved. One of the first areas to receive attention was automated interpretation of chest X-ray images, because, previously, most patients admitted to a hospital were subjected to routine chest X-ray examinations. (This practice is no longer considered cost effective except for selected subgroups of patients.) Interestingly, recent research in deep learning (discussed below), however, has raised enthusiasm and hopes for automating certain tasks of radiographic image interpretation, such as detection of pneumonia (Rajpurkar et al. 2017). While most of the emphasis of image processing

continues to be on systems that aid the user in viewing and manipulating images, there is a quickly growing body of work completely automated analysis of images, particularly for lesion detection, image segmentation, and image classification (diagnosis).

Medical image processing utilizes tools similar to general image processing. But there are unique features to the medical imagery that present different, and often more difficult, challenges from those that exist in general image processing tasks. To begin with, the images analyzed all represent the 3D body; thus, the information extracted (be it in 2D or 3D) is based on a 3D volumetric object. The images themselves are often taken from multi-modalities (CT, MRI, PET), where each modality has its own unique physical characteristics, leading to unique noise, contrast and other issues that need to be addressed. The fusion of information across several modalities is a challenge that needs to be addressed as well.

When analyzing the data, it is often desirable to segment and characterize specific organs. The human body organs, or various tissue of interest within them, cannot be described with simple geometrical rules, as opposed to objects and scenes in non-medical images that usually can be described with such representations. This is mainly because the objects and free-form surfaces in the body cannot easily be decomposed into simple geometric primitives. There is thus very little use of geometric shape models that can be defined from *a-priori* knowledge. Moreover, when trying to model the shape of an organ or a region, one needs to keep in mind that there are large inter-person variations (e.g., in the shape and size of the heart, liver and so on), and, as we are frequently analyzing images of patients, there is a large spectrum of abnormal states that can greatly modify tissue properties or deform structures. Finally, especially in regions of interest that are close to the heart, complex motion patterns need to be accounted for as well. These issues make medical image processing a very challenging domain.

The widespread availability of digital images, combined with image manage-

ment systems such as PACS (► Chap. 22) and powerful workstations, has led to many applications of image processing techniques. In general, routine techniques are available on the manufacturer's workstations (e.g., a vendor-provided console for an MR machine or an ultrasound machine), whereas more advanced image-processing algorithms are available as software packages that run on independent workstations.

The primary uses of image processing in the clinical environment are for image enhancement, screening, and quantitation. Software for such image processing is primarily developed for use on independent workstations. Several journals are devoted to medical image processing (e.g., *IEEE Transactions on Medical Imaging*, *Journal of Digital Imaging*, *Neuroimage*), and the number of journal articles is rapidly increasing as digital images become more widely available. Several books are devoted to the spectrum of digital imaging processing methods (Yoo 2004; Gonzalez et al. 2009), and the reader is referred to these for more detailed reading on these topics. We describe a few examples of image-processing techniques in the remainder of this section.

#### 10.4.1 Types of Image-Processing Methods

Image processing methods are applied to representations of image content (► Sect. 10.3). One may use the very low-level, pixel representation. The computational effort is minimal in the representation stage, with substantial effort (computational cost) in further analysis stages such as segmentation of the image, matching between images, registration of images, etc. A second option is to use a very high-level image content representation, in which each image is labeled according to its semantic content (medical image categories such as “abdomen vs chest”, “healthy vs pathology”). In this scenario, a substantial computational effort is needed in the representation stage, including the use of automated image segmentation methods to recognize ROIs as well as advanced learning techniques to clas-

■ Fig. 10.16 Diagram of a typical image processing pipeline

sify the regions of image content. Further analysis can utilize knowledge resources such as ontologies, linked to the images using category labels. A mid-level representation exists, that balances the above two options, in which a transition is made from pixels to semantic features. Feature vectors are used to represent the spectrum of image content compactly and subsequent analysis is done on the feature vector representation.

Image processing is the foundation for creating image-based applications, such as image enhancement to facilitate human viewing, to show views not present in the original images, to flag suspicious areas for closer examination by the clinician, to quantify the size and shape of an organ, and to prepare the images for integration with other information. To create such applications, several types of image processing are generally performed sequentially in an *image processing pipeline*, although some processing steps may feed back to earlier ones, and the specific methods used in a pipeline varies with the application. Most image processing pipelines and applications generalize from two-dimensional to three-dimensional images, though three-dimensional images pose unique image processing opportunities and challenges. Image processing pipelines are generally built using one or more of the following fundamental image processing methods: **global processing**, **image enhancement**, **image rendering/visualization**, **image quantitation**, **image segmentation**, **image registration**, and **image reasoning** (e.g., classification). Those steps are shown in ■ Fig. 10.16. In the remainder of this section we describe these

methods, except for image reasoning which is discussed in ► Sect. 10.5.

## 10.4.2 Global Processing

Global processing involves computations on the entire image, without regard to specific regional content. The purpose is generally to enhance an image for human visualization or for further analysis by the computer (“pre-processing”). A simple but important example of global image processing is gray-scale windowing of CT images. The CT scanner generates pixel values (**Hounsfield numbers**, or CT numbers) in the range of  $-1000$  to  $+3000$ . Humans, however, cannot distinguish more than about 100 shades of gray. To appreciate the full precision available with a CT image, the operator can adjust the midpoint and range of the displayed CT values. By changing the level and width (i.e., intercept and slope of the mapping between pixel value and displayed gray scale or, roughly, the brightness and contrast) of the display, radiologists enhance their ability to perceive small changes in contrast resolution within a subregion of interest.

Other types of global processing change the pixel values to produce an overall enhancement or desired effect on the image: *histogram equalization*, *convolution*, and *filtering*. In histogram equalization, the pixel values are changed, spreading out the most frequent intensity values to increase the global contrast of the image. It is most effective when the usable data of the image are represented by a

narrow range of contrast values. Through this adjustment, the intensities can be better distributed on the histogram, improving image contrast by allowing for areas of lower local contrast to gain a higher contrast. In convolution and filtering, mathematical functions are applied to the entire image for a variety of purposes, such as de-noising, edge enhancement, and contrast enhancement.

### 10.4.3 Image Enhancement

Image enhancement uses global processing to improve the appearance of the image either for human use or for subsequent processing by computer. The consoles of all vendor image viewing platforms and independent image-processing workstations provide some form of image enhancement. We have already mentioned CT windowing. Another technique is unsharp masking, in which a blurred, or “unsharp,” positive is created to be used as a “mask” that is combined with the original image, creating the illusion that the resulting image is sharper than the original. The technique increases local contrast and enhances the visibility of fine-detail (high-frequency) structures. Histogram equalization spreads the image gray levels throughout the visible range to maximize the visibility of those gray levels that are used frequently. Temporal subtraction subtracts a reference image from later images that are registered to the first. A common use of temporal subtraction is **digital-subtraction angiography** (DSA) in which a background image is subtracted from an image taken after the injection of contrast material.

### 10.4.4 Image Rendering/ Visualization

Image rendering and visualization refer to a variety of techniques for creating image displays, diagrams, or animations to display images more in a different perspective from the raw images. Image volumes are comprised of a stack of 2-D images. If the voxels in each

image are isotropic, then a variety of arbitrary projections can be derived from the volume, such as a sagittal or coronal view, or even curved planes. A technique called maximum intensity projection (MIP) and minimum intensity projection (MinIP) can also be created in which imaginary rays are cast through the volume, recording the maximum or minimum intensity encountered along the ray path, respectively, and displaying the result as a 2-D image.

In addition to these planar visualizations, the volume can be visualized directly in its entirety using **volume rendering** techniques (Lichtenbelt et al. 1998) (■ Fig. 10.17) which project a two-dimensional image directly from a three-dimensional voxel array by casting rays from the eye of the observer through the volume array to the image plane. Because each ray passes through many voxels, some form of segmentation (usually simple thresholding) often is used to remove obscuring structures. As workstation memory and processing power have advanced, volume rendering has become widely used to display all sorts of three-dimensional voxel data—ranging from cell images produced by confocal microscopy, to three-dimensional ultrasound images, to brain images created from MRI or PET.

Volume images can also be given as input to image-based techniques for warping the image volume of one structure to other. However, more commonly the image volume is processed in order to extract an explicit *spatial* (or quantitative) representation of anatomy (► Sect. 10.4.5). Such an explicit representation permits improved visualization, quantitative analysis of structure, comparison of anatomy across a population, and mapping of functional data. It is thus a component of most research involving 3-D image processing.

### 10.4.5 Image Quantitation

Image quantitation is the process of extracting useful numerical parameters or deriving calculations from the image or from ROIs in the image (often as part of “radiomics” analyses, described below) (Scheckenbach et al. 2017;

■ **Fig. 10.17** Three-dimensional CT scan of the full abdomen and pelvis **a** and of the liver **b**. The volumetric CT scan comprises a set of contiguous slices containing

isotropic voxels (the dimension of pixels in the x,y plane is the same as in the z dimension). The volume is rendered directly using volume-rendering techniques

Lohmann et al. 2018; Valdora et al. 2018). These values are also referred to as “quantitative imaging features.” These parameters may themselves be informative—for example, the volume of the heart or the size of the fetus. They also may be used as input into an automated classification procedure, which determines the type of object found. For example, small round regions on chest X-ray images might be classified as tumors, depending on such features as intensity, perimeter, and area.

Mathematical models often are used in conjunction with image quantitation. In classic pattern-recognition applications, the mathematical model is a classifier (learned using some type of supervised machine learning) that assigns a label to the image; e.g., to indicate if the image contains an abnormality, or indicates the diagnosis underlying an abnormality.

#### ■ Quantitative Image Features

Quantitation of images uses global processing and segmentation to characterize regions of interest in the image with numerical values. There are two kinds of *quantitative image features*, pre-defined image features and *learned features*. Pre-defined image features encode

domain knowledge, since they are designed to capture specific characteristics of the image or image region, such as texture, shapes, lesion margin characteristics, and image noise. Pre-defined image features are generally designed to capture characteristics of the image that reflect underlying biology, tissue function, or disease. For example, heart size, shape, and motion are subtle indicators of heart function and of the response of the heart to therapy (Clarysse et al. 1997). Similarly, fetal head size and femur length, as measured on ultrasound images, are valuable indicators of fetal well-being (Brinkley 1993).

Pre-defined image features are quantitative representations of visual signals contained in an image. Two types of pre-defined image features are *photometric* features, which exploit color and texture cues, derived directly from raw pixel intensities, and *geometric* features, which use shape-based cues. While color is one of the visual cues often used for content description (Hersh et al. 2009), most medical images are grayscale. Texture features encode spatial organization of pixel values of an image region. Shape features describe in quantitative terms the contour of a lesion and complement the information captured by

color or texture (Depeursinge et al. 2014). In addition, the histogram of pixel values within an ROI or transforms on those values is commonly performed to compute quantitative image features.

Pre-defined image features are commonly represented by feature-vectors in a N-dimensional space, where each dimension of the feature vector describes an aspect of the individual pixel (e.g., color, texture, etc.) (Haralick and Shapiro 1992) Image analysis tasks that use the quantitative features, such as segmentation and classification are then approached in terms of distance measurements between points (samples) in the chosen N-dimensional feature space.

In contrast to pre-defined image features, *learned features* are derived by computational analysis of the image itself without incorporating any domain knowledge. Deep learning methods (described below) are a common and popular approach for deriving learned features. In deep learning, the goal is to learn a task directly from a large collection of images; the parameters of deep learning models reflect image features that are extracted during the learning of these models (Milletari et al. 2016; Yasaka et al. 2018).

### ■ Image Patches

In the last several years, “patch-based” representations and “bag-of-features” classification techniques have been proposed and used as an approach to processing image contents (Jurie and Triggs 2005; Nowak et al. 2006; Avni 2009). An overview of the methodology is shown in ■ Fig. 10.18, and represents one of the types of “feature learning” being used for automated computer analysis of images (the other type of feature learning, deep learning, is discussed below). In image patch approaches, a shift is made from the pixel as being the atomic entity of analysis to a “patch” – a small window centered on the pixel, thus region-based information is included. A very large set of patches is extracted from an image. Each small patch shows a localized “glimpse” at the image content; the collection of thousands and more such patches, randomly selected,

have the capability to identify the entire image content (similar to a puzzle being formed from its pieces).

Patch extraction approaches include using a regular sampling grid, a random selection of points, or the selection of points with high information content using salient point detectors, such as SIFT (Lowe 1999). Once patches are selected, the information content within a patch is extracted. It is possible to take the patch information as a collection of pixel values, or to shift the representation to a different set of features based on the pixels, such as SIFT features. A final step in the process is to learn a dictionary of words over a large collection of patches, extracted from a large set of images. The vector represented patches are converted into “visual words” which form a representative “dictionary”. A visual word can be considered as a representative of several similar patches. A frequently-used method is to perform K-means clustering (Bishop 1995) over the vectors of the initial collection, and then cluster them into K groups in the feature space. The resultant cluster centers serve as a vocabulary of K visual words, with K often in the hundreds and thousands.

Once a global dictionary is learned, each image is represented as a collection of words (also known as a “bag of words”, or “bag of features”), using an indexed histogram over the defined words. Various image processing tasks can then be undertaken, ranging from the categorization of the image content, giving the image a “high-level,” more semantic label, the matching between images, or between an image and an image class, using patches for image segmentation and region-of-interest detection within an image. For these various tasks, images are compared using a distance measure between the representative histograms. In categorizing an image as belonging to a certain image class, well-known classifiers, such as the k- nearest neighbor and support-vector machines (SVM) (Vapnik 2000), can be used.

Using patches in a bag-of-visual-words (BoW) representation was shown to be successful in general scene and object recognition

**Fig. 10.18** A block diagram of the patch-based image representation. A radiographic image is shown with a set of patches indicated for processing the image data. Subsequent image processing is performed on each patch, and on the entire set of patches, rather than on

individual pixels in the image. A dictionary of visual words is learned from a large set of images, and their respective patches. Further analysis of the image content can then be pursued based on a histogram across the dictionary words

tasks (Fei-Fei and Perona 2003, Varma and Zisserman 2003, Sivic and Zisserman 2003, Nowak et al. 2006, Jiang et al. 2007). A few research studies were conducted in the medical domain as well. For example, in (André et al. 2009) BoW was used as the representation of endomicroscopic images and achieved high accuracy in the tasks of classifying the images into neoplastic (pathological) and benign. In (Bosch et al. 2006) an application to texture representation for mammography tissue classification and segmentation was presented. The use of BoW techniques for large scale radiograph archive categorization can be found in the ImageCLEF competition, in a task to classify over 12,000 X-ray images to 196 different (organ-level) categories (Tommasi et al. 2010). This competition provides an important

benchmarking tool to assess different feature sets as well as classification schemes on large archives of Radiographs. For several years, approaches based on local patch representation achieved the highest scores for categorization accuracy (Deselaers et al. 2006; Caputo et al. 2008; Greenspan et al. 2011).

#### ■ Radiomics, Machine Learning and Deep Learning

**Radiomics** describes a broad set of computational methods that extract quantitative features from radiology images (though similar approaches can be applied to other image types like histopathology or ophthalmology images) (Kumar et al. 2012; Lambin et al. 2012; Grossmann et al. 2017). The term “radiomics” has been used to mean a variety

of concepts, being wide in scope to include several fields, including clinical radiology (eg, imaging interpretation), computer vision (eg, quantitative feature extraction), and machine learning (eg, classifier evaluation). In recent years, radiomics is commonly used to refer to the quantitation of image features in large collections of images, akin to the use of “omics” for large scale collection and analysis of other types of biomedical data. It includes all the quantification techniques described in this Chap. A more distinctive and unique formalism for the term is to view the quantitation that it represents as one that focuses on the identification of quantitative imaging indicators that predict important clinical outcomes, e.g. prognosis and response or resistance to a specific cancer treatment (Zhou et al. 2018).

One motivation of radiomics is information integration—to merge image features with other known quantitative descriptors, including patient information and genomic data to generate a unique patient signature (or electronic phenotype). Initially, *pre-defined image features* were extracted, including for example a large number of quantifications defined from texture features, SIFT features, etc. (Napel et al. 2010) Once machine learning tools, specifically *deep learning* tools emerged, the latter have begun to take over several of the stages within the radiomics processing cycle – specifically, the generation of large sets of automatically extracted features for the quantification of the data, since deep learning models learn image features as part of the training process (Kontos et al. 2017; Giger 2018).

Radiomics relies on computational techniques in computer vision to extract many quantitative features from radiologic images. The extracted quantitative features are typically within a defined ROI that could include the whole tumor or specific regions within it. Computational image descriptors quantify visual characteristics at different scales from ROIs. For example, the scale-invariant feature transform (SIFT) (Lowe 1999) is computed through key point detection using a difference of Gaussian function and local image gradient measurement with radius and scale

selections. This permits a quantitative measurement of the tumor shape so that subtle variations during treatment can be observed and quantified. Local-level feature extraction provides an image descriptor used to compare a pixel being tested with its immediate pixel neighborhood. This allows identification of a small area within an otherwise homogeneous, larger tumor region. This can be achieved, for example, with local binary patterns (LBP). These are local image descriptors sensitive to small monotonic gray-level differences (Ojala et al. 2002). Texture descriptors, such as the LBP are very common in ROI descriptions, including gray-level co-occurrence matrices (Haralick et al. 1973) that examine the spatial relationships of pixels through a series of statistical measures, and histogram of oriented gradients (HOG) (Dalal and Triggs 2005) features to quantify image-gradient statistics with multiple directions not obvious to radiologists.

**Machine Learning** is commonly used for discovering predictive radiomics features. In machine learning, the parameter space is searched for an imaging feature statistically associated with clinical outcome (Zhou et al. 2018). Before one evaluates machine-learning models, a specification for the medical diagnostic task is needed so that models can be appropriately trained. For example, supervised, unsupervised, and semisupervised learning models are fundamental learning strategies used in accordance with the different levels of available clinical outcome labels.

In *supervised learning*, the goal is to learn from a certain portion of trained samples with known class labels and to predict classes or numeric values for unknown patterns from large and noisy datasets. Conversely, *unsupervised learning* finds the natural structure from data without having any prior labels. As a hybrid setting, *semisupervised learning* needs only a small portion of labeled training data. The unlabeled data samples,

instead of being discarded, are also used in the learning process.

**Deep Learning** as a new frontier in machine learning that is quickly rising as a primary

■ **Fig. 10.19** Above is a simply 5-layer fully convolutional network. The first convolutional block is separated out into three components. The first is the actual 2-dimensional convolution. Different convolutional weights act on the input tensor to create the output tensor, each weight acting as a feature extractor. This is followed by a nonlinearity. Common nonlinearities include the sigmoid, hyperbolic tangent, and the rectified linear

unit, or ReLU. Finally, should we need to conserve some memory, we can use pooling operations, such as a Max-Pool layer to decrease the size of our tensors. This fundamental combination of convolutions, nonlinearities, and pooling operations is used in every convolutional neural network since its rise to prominence in 2012. (Figure courtesy of Darwin Yi)

approach to many image analysis problems, and it has advanced large-scale medical image analysis. (Greenspan et al. 2016; Shen et al. 2017). Excitement for using deep learning for attacking many image analysis problems in medical imaging has grown quickly because these methods were the first to be top performing methods in the ImageNet classification challenge (Krizhevsky et al. 2012), and much of medical imaging analysis is an image classification problem. The development of deep learning, as part of the machine-learning field, provided a new approach in which the input data is automatically quantified while being analyzed.

Deep learning has been termed one of the 10 breakthrough technologies as of 2013 (MIT Technology Review 2013). It is an improvement of artificial neural networks, architectures of computational units (“neurons”), which are designed in several (all the way to thousands) of layers (“deep”) – where it was found that more layers permit higher levels of abstraction and improved predictions from data (LeCun et al. 2015). To date, it is emerging as the leading machine-learning tool in the general imaging and computer vision domains.

Deep learning methods have achieved record-breaking performances for numerous computer vision applications when the number of available training samples is sufficiently large (Deng et al. 2009).

Among the network architectures and models, convolutional neural networks (CNNs) have proven to be powerful tools for a broad range of computer vision tasks. The typical CNN architecture for image processing consists of a series of layers of convolution filters, followed by or interspersed with a series of data reduction or pooling layers (■ Fig. 10.19). The convolution filters are applied to small patches of the input image. Like the low-level vision processing in the human brain, the convolution filters detect increasingly more relevant image features, for example lines or circles that may represent straight edges (such as for organ detection) or circles (such as for round objects like colonic polyps), and then higher order features like local and global shape and texture. The output of the CNN is typically one or more probabilities or class labels. The convolution filters are learned from training data. This is desirable because it reduces the necessity of the time-consuming hand-crafting of features

**Fig. 10.20** Image segmentation. This figure illustrates the process of segmenting and labeling the chambers of the heart. On the left, a cross sectional atlas image of the heart has been segmented by hand and each chamber was labeled (RAA right atrial appendage,

RA right atrium, LA left atrium, RV right ventricle, LV left ventricle). The boundary of each circumscribed anatomic region can be converted into a digital mask (right) which can be used in different applications where labeling anatomic structures in the image is needed

that would otherwise be required to pre-process the images with application-specific filters or by calculating computable features.

Deep CNNs automatically learn mid-level and high-level abstractions obtained from raw data (e.g., images). Recent results indicate that the generic descriptors extracted from CNNs are extremely effective in object recognition and localization in natural images. In the medical imaging domain, in many detection, classification and segmentation tasks, deep learning has proved to be the state-of-the-art foundation, leading to improved accuracy. It has also opened new frontiers in data analysis with rates of progress not before experienced. For an overview on deep learning for medical image quantification and analysis see (Greenspan et al. 2016; Zhou et al. 2017a).

#### 10.4.6 Image Segmentation

Segmentation of images involves automatically circumscribing regions within an image to generate ROIs in the image. The ROIs usually correspond to anatomically meaningful structures, such as organs or parts of organs, or they may be lesions or other types of regions in the image pertinent to the application. The structures may be delineated by their borders, in which case edge-detection techniques (such

as edge-following algorithms) are used, or by their composition in the image, in which case region-detection techniques (such as texture analysis) are used (Haralick and Shapiro 1992). Neither of these techniques has been completely successful as fully automated image segmentation methods; regions often have discontinuous borders or nondistinctive internal composition. Furthermore, contiguous regions often overlap. These and other complications make segmentation the most difficult subtask of the medical image processing problem. Because segmentation is difficult for a computer, it is usually performed either by hand or in a semi-automated manner with assistance by a human through operator-interactive approaches (Fig. 10.20). In both cases, segmentation is time intensive, and it therefore remains a major bottleneck that prevents more widespread application of image processing techniques.

A great deal of progress has been made in automated segmentation in the brain, partially because the anatomic structures tend to be reproducibly positioned across subjects and the contrast delineation among structures is often good. In addition, MRI images of brain tend to be high quality. Several software packages are currently available for automatic segmentation, particularly for normal macroscopic brain anatomy in cor-

tical and sub-cortical regions (Collins et al. 1995; Friston et al. 1995; Subramaniam et al. 1997; Dale et al. 1999; MacDonald et al. 2000; Brain Innovation B.V. 2001; FMRIB Image Analysis Group 2001; Van Essen et al. 2001; Hinshaw et al. 2002). The Human Brain Project's Internet Brain Segmentation Repository (Kennedy 2001) has been developing a repository of segmented brain images to use in comparing these different methods.

Popular segmentation techniques can be (1) region-based Vs. edge-based methods, (2) knowledge-based Vs. data-driven methods, and combined methods.

#### ■ Region-Based Vs. Edge-Based

In region-based segmentation, voxels are grouped into contiguous regions based on characteristics such as intensity ranges, spatial statistics and similarity to neighboring voxels (Shapiro and Stockman 2001; Li et al. 2011b). In brain MR images, a common class separation is into: gray matter, white matter, cerebrospinal fluid and background. One then uses these classifications as a basis for further segmentation (Choi et al. 1991; Zijdenbos et al. 1996). Another region-based approach is called region-growing, in which regions are grown from seed voxels manually or automatically placed within candidate regions (Davatzikos and Bryan 1996; Modayur et al. 1997). The regions found by any of these approaches are often further processed by mathematical morphology operators (Haralick 1988) to remove unwanted connections and holes (Sandor and Leahy 1997). Other well-known techniques include active contour and level set models (Li et al. 2011b; Hoogi et al. 2017) graph-based models (Shattuck and Leahy 2001) and clustering-based methods (Li et al. 2011a).

Contrary to region-based techniques, Edge-based segmentation relies on detecting the gradients in the image. These gradients are considered as the organ boundary. However, edge-based technique is very sensitive to image noise and to inconsistent broken boundaries.

Other techniques can be considered as hybrid frameworks, in which both region statistics and gradients information are included (Chakraborty et al. 1996; Shao et al. 2008).

All the above techniques are essentially low-level techniques that only look at local or global regions in the image data.

#### ■ Model-Based and Data-Driven Segmentation

Segmentation methods are mostly divided into model-based and data-driven approaches. The former considers prior knowledge about the organ/medical images to be analyzed, while the latter is based only on the specific analyzed image data, with no prior examples or knowledge. Deformable models that are part of the model-based curve evolution approach and called "Snakes" (Kass et al. 1987; Davatzikos and Bryan 1996; Dale et al. 1999; MacDonald et al. 2000; Van Essen et al. 2001). These models can include knowledge of the expected anatomy of the organ. For example, the cost function employed in the method developed by MacDonald (MacDonald et al. 2000) includes a term for the expected thickness of the brain cortex. Thus, these methods can become somewhat knowledge-based, where knowledge of anatomy is encoded in the cost function. Level set is another form of curve evolution technique but on contrary to Snake, level set is an implicit approach (Li et al. 2011b; Hoo-Chang et al. 2016; Hoogi et al. 2017). In both Snakes and level set, the contour is deformed according to a cost function that should be minimized and includes both intrinsic terms regarding the contour itself (e.g. contour smoothness), and extrinsic terms that depends on the image data.

#### ■ Clustering-Based Segmentation

The core operation in a segmentation task is the division of the image into a finite set of clusters/regions with similar statistics, which are smooth and homogeneous in their content and their representation. When posed in this way, segmentation can be regarded as a problem of finding clusters in a selected feature space. The segmentation task can be seen as a combination of two main processes: (a) The generation of an image representation over a selected feature space. This can be termed the modeling stage. The model components are often viewed as groups, or *clusters* in the high-dimensional space. (b) The assignment

of pixels to one of the model components or segments. In order to be directly relevant for a segmentation task, the clusters in the model should represent homogeneous regions of the image. In general, the better the image modeling, the better the segmentation produced. Since the number of clusters in the feature space is often unknown, segmentation can be regarded as an *unsupervised clustering* task in the high-dimensional feature space.

There are many works on **clustering algorithms**. We can categorize them into three broad classes: (a) deterministic algorithms, (b) probabilistic model-based algorithms, and (c) graph-theoretic algorithms. The simplest of these are the deterministic algorithms such as k-means (Bishop 1995), mean-shift (Comaniciu and Meer 2002), and agglomerative methods (Duda et al. 2001). For certain data distributions, i.e., distributions of pixel feature vectors in a feature space, such algorithms perform well. For example, k-means provides good results when the data are convex or blob-like and the agglomerative approach succeeds when clusters are dense and there is no noise. These algorithms, however, have a difficult time handling more complex structures in the data. The probabilistic algorithms, on the other hand, model the distribution in the data using parametric models (McLachlan and Peel 2000). Such models include autoregressive (AR) models, Gaussian mixture models (GMM), Markov random fields (MRF), conditional random fields, and others. Efficient ways of estimating these models are available using maximum likelihood algorithms such as the Expectation-maximization (EM) algorithm (Dempster et al. 1977). While probabilistic models offer a principled way to explain the structures present in the data, they could be restrictive when more complex structures are present.

Another type of clustering algorithms is non-parametric in that this class imposes no prior shape or structure on the data. Examples of these are graph-theoretic algorithms based on spectral factorization (e.g., (Ng et al. 2001, Shi and Malik 2000)). Here, the image data are modeled as a graph. The entire image data along with a global cost function are used to partition the graph, with each parti-

tion now becoming an image segment. In this approach, global considerations determine localized decisions. Moreover, such optimization procedures are often compute-intensive.

Consider an example application in brain image segmentation using parametric modeling and clustering. The tissue and lesion segmentation problem in Brain MRI is a well-studied topic of research. In such images, there is interest in three main tissue types: white matter (WM), gray matter (GM) and cerebro-spinal fluid (CSF). The volumetric analysis of such tissue types in various part of the brain is useful in assessing the progress or remission of various diseases, such as Alzheimer's disease, epilepsy, sclerosis and schizophrenia. A segmentation example is shown in  Fig. 10.21. In this example, images from 3 MRI imaging sequences are input to the system, and the output is a segmentation map, with different colors representing three different normal brain tissues, as well as a separate color to indicate regions of abnormality (multiple-sclerosis lesions).

Various approaches to the segmentation task are reviewed in (Pham et al. 2000). Among the approaches used are pixel-level intensity based clustering, such as K-means and Mixture of Gaussians modeling (e.g., (Kapur et al. 1996)). In this approach, the intensity feature is modeled by a mixture of Gaussians, where each Gaussian is assigned a semantic meaning, such as one of the tissue regions (or lesion). Using pattern recognition methods and learning, the Gaussians can be automatically extracted from the data, and once defined, the image can be segmented into the respective regions.

Algorithms for tissue segmentation using pixel-level intensity-based classification often exhibit high sensitivity to various noise artifacts, such as intra-tissue noise, inter-tissue intensity contrast reduction, partial-volume effects and others. Due to the artifacts present, classical voxel-wise intensity-based classification methods, including the K-means modeling and Mixture of Gaussians modeling, often give unrealistic results, with tissue class regions appearing granular, fragmented, or violating anatomical constraints. Specific works can be found addressing various aspects

■ **Fig. 10.21** Brain MRI segmentation example. Brain slice from multiple acquisition sequences (with 9% noise) was taken from BrainWEB (<http://www.bic.mni.mcgill.ca/brainweb/>). From left to right: T1-, T2-, and proton density (PD)-weighted image. Segmentation

of the images is shown on the right: Blue: CSF; Green: Gray matter (GM); Yellow: white matter (WM); Red: Multiple-sclerosis lesions (MSL). (Friefeld et al. 2009). (Reused with permission © Brainweb)

of these concerns (e.g., partial-volume effect quantification (Dugas-Phocion et al. 2004)). One way to address the smoothness issue is to add spatial constraints. This is often done during a pre-processing phase by using a statistical atlas, or as a post-processing step via Markov Random Field models. A statistical atlas provides the prior probability for each pixel to originate from a particular tissue class (e.g., (Van Leemput et al. 1999; Marroquin et al. 2002; Prastawa et al. 2004)).

Algorithms exist that use the maximum-a-posteriori (MAP) criterion to augment intensity information with the atlas. However, registration between a given image and the atlas is required, which can be computationally prohibitive (Rohlfing and Maurer Jr. 2003). Further, the quality of the registration result is strongly dependent on the physiological variability of the subject and may converge to an erroneous result in the case of a diseased or severely damaged brain. Finally, the registration process is applicable only to complete volumes. A single slice cannot be registered to the atlas. Therefore it cannot be segmented using these state-of-the-art algorithms. In (Greenspan et al. 2006) a robust, unsupervised, parametric method for segmenting 3D (or 2D) MR brain images with a high degree of noise and low contrast, is presented. A Constrained Gaussian Mixture Model (CGMM) framework is proposed, in which each tissue is modeled with multiple four-dimensional Gaussians, where each Gaussian represents a localized region (3 spatial fea-

tures) and the intensity characteristic per region (T1 intensity feature). Incorporating the spatial information within the feature space is novel, as is using a large number of Gaussians per brain tissue to capture the complicated spatial layout of the individual tissues. Two key features of the proposed framework are: 1) combining global intensity modeling with localized spatial modeling, as an alternative scheme to MRF modeling, and 2) segmentation is entirely unsupervised; thus eliminating the need for atlas registration, or any intensity model standardization.

Segmentation can also be improved using a post-processing phase in which smoothness and immunity to noise can be achieved by modeling the interactions among neighboring voxels. Such interactions can be modeled using a Markov Random Field (MRF), and thus this technique has been used to improve segmentation (Held et al. 1997; Van Leemput et al. 1999; Zhang et al. 2001).

#### ■ Segmentation Using Deep Learning

As noted earlier in this chapter, one of the fastest emerging research field over the last few years is deep learning. Deep learning can help outperform classical machine learning algorithms due to its ability to learn latent variables within the features space, features that the user can barely detect. On the other hand, deep learning requires a huge labeled training size that is not always available, which makes developing robust classification models challenging. However, there are methods to help

overcome these challenges, such as data augmentation (Greenspan et al. 2016), transfer learning (Hoo-Chang et al. 2016), and metric learning (Yang et al. 2010) that were specifically designed to handle these challenges. In transfer learning one uses a network that was pre-trained on another set of images, and we use the weights of this network as weights initialization for the current network that is analyzed. The initial weights are fine-tuned on the relevant current dataset, which should give better results than just using random weights. In metric learning, one actually learns the best metric that can represent and classify the data – instead of learning the classes themselves. In that way, we actually teach the network how to learn. In addition, metric learning is a kind of “image ontology,” and as a result, it sketches the distances between different instances. Therefore, if a new test case will not be part of the training classes, it will not be misclassified to one of those classes.

The core idea of deep learning is to convolve the input image with different filters and within different scales (i.e. pooling), such as they will be able to detect both low-level and high-level features. Many deep learning architectures are considered as patch-wise techniques.

Convolutional neural networks such as U-Net (Ronneberger et al. 2015; Trebeschi et al. 2017) and V-Net (Trebeschi et al. 2017) were designed specifically to deal with the typical challenges of the medical domain such as small amount of labeled data. Autoencoders, Variational Autoencoders and stacked-autoencoders can be used for image denoising and as for unsupervised feature extraction (Vincent et al. 2010; Bengio et al. 2013). Other methods were designed to handle with various of classifications tasks such as lesion detection (Wang et al. 2016), segmentation (Kayalibay et al. 2017; Trebeschi et al. 2017) and disease classification (Esteva et al. 2017).

### 10.4.7 Image Registration

The growing availability of 3-D and higher dimensionality structural and functional images leads to exciting opportunities for realistically observing the structure and func-

tion of the body. These opportunities are particularly widely exploited in brain imaging. Therefore, this section concentrates on 3-D brain imaging, with the recognition that many of the methods developed for the brain have been or will be applied to other areas as well.

The basic 2-D image processing operations of global processing, segmentation, feature detection, and classification generalize to higher dimensions, and are usually part of any image processing application. However, 3-D and higher dimensionality images give rise to additional informatics issues, which include image *registration* (which also occurs to a lesser extent in 2-D), *spatial* representation of anatomy, *symbolic* representation of anatomy, integration of spatial and symbolic anatomic representations in *atlases*, anatomical *variation*, and *characterization* of anatomy. All but the first of these issues deal primarily with anatomical structure, and therefore could be considered part of the field of structural informatics. They could also be thought of as being part of imaging informatics and **neuroinformatics**.

As noted previously, 3-D image volume data are represented in the computer by a 3-D volume array, in which each voxel represents the image intensity in a small volume of space. In order to depict anatomy accurately, the voxels must be accurately registered (or located) in the 3-D volume (*voxel registration*), and separately acquired image volumes from the same subject must be registered with each other (*volume registration*).

#### ■ Voxel Registration

Imaging modalities such as CT, MRI, and confocal microscopy (► Sects. 10.2.3 and 10.2.5) are inherently 3-D: the scanner generally outputs a series of image slices that can easily be reformatted as a 3-D volume array, often following alignment algorithms that compensate for any patient motion during the scanning procedure. For this reason, almost all CT and MR manufacturers’ consoles contain some form of three-dimensional reconstruction and visualization capabilities.

As noted in ► Sect. 10.4.4, two-dimensional images can be converted to 3-D volumes if they are closely spaced parallel

sections through a tissue or whole specimen and contain isotropic voxels. In this case, the problem is how to align the sections with each other. For whole sections (either frozen or fixed), the standard method is to embed a set of thin rods or strings in the tissue prior to sectioning to manually indicate the location of these **fiducials** on each section, then to linearly transform each slice so that the corresponding fiducials line up in 3-D (Prothero and Prothero 1986). An example of this technique is the Visible Human, in which a series of transverse slices were acquired, then reconstructed to give a full 3-D volume (Spitzer and Whitlock 1998) (► Chap. 22).

It is difficult to embed fiducial markers at the microscopic level, so intrinsic tissue landmarks are often used as fiducials, but the basic principle is similar. However, in this case tissue distortion may be a problem, so non-linear transformations may be required. For example Fiala and Harris (Fiala and Harris 2001) developed an interface that allows the user to indicate, on electron microscopy sections, corresponding centers of small organelles such as mitochondria. A non-linear transformation (warp) is then computed to bring the landmarks into registration.

An approach being pursued (among other approaches) by the National Center for Microscopy and Imaging Research (► <http://ncmir.ucsd.edu/>) combines reconstruction from thick serial sections with electron tomography (Soto et al. 1994). In this case the tomographic technique is applied to each thick section to generate a 3-D digital slab, after which the slabs are aligned with each other to generate a 3-D volume. The advantages of this approach over the standard serial section method are that the sections do not need to be as thin, and fewer of them need be acquired.

An alternative approach to 3-D voxel registration from 2-D images is stereo-matching, a technique developed in computer vision that acquires multiple 2-D images from known angles, finds corresponding points on the images, and uses the correspondences and known camera angles to compute 3-D coordinates of pixels in the matched images. The technique is being applied to the reconstruction of synapses from electron micrographs

by a Human Brain Project collaboration between computer scientists and biologists at the University of Maryland (Agrawal et al. 2000).

#### ■ Volume Registration

A related problem to that of aligning individual sections is the problem of aligning separate image volumes from the same subject, that is, *intra-subject* alignment. Because different image modalities provide complementary information, it is common to acquire more than one kind of image volume on the same individual. This approach has been particularly useful for brain imaging because each modality provides different information. For example, PET (► Sect. 10.2.3) provides useful information about function, but does not provide good localization with respect to the anatomy. Similarly, MRV and MRA (► Sect. 10.2.3) show blood flow but do not provide the detailed anatomy visible with standard MRI. By combining images from these modalities with MRI, it is possible to show functional images in terms of the underlying anatomy, thereby providing a common neuro-anatomic framework.

The primary problem to solve in multimodality image fusion is volume registration—that is, the alignment of separately acquired image volumes. In the simplest case, separate image volumes are acquired during a single sitting. The patient's head may be immobilized, and the information in the image headers may be used to rotate and resample the image volumes until all the voxels correspond. However, if the patient moves, or if examinations are acquired at different times, other registration methods are needed. When intensity values are similar across modalities, registration can be performed automatically by intensity-based optimization methods (Woods et al. 1992; Collins et al. 1994). When intensity values are not similar (as is the case with MRA, MRV and MRI), images can be aligned to templates of the same modalities that are already aligned (Woods et al. 1993; Ashburner and Friston 1997). Alternatively, landmark-based methods can be used. The landmark-based methods are similar to those

used to align serial sections (see earlier discussion of voxel registration in this section), but in this case the landmarks are 3-D points. The Montreal Register Program (MacDonald 1993) is an example of such a program. Techniques and applications of volume registration in other domains have been described (Pelizzari 1998; Ferrante and Paragios 2017).

## 10.5 Image Interpretation and Computer Reasoning

The preceding sections of this chapter as well as ► Chap. 22 describe informatics aspects of image generation, storage, manipulation, and display of images. Rendering an interpretation is a crucial final stage in the chain of activities related to imaging. *Image interpretation* is this final stage in which the physician has direct impact on the clinical care process, by rendering a professional opinion as to whether abnormalities are present in the image and the likely significance of those abnormalities. The process of image interpretation requires “reasoning”—drawing inferences from facts; the facts are the image abnormalities detected and the known clinical history, and the inferred information is the diagnosis and management decision (what to do next, such as another test or surgery, etc.). Such reasoning usually entails uncertainty, and optimally would be carried out using probabilistic approaches (► Chap. 3), unless certain classic imaging patterns are recognized. In reality, radiology practice is usually carried out without formal probabilistic models that relate imaging observations to the likelihood of diseases. However, variation in practice is a known problem in image interpretation (Robinson 1997), and methods to improve this process are desirable.

Informatics methods can enhance radiological interpretation of images in two major ways: (1) image retrieval systems and (2) computer-based inference systems. The concept of *image retrieval* is similar to that of information retrieval (see ► Chap. 23), in which the user retrieves a set of documents pertinent to a question or information need. The information being sought when doing

image retrieval is images with specific content—typically to find images that are similar in some ways to a query image (e.g., to find images in the PACS containing similar-appearing abnormalities to that in an image being interpreted). Finding images containing similar content is referred to as **content based image retrieval (CBIR)**. By retrieving similar images and then looking at the diagnosis of those patients, the radiologist can gain greater confidence in interpreting the images from patients whose diagnosis is not yet known.

As with the task of medical diagnosis (► Chap. 24), radiological diagnosis can be enhanced using computer-based inference systems, the commonest type of which is *decision support systems*, which assist the physician in making clinical decisions. In computer inference (also referred to as “reasoning”), the machine takes in the available data (the images and possibly other clinical information), performs a variety of image processing methods (► Sect. 10.4), and uses one or more types of knowledge resources and/or mathematical models to render an output comprising either a decision or a ranked list of possible choices (e.g., diagnoses or locations on the image suspected of being abnormal).

In this section we describe informatics methods for image retrieval and computer inference with images.

### 10.5.1 Content-Based Image Retrieval

Since a key aspect of radiological interpretation is recognizing characteristic patterns in the imaging features which suggest the diagnosis, searching databases for similar images with known diagnoses could be an effective strategy to improving diagnostic accuracy. **CBIR** is the process of performing a match between images using their visual content. A query image can be presented as input to the system (or a combination of a query image and the patient’s clinical record), and the system searches for similar cases in large archive settings (such as PACS) and returns a ranked list of such similar data (images).

This task requires an informative representation for the image data, along with similarity measures across image data. CBIR methods are already useful in non-medical applications such as consumer imaging and on the Web (Wang et al. 1997; Smeulders et al. 2000; Datta et al. 2008).

There has also been ongoing work to develop CBIR methods in radiology and several reviews on this subject have been published (Akgul et al. 2011; Endo et al. 2012; Kumar et al. 2013; Muramatsu 2018). The approach generally is based on deriving quantitative characteristics from the images (e.g., pixel statistics, spatial frequency content, etc.; ▶ Sect. 10.4.5), followed by application of similarity metrics to search databases for similar images (Lehmann et al. 2004; Muller et al. 2004; Greenspan and Pinhas 2007; Datta et al. 2008; Deserno et al. 2009; Napel et al. 2010; Faruque et al. 2013, 2015). The focus of the current work is on entire images, describing them with sets of numerical features, with the goal of retrieving similar images from medical collections (Hersh et al. 2009; Napel et al. 2010; Faruque et al. 2013, 2015) that provide benchmarks for image retrieval. However, in many cases only a particular region of the image is of interest when seeking similar images (e.g., finding images containing similar-appearing lesions to those in the query image). More recently, “localized” CBIR methods are being developed in which a part of the image containing a region of interest is analyzed (Deselaers et al. 2007; Rahmani et al. 2008; Napel et al. 2010).

There are several unsolved challenges in CBIR. First, CBIR has been largely focused on query based on single 2-D images; methods need to be developed for 3D retrieval in which a volume is the query “image.” A second challenge is the need to integrate images with non-image clinical data to permit retrieval based on entire patient cases and not single images (e.g., the CBIR method should take into consideration the clinical history in addition to the image appearance in retrieving a similar “case”).

Another limitation of current CBIR is that image semantics is not routinely included.

The qualitative image features reported by the radiologist (“semantic features”) are complementary to the quantitative data contained in image pixels. One approach to capturing image semantics is analyzing and processing “visual words” in images, captured as image patches or codebooks (▶ Sect. 10.4.5). These techniques have been shown to perform well in CBIR applications (Qiu 2002). Another approach to capture image semantics is to use the radiologist’s imaging observations as image features. Several studies have found that combining the semantic information obtained from radiologists’ imaging reports or annotations with the pixel-level features can enhance performance of CBIR systems (Ruiz 2006; Zhenyu et al. 2009; Napel et al. 2010). The knowledge representation methods described in ▶ Sects. 10.3.2 and 10.4.5 make it possible to combine these types of information.

## 10.5.2 Computer-Based Inference

Though image retrieval described above (and information retrieval in general) can be helpful to a practitioner interpreting images, it does not directly answer a specific question at hand, such as, “what is the diagnosis in this patient” or “what imaging test should I order next?” Answering such questions requires inference, either by the physician with all the available data, or by a computer, using physician inputs and the images. As the use of imaging proliferates and the number of images being produced by imaging modalities explodes, it is becoming a major challenge for practicing radiologists to integrate the multitude of imaging data, clinical data, and soon molecular data, to formulate an accurate diagnosis and management plan for the patient. Computer-based inference systems—specifically decision support systems—can help radiologists understand the biomedical import of this information and to provide guidance (Hudson and Cohen 2009).

There are two major approaches to computer-based inference using images: (1) using quantitative image features only (quan-

titative imaging computer inference systems), and (2) use knowledge associated with the images (knowledge-based computer inference systems).

#### ■ Quantitative Imaging Computer Inference Systems

The process of deriving quantitative image features was described in ► Sect. 10.4.5. Quantitative imaging applications such as CAD and CADx use these quantifiable features extracted from medical images for a variety of decision support applications, such as the assessment of an abnormality to suggest a diagnosis, or to evaluate the severity, degree of change, or status of a disease, injury, or chronic condition. In general, the quantitative imaging computer reasoning systems apply a mathematical model (e.g., a *classifier*) or other machine learning methods to obtain a decision output based on the imaging inputs.

There are three types of systems that make inferences using quantitative imaging data, *computer-assisted detection* (CAD), *computer-assisted diagnosis* (CADx), and *computerized prediction* systems. In CAD, the computer locates ROIs in the image where abnormalities are suspected and the radiologist must evaluate their medical significance. This is generally accomplished using quantitative image analysis methods (► Sect. 10.4.5). In CADx, the computer is given an ROI corresponding to a suspected abnormality (possible with associated clinical information) and it outputs the likely diagnoses and possibly management recommendations (ideally with some sort of confidence rating as well as explanation facility). Ideally, the confidence of the algorithm in making this diagnosis is also provided as well as explanation or transparency to the user to understand how that diagnosis was determined from the facts. These systems generally use both quantitative imaging methods (► Sect. 10.4.5) as well as computer reasoning methods that leverage knowledge associated with the image (► Sect. 10.3.2). In computerized predication, a computational model based on analysis of the images (potentially integrated with other data) makes a clinical prediction about the patient.

#### ■ CAD

In CAD applications, the goal is *detection* of abnormalities that are visible in the image, to scan the image and identify suspicious regions that may represent regions of disease in the patient. A common use for CAD is *screening*, the task of reviewing many images and identifying those that are suspicious and require closer scrutiny by a radiologist (e.g., mammography interpretation). Most CAD applications comprise an image processing pipeline (► Sect. 10.4) that uses global processing, segmentation, image quantitation with feature extraction, and classification to determine whether an image should be flagged for careful review by a radiologist or pathologist. In CAD and in screening in general, the goal is to detect disease; thus, the tradeoff favors having false positive instead of missing false negatives. Thus CAD systems tend to flag a reasonable number of normal images (false positives) and they miss very few abnormal images (false negatives). If the number of flagged images is small compared with the total number of images, then automated screening procedures can be economically viable. On the other hand, too many false positives are time-consuming to review and lessens user confidence in the CAD system; thus for CAD to be viable, they must minimize the number of false positives as well as false negatives.

CAD techniques for screening have been applied successfully to many different types of images (Doi 2007), including mammography images for identifying mass lesions and clusters of microcalcifications, chest X-rays and CT of the chest to detect small cancerous nodules, and volumetric CT images of the colon (“virtual colonoscopy”) to detect polyps. In addition, CAD methods have been applied to Papanicolaou (Pap) smears for cancerous or precancerous cells (Giger and MacMahon 1996), as well as to many other types of non-radiologic images.

As noted in ► Sect. 10.4.5, detection tasks in images can be accomplished using pre-defined image features or using learned features (deep learning), which is becoming a very popular approach to CAD with encour-

aging results (Firmino et al. 2014; Shin et al. 2016).

#### ■ CADx

In CADx applications, a suspicious region in the image has already been identified (by the radiologist of a CAD application), and the goal is to evaluate it to render a diagnosis or differential diagnosis. CADx systems usually need to be provided an ROI, or they need to segment the image to locate specific organs and lesions in order to perform analysis of quantitative image features that are extracted from the ROI and use that to render a diagnosis. However, recently, CADx systems have begun to be developed using deep learning, which generally does not require any ROI, since the models are built using the raw image data (Al-Antari et al. 2018; Ishioka et al. 2018; Lee et al. 2018; Nishio et al. 2018).

In general, a mathematical model is created to relate the quantitative (or semantic) features to the likely diagnoses. These models are built either using pre-defined image features or using learned features (► Sect. 10.4.5). Most of the historical CADx systems have been built using pre-defined image features (Doi 2007), but if a sufficient number of labeled cases is available for training, deep learning appears to hold much promise for developing CADx systems (Chen et al. 2017; Hosny et al. 2018).

A particularly important emerging role for CADx systems is in the diagnosis of infection by the SARS-CoV-2 virus (COVID-19). The COVID-19 pandemic created extremely rapid and widespread person-to-person transmission of the disease (World Health Organization 2020). Definitive diagnosis is made using the reverse transcriptase polymerase chain reaction (RT-PCR) test. Since test can take up to 2 days to complete, and given the shortage of RT-PCR test kits, there was an urgent need for alternative and rapid methods to identify COVID-19 patients. Imaging (radiography or CT) are commonly used to identify pneumonia, but imaging has not, to date, been used to establish a diagnosis of COVID-19 since imaging findings are not specific. Thus, routine screening CT for the identification of COVID-19 pneumonia is currently not recommended

by most radiology societies (Simpson et al. 2020). A number of recent works have been undertaken to detect COVID-19 pneumonia in patient using deep learning (Wang and Wong 2020, Greenspan et al. 2020). Systems that integrate clinical data with images may be particularly promising (Mei et al. 2020). Nonetheless, given the accuracy of current CADx systems for COVID-19 likely have insufficient accuracy, and new diagnostic tests are being developed that are processed in a shorter time (Billingsley 2020), imaging will not likely have a sustained major role in diagnosis. Other applications for CADx systems in COVID-19 were reviewed in (Kumar et al. 2020). Perhaps the most exciting role for computerized systems in this disease will be for making clinical predictions, such as survival, need for intensive care, ventilator support, and ultimate survival (Liang et al. 2020; Liu et al. 2020; Luo et al. 2020; Sperrin et al. 2020; Wynants et al. 2020; Yang et al. 2020; Yuan et al. 2020).

A limitation of using only pre-defined image features or unsupervised learned image features is that these models do not encode domain knowledge that may be critical to the accuracy of a CADx system; the presumption of using only image features is that all the knowledge needed for the diagnostic classification task is represented in image data itself. However in some cases, it is very useful to encode knowledge in a CADx system. Probabilistic models provide a strategy for incorporating domain knowledge and have been shown to be effective (Burnside et al. 2000, 2004a, b, 2006, 2007; Lee et al. 2009; Liu et al. 2009; Liu et al. 2011). Image features are generated based on the underlying disease, so there is probabilistic dependence on the disease and the quantitative and perceived imaging features. In fact, it can be argued that radiological interpretation is fundamentally a Bayesian task (Lusted 1960; Ledley and Lusted 1991; Donovan and Manning 2007) (see ► Chaps. 3 and 22), and thus decision-support strategies based on Bayesian models may be quite effective.

CADx can be very effective in practice, reducing variation and improving positive predictive value of radiologists (Burnside

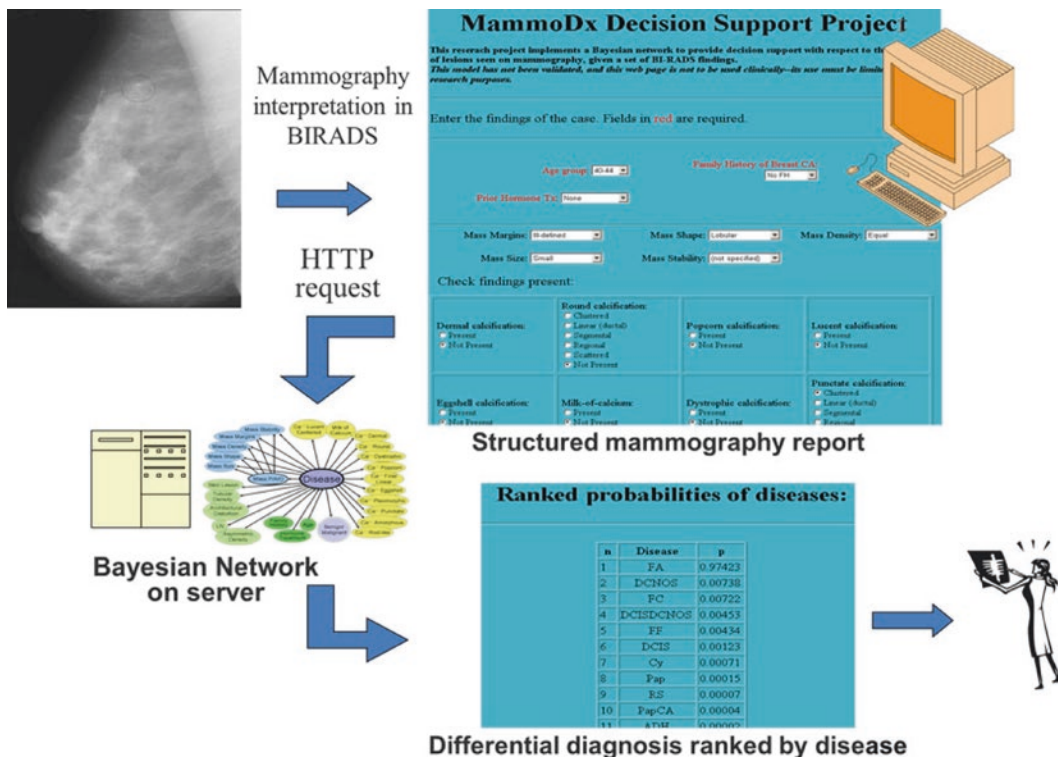

Fig. 10.22 Bayesian network-based system for decision support in mammography CADx. The radiologist interpreting the image enters the radiology observations and clinical information (patient history) in a structured reporting Web-based data capture form to render the report. This form is sent to a server which inputs the observations into the Bayesian network to calculate pos-

terior probabilities of disease. A list of diseases, ranked by the probability of each disease, is return to the user who can make a decision based on a threshold of probability of malignancy, or based on shared decision making with the patient. (Figure reprinted with permission from (Rubin 2011). © Radiological Society of North America)

et al. 2006). Deploying CADx systems, however, can be challenging. Since the inputs to CADx generally need to be structured (semantic features from the radiologist and/or quantitative features from the image), a means of capturing the structured image information as part of the routine clinical workflow is required. A promising approach is to combine structured reporting with CADx (Fig. 10.22); the radiologist records the imaging observations with a data capture form, which provides the structured image content required to the CADx system. Ideally the output would be presented immediately to the radiologist as the report is generated so that the output of decision support can be incorporated into the radiology report. Such implementations will be greatly facilitated by informatics methods to extract and record the image information in structured and

standard formats and with controlled terminologies (Sect. 10.3.2).

### Computerized Prediction

The goal of computerized prediction using images is to analyze characteristics of the disease manifest in the image and use that (without or with additional clinical data) to make predictions about the disease (e.g., life expectancy of the patient, whether or not the patient's disease will respond to a particular treatment, or whether the disease will recur or progress at some time in the future). Many methods have been developed to predict such future event, using both predefined image features and unsupervised feature learning (Sect. 10.4.5) (Huang et al. 2016; Jun et al. 2016; Li et al. 2016; Nie et al. 2016; Bogowicz et al. 2017; Fave et al. 2017; van Timmeren et al. 2017; Wu et al. 2017;

Zhou et al. 2017b; Betancur et al. 2018; Cha et al. 2018; Gastouniotti et al. 2018; Shi et al. 2018).

### ■ Knowledge-Based Image Inference Systems

The CAD and CADx systems do not require processing radiological knowledge (e.g., anatomic knowledge) in order to carry out their tasks; they are based on quantitative modeling of relationships of images features to diagnoses. However, not all image-based reasoning problems are amenable to this approach. In particular, knowledge-based tasks such as reasoning about anatomy, physiology, and pathology—tasks that entail symbolic manipulations of biomedical knowledge and application of logic—are best handled using different methods, such as ontologies and logical inference (see ► Chap. 24).

Knowledge-based computer reasoning applications use knowledge representations, generally ontologies, in conjunction with rules of logic to deduce information from asserted facts (e.g., from observations in the image). For example, an anatomy ontology may express the knowledge that “if a segment of a coronary artery is severed, then branches distal to the severed branch will not receive blood,” and “the anterior and lateral portions of the right ventricle are supplied by branches of the right coronary artery, with little or no collateral supply from the left coronary artery.” Using this knowledge, and recognition via image processing that the right coronary artery is severed in an injury, a computer reasoning application could deduce that the anterior and lateral portions of the right ventricle will become ischemic (among other regions; ■ Fig. 10.23). In performing this reasoning task, the application uses the knowledge to draw correct conclusions by manipulating the anatomical concepts and relationships using the rules of logical inference during the reasoning process.

Computer reasoning with ontologies is performed by one of two methods: (1) *reasoning by ontology query* and (2) *reasoning by logical inference*. In reasoning by ontology query, the application traverse relationships that link particular entities in the ontology

to directly answer particular questions about how those entities relate to each other. For example, by traversing the *part-of* relationship in an anatomy ontology, a reasoning application can infer that the left ventricle and right ventricle are part-of the chest (given that the ontology asserts they are each part of the heart, and that the heart is part of the chest), without our needing to specify this fact explicitly in the ontology.

In reasoning by logical inference, ontologies that encode sufficient information (“explicit semantics”) to apply generic reasoning engines are used. The Web Ontology Language (OWL) (Bechhofer et al. 2004; Smith et al. 2004; Motik et al. 2008) is an ontology language recommended by the World Wide Web Consortium (W3C) as a standard language for the Semantic Web (WorldWideWeb Consortium W3C Recommendation 10 Feb 2004). OWL is similar to other ontology languages in that it can capture knowledge by representing the entities (“classes”) and their attributes (“properties”). In addition, OWL provides the capability of defining “formal semantics” or meaning of the entities in the ontology. Entities are defined using logic statements that provide assertions about entities (“class axioms”) using **description logics** (DL) (Grau et al. 2008). DLs provide a formalism enabling developers to define precise semantics of knowledge in ontologies and to perform automated deductive reasoning (Baader et al. 2003). For example, an anatomy ontology in OWL could provide precise semantics for “hemopericardium,” by defining it as a pericardial cavity that contains blood.

Highly optimized computer reasoning engines (“reasoners”) have been developed for OWL, helping developers to incorporate reasoning efficiently and effectively in their applications (Tsarkov and Horrocks 2006; Motik et al. 2009). These reasoners work with OWL ontologies by evaluating the asserted logical statements about classes and their properties in the original ontology (the “asserted ontology”), and they create a new ontology structure that is deduced from the asserted knowledge (the “inferred ontology”). This reasoning process is referred to as “automatic classification.” The inferences obtained

10

**Fig. 10.23** Knowledge-based reasoning with images in a task to predict the portions of the heart that will become ischemic after a penetrating injury that injures particular anatomic structures. The application allows the user to draw a trajectory of penetrating injury on the image, a 3-D rendering of the heart obtained from segmented CT images. The reasoning application automatically carries out two tasks. **a** The application first deduces the anatomic structures that will be injured consequent to the trajectory (arrow, right) by interrogating

semantic annotations on the image based on the trajectory of injury (injured anatomic structures shown in bold in the left panel). **b** The anatomic structures that are predicted to be initially injured are displayed in the volume rendering (dark gray = total ischemia; light gray = partial ischemia). In this example, the right coronary artery was injured, and the reasoning application correctly inferred there will be total ischemia of the anterior and lateral wall of the right ventricle and partial ischemia of the posterior wall of the left ventricle

from the reasoning process are obtained by querying the inferred ontology and looking for classes (or individuals) that have been assigned to classes of interest in the ontology. For example, an application was created to infer the consequences of cardiac injury in this manner (■ Fig. 10.23).

Several knowledge-based image reasoning systems have been developed that use ontologies as the knowledge source to process the image content and derive inferences from them. These include: (1) reasoning about the anatomic consequences of penetrating injury, (2) inferring and simulating the physiological changes that will occur given anatomic abnormalities seen in images, (3) automated disease grading/staging to infer the grade and/or stage of disease based on imaging features of disease in the body (4) surgical planning by deducing the functional significance of disruption of white matter tracts in the brain, (5) inferring the types of information users seek based on analyzing query logs of image searches, and (6) inferring the response of disease in patients to treatment based on analysis of serial imaging studies. We briefly describe these applications.

#### ■ Reasoning about anatomic consequences of penetrating injury

In this system, images were segmented and semantic annotations applied to identify cardiac structures. An ontology of cardiac anatomy in OWL was used to encode knowledge about anatomic structures and the portions of them that are supplied by different arterial branches. Using knowledge about part-of relationships and connectivity, the application uses the anatomy ontology to infer the anatomic consequences of injury that are recognized on the input images (■ Fig. 10.23) (Rubin et al. 2004, 2005, 2006a).

#### ■ Inferring and simulating the physiological changes

Morphological changes in anatomy have physiological consequences. For example, if a hole appears in the septum dividing the atria or ventricles of the heart (a septal defect), then blood will flow abnormally

between the heart chambers and will produce abnormal physiological blood flow. The simulation community has created mathematical models to predict the physiological signals, such as time-varying pressure and flow, given particular parameters in the model such as capacitance, resistance, etc. The knowledge in these mathematical models can be represented ontologically, in which the entities correspond to nodes in the simulation model; the advantage is that a graphical representation of the ontology, corresponding to a graphical representation of the mathematical model, can be created. Morphological alterations seen in images can be directly translated into alterations in the ontological representation of the anatomic structures, and simultaneously can update the simulation model appropriately to simulate the physiological consequences of the morphological anatomic alteration (Rubin et al. 2006b). Such knowledge-based image reasoning methods could greatly enable functional evaluation of the static abnormalities seen in medical imaging.

#### ■ Automated disease grading/staging

A great deal of image-based knowledge is encoded in the literature and not readily available to clinicians needing to apply it. A good example of this is the criteria used to grade and stage disease based on imaging criteria. For example, there are detailed criteria specified for staging tumors and grading the severity of disease. This knowledge has been encoded in OWL ontologies and used to automate grading of brain gliomas (Marquet et al. 2007) and staging of cancer (Dameron et al. 2006) based on the imaging features detected by radiologists. This ontology-based paradigm could provide a good model for delivering current biomedical knowledge to practitioners “just-in-time” to help them grade and stage disease as they view images and record their observations.

#### ■ Surgical planning

Understanding complex anatomic relationships and their functional significance in the patient is crucial in surgical planning, par-

ticular for brain surgery, since there are many surgical approaches possible, and some will have less severe consequences to patients than others. It can be challenging to be aware of all these relationships and functional dependencies; thus, surgical planning is an opportune area to develop knowledge-based image reasoning systems. The anatomic and functional knowledge can be encoded in an ontology and used by an application to plan the optimal surgical approach. In recent work, such an ontological model was developed to assess the functional sequelae of disruptions of motor pathways in the brain, which could be used in the future to guide surgical interventions (Talos et al. 2008; Rubin et al. 2009b).

#### ■ ■ Inferring types of information users seek from images

Knowledge-based reasoning approaches have been used to evaluate image search logs on Web sites that host image databases to ascertain the types of queries users submit. RadLex (► Sect. 10.3.2) was used as the ontology, and by mapping the queries to leaf classes in RadLex and then traversing the subsumption relations, the types of queries could be deduced by interrogating the higher-level classes in RadLex (such as “visual observation” and “anatomic entity”) (Rubin et al. 2011).

#### ■ ■ Inferring the response of disease treatment

As mentioned above, the complex knowledge required to grade and stage disease can be represented using an ontology. Similarly, the criteria used to assess the response of patients to treatment is also complex, evolving, and dependent on numerous aspects of image information. The knowledge needed to apply criteria of disease response assessment have been encoded ontologically, specifically in OWL, and used to determine automatically the degree of cancer response to treatment in patients (Levy et al. 2009, Levy and Rubin 2011). The inputs to the computerized reasoning method are the quantitative information about lesions seen in the images, recorded as semantic annotations using the AIM information model (► Sect. 10.3.2).

This application demonstrates the potential for a streamlined workflow of radiology image interpretation and lesion measurement automatically feeding into decision support to guide patient care.

## 10.6 Conclusions

This chapter focuses on methods for computational representation and for processing images in biomedicine, with an emphasis on radiological imaging and the extraction and characterization of anatomical structure and abnormalities. It has been emphasized that the content of images is complex—comprising both quantitative and semantic information. Methods of making that content explicit and computationally-accessible have been described, and they are crucial to enable computer applications to access the “biomedical meaning” in images; presently, the vast archives of images are poorly utilized because the image content is not explicit and accessible. As the methods to extract quantitative and semantic image information become more widespread, image databases will be as useful to the discovery process as the biological databases (they will even likely become linked), and an era of “data-driven” and “high-throughput imaging” will be enabled, analogous to modern “high-throughput” biology. In addition, the computational imaging methods will lead to applications that leverage the image content, such as CAD/CADx and knowledge-based image reasoning that use image content to improve physicians’ capability to care for patients.

Though this chapter has focused on radiology, we stress that the biomedical imaging informatics methods presented are generalizable and either have been or will be applied to other domains in which visualization and imaging are becoming increasingly important, such as microscopy, pathology, ophthalmology, and dermatology. As new imaging modalities increasingly become available for imaging other and more detailed body regions, the techniques presented in this chapter will increasingly be applied in all areas of biomedicine. For example, the development

of molecular imaging methods is analogous to functional brain imaging, since functional data, in this case from gene expression rather than cognitive activity, can be mapped to an anatomical substrate.

Thus, the general biomedical imaging informatics methods described here will increasingly be applied to diverse areas of biomedicine. As they are applied, and as imaging modalities continue to proliferate, a growing demand will be placed on leveraging the content in these images to characterize the clinical phenotype of disease and relate it to genotype and clinical data from patients to enhance research and clinical care.

### Questions for Discussion

1. How might you create an image processing pipeline to build an image-analysis program looking for abnormal cells in a PAP smear? How would you collect and incorporate semantic features into the program?
2. Why is segmentation so difficult to perform? Give two examples of ways by which current systems avoid the problem of automatic segmentation.
3. How might you build a decision-support system that is based on searching the hospital image archive for similar images and returning the diagnosis associated

with the most similar images? How might you make use of the semantic information in images to improve the accuracy of retrieval?

4. What are limitations of deep learning compared with other machine learning methods for creating image interpretation systems? When might a classical machine learning approach be better than deep learning?
5. Give an example of how knowledge about the problem to be solved (e.g., local anatomy in the image) could be used in future systems to aid in automatic segmentation.
6. Both images and free text share the characteristic that they are unstructured information; image processing methods to make the biomedical content in images explicit are very similar to related problems in natural language processing (NLP; ► Chap. 8). How are image processing methods and NLP similar in terms of (1) computer representation of the raw content? (2) representation of the semantic content? (3) processing of the content (e.g., what is the NLP equivalent of segmentation, or the image processing equivalent of named entity recognition)?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

1. What is the role of the patient or consumer in healthcare decisions?
2. How does patient empowerment come into play in the various care delivery settings and phases of health care?
3. What are some examples of sensors that can be used to assist in personal health management?
4. How can you ensure patient privacy and the security of patient generated data in the home and environment?
5. What are the various features of personal health technologies (e.g., personal health records, mobile applications, etc.)?
6. How do individuals obtain various types of health information?

## 11.1 Introduction

Complexity and collaboration characterize health care in the early twenty-first century. Complexity arises from our deeper and more sophisticated understanding of health and disease, including the addition of molecular/genomic processes and social/behavioral determinants. Complexity also arises from the myriad of new treatments available for many diseases, and emerging data about the role of nutrition, exercise, sleep, and stress in preserving health. Collaboration begins with the realization that successful attainment of optimal wellbeing and effective management of disease processes necessitate active engagement of clinicians, laypersons, support systems, and society as a whole. Collaboration extends beyond the societally-focused opportunities into the healthcare system itself, where care is more fragmented, leading to greater needs for collaboration and communication.

Now more than ever before, the healthcare system recognizes the role of the person who interacts with this system, who is increasingly interested in engaging or called upon to engage through various states of health and

disease. This recognition has given rise to a movement that underpins the birth of personal health informatics, as described below.

## 11.2 Patient-Centered Care and Personal Health Informatics

Patient-centered care has become a core component of medical care. From early work in the 1960s and 70s (Balint 1969; Waitzkin and Stoeckle 1972), to the concept of the chronic disease model (Bodenheimer et al., 2002c; Coleman et al. 2009), the National Academy of Medicine landmark report *Crossing the Quality Chasm* (Institute of Medicine (US) Committee on Quality of Health Care in America 2001) making “patient-centered” one of the six aims of health care, and the development and incorporation of the medical home (Kellerman and Kirk 2007) and patient engagement (Dentzer 2013),<sup>1</sup> patient-centered care has taken center stage in medicine.

As a result of this visibility, healthcare institutions, health planners, congressional representatives, and hospital public relations departments are among many promoters of patient-centered care, a concept rooted in “deep respect for patients as unique living beings, and the obligation to care for them on their terms” (Epstein and Street Jr 2011). To be patient-centered, one must accept people seeking care as persons with a unique social world, who should be listened to, informed, respected, and involved in their own care—and whose wishes are heard, if not acted upon, during their healthcare journey. Patient-centered care complements evidence-based medicine by including patient preferences into the decision making about treatment options. Berwick, described three maxims of patient-

1 Health CfA. A New Definition of Patient Engagement. What is Engagement and Why is it Important? 2010. Available from: ► [http://www.cfah.org/file/CFAH\\_Engagement\\_Behavior\\_Framework\\_current.pdf](http://www.cfah.org/file/CFAH_Engagement_Behavior_Framework_current.pdf)

centered care: (1) “The needs of the patient come first.” (2) “Nothing about me without me.” (3) “Every patient is the only patient” (Berwick 2009).

Patient-centered care represents a shift in the physician’s role from paternalistic and authoritative to collaborative--leveraging the perspectives of people and their support system, whether the support system consists of family, caregivers, or even technology, as partners in making decisions and delivering care. Patient-centered care requires the entire healthcare team to be more mindful, informative, and empathic, and for patients to actively participate in their care. Patient-centered care encourages inclusiveness and engagement for shared decision making among the stakeholders to develop a comprehensive care plan aligned with the whole person.

The maxims of patient-centered care form the basis of the field personal health informatics, as originally proposed by Warner Slack and Tom Ferguson in 1993 (Demiris 2016). In particular, these maxims translate into the following desiderata:

- People are able to access care that is coordinated and collaborative
- Care is focused on the whole person, not just the physical comfort
- Care considers people’s values, culture, and socioeconomic status
- People and their support system are active partners in care, not passive listeners
- People’s goals within the healthcare system align with the system’s mission, values, and quality metrics
- People and their caregivers participate in shared decision making with their providers and play a role in the decisions at the personal, population, and system level
- Sharing health information with people and caregivers enables informed decision making
- Support systems’ presence in the care setting are encouraged and facilitated

As described in ► Sect. 13.5, these desiderata provide a new lens through which the whole of biomedical informatics should be viewed.

## 11.2.1 Using Biomedical Informatics to Impact Patient-Centered Medicine

To conclude this section, we provide a few illustrative examples of how patient-centered care and personal health informatics can help shape the care delivered.

### 1. Patient-centered ambulatory care.

Routine ambulatory care, by its very nature, focuses on the whole person, and not just their diagnosis. Caring for the whole person requires the ability to utilize resources such as social workers, financial counselors, mental health providers, transportation, peer support programs, daily living assistance, and language and literacy education and resources. Making the provider aware of the needs of the person being cared for can be enabled through electronic health records (EHRs) and clinical decision support that work within the provider workflow, potentially utilizing data provided by the patient or the patient’s social and family network. In addition, using tools like a patient portal, the healthcare system can provide alerts and reminders to patients for care such as the Influenza vaccine, nutrition counseling, and medication refill reminders.

Access to care can be facilitated through telemedicine and telehealth (see ► Chap. 20), as well as through apps that could enable daily living assistance and peer support programs (see ► Chap. 19). All of these applications need to consider language and literacy (health and technology), as well as challenges created by asynchronous healthcare-related discussions.

Example: Jane uses her mobile app to remind her when to fill her asthma medications and communicate with her social worker and financial counselor to help her purchase those medications. She uses the same app to talk with her support system and other people with asthma who can understand and support her journey through the stages of her disease.

## 2. Patient-centered acute care and care transitions.

Acute care settings are characterized by sudden and rapid changes in patient status, *ad hoc* appointments, and frequent handoffs of care. To help patients understand what is happening to them and to facilitate decision-making, patients often request unrestricted and continuous access to their social support network in this setting. Patients and their support system should be present during rounds, which are performed at the bedside, and at shift changes. Family interaction should take place in an environment that is as comfortable as possible, equipped with access to information and to experts as necessary. Information technology can help make this scenario possible through inpatient personal health records, where patients and their families can view information in real time to help participate in rounds and make informed decisions (Huerta et al. 2017; O’Leary et al. 2016; Prey et al. 2014). Mobile devices can improve communication, care plan management, and knowledge transfer, even when family members are not present. Other personal informatics tools, such as wearable sensors or smart scales, could be introduced during a hospital stay to develop behavior changes that could carry over into the home environment (Steinberg et al. 2013).

Example: Through her mobile phone, Beverly’s family was present remotely in the hospital during rounds to ask the health care team questions. Her family also encouraged Beverly to learn to use the hospital’s smart scale, which can monitor her weight and keep her heart failure under control. Beverly now uses her smart scale daily at home to send updates to her family and healthcare providers who can encourage her and help her stay out of the hospital.

## 3. Patient-centered care at home.

A significant amount of health care can and should occur in the home setting. This setting is where social, financial, sup-

porting, and behavioral factors can affect a person’s health care and management. Applications like patient portals or personal health records can enable a person to review lab results and clinical notes, communicate with their healthcare providers, schedule appointments, pay bills, and obtain educational information. Wearable technologies enable self-management and monitoring of critical information, such as weight, blood pressure, glucose levels, and medication adherence (Marcolino et al. 2018). Finally, informatics applications could deliver information that can help augment knowledge about disease status that can enable people to make informed decisions about the need to escalate home care or schedule a return visit (Asnani et al. 2016).

Example: Richard knows a lot about his heart failure, but when given the right personal health informatics tools, he learned about signs and symptoms when his heart failure gets worse. He avoids costly readmissions to the hospital by remembering to take his medications daily thanks to reminders from his wearable technologies, and now knows when to communicate with his providers through his patient portal when his heart failure worsens.

## 4. Personalized medicine.

At its core, the maxims of patient-centered care require that any management plan provided by healthcare providers to patients will need to be personalized (see ► Chap. 28). Medications, procedures, supportive or curative plans all should be tailored to the person/family receiving them. However, the augmentation of our knowledge about the impact of a person’s omics (genomics, proteomics, metabolomics, etc.), and environment can now be used to personalize therapy (Collins 2004).

Example: Using sensors on James’ phone along with his genetic information, his providers can use targeted medications to treat his cancer and can help him meet his treatment goal of golfing again.

### 11.2.2 Limitations of Patient-Centered Care

---

As with any change in the locus of control, the transition from authoritative to collaborative decision-making that is the hallmark of patient-centered care raises some concerns. For example, there are concerns that patient-centered medicine conflicts with evidence-based medicine (Weaver 2015). One of the current challenges in medicine is to bring these two worlds together, which could be accomplished using more sophisticated searching of the literature or mining EHR data to uncover evidence supporting deviations in care (Gallego et al. 2015). Another concern is that physicians are stewards of social resources, but some would argue that physicians do not know the social responsibility of patient-centered medicine (Berwick 2009). A third concern is the juxtaposition between a patient needing and wanting improved access to the healthcare system, and a healthcare system that is already both expensive to run, in part because of fragmentation and attempts to improve access (see ► Chap. 29) (Enthoven 2009).

Aside from clinician concerns, there are design constraints on the healthcare system that limit patient-centered medicine. First, the system must support a shift in the locus of control of care decisions towards patients and their caregivers. Developing health informatics tools such as delivering information through mHealth and providing decision aids for people can facilitate informed decision making about care. Second, transparency of care options and their associated costs and outcomes needs to extend to all components of care, including research, and education. While informatics researchers are working on these issues, further work is needed in this area, especially in providing transparent care coordination choices and data liquidity. Third, individualization and customization need to be design targets, creating health care and health informatics systems and tools that can adapt to the individual needs and circumstances of people. Research in personal health informatics demonstrates the importance of

personalization and individualization, but significant work remains. Finally, it is critical to train young healthcare professionals in the expectations of their profession related to patient-centered care. Education informatics can help bridge gaps between what young health professionals currently know and practice and what a patient-centered care model could look like with an appropriate curriculum of educational modules, knowledge testing, and practice modeling.

### 11.3 Historical Perspective of Personal Health Informatics

---

In essence, what we think of as consumer/patient engagement reflects a shift from the person as the silent recipient of ministrations from a wise, beneficent clinician, to an active collaborator whose values, preferences, and lifestyle not only alter predisposition to certain illnesses but also shape the characteristics of desirable treatments. In this section, we will describe the ancient concept of paternalism, the rise of patient-centered medicine, and how personal health informatics has supported and enabled the ability of the person who used to have health care enacted upon them, to be an engaged and active participant in their health care.

#### 11.3.1 Paternalism and Professionalism of Medicine and Informatics

---

Paternalism is thought to go back as far as the history of medicine. Hippocrates was the father of medical paternalism as he wrote that physicians should conceal most things from the patient including the patient's present and future condition. He believed that medical knowledge be kept secret from patients. The Hippocratic oath, which is recited today by medical students, is silent about the communication between the doctor and patient relevant to the patient's treatment. Paternalistic medicine continued through medieval times where patients were told to honor doctors since doc-

tors received their authority from God and patients must promise obedience.

Paternalistic medicine is about keeping information primarily in the hands of the physician and medical system and in certain cases giving misinformation to patients to keep accurate information from them. Healthcare decisions are made by the physician and medical system, and patients are expected to abide by these decisions with no or minimal input. In the 16th and 17th centuries, some physicians started to acknowledge that patients might have a voice in their care. However, doctors of eminence, like Dr. Benjamin Rush, wrote that doctors could yield to patients in matters of little consequence, but maintain an inflexible authority over them in matters essential to life.

Paternalism is still present today. Most biomedical publications are inaccessible and costly without a subscription. Getting complete medical records can be difficult, even when through conventional information technology applications. Informed consent, in many cases, is not sufficiently explained to the person having the treatment for the person to understand all the risks, benefits, other options, and details of what is being done. The discharge process is perhaps the best example of present-day paternalism, where patients have little say about their readiness for discharge and often are made responsible complying with complicated discharge instructions. Patients who believe they are ready before their care team agrees, or who are dissatisfied with their care, are required to sign a form attesting to leaving against medical advice. The final source of paternalism comes from guidelines that healthcare providers get to guide their decisions. These guidelines, discharge forms, and other processes typically do not involve patients in their creation.

Although early information systems were almost exclusively provider-centric, recent advances in computer system availability has prompted the development of less paternalistic tools that may be used by people and families, as described below.

### 11.3.2 The Rise of Patient-Centered Medicine and Personal Health Informatics

---

Enid Balint coined the term patient-centered care in 1969 (Balint 1969). A few pioneers of patient-centered medicine include Barbara Korsch who explored the listening skills of physicians in training (Korsch 1989), John Ware who discovered the components of patient satisfaction (Ware Jr et al. 1983), Debra Roter and Judith Hall who described the properties and dysfunction of doctor-patient communication and how to improve this communication (Roter and Hall 2006), Howard Waitzkin and John Stoeckle who demonstrated how to tap into patient's views and knowledge of their symptoms to what causes them could lead to improved doctor-patient relationships (Waitzkin and Stoeckle 1972), Michael Barry, Jack Fowler, Al Mulley, Joseph Henderson, and Jack Wennberg, who developed shared decision making theory and technology and associations with improved outcomes (Barry et al. 1995), and Judith Hibbard who helped us understand patient's desires for knowledge (Hibbard et al. 2007) and advanced our knowledge and tools about patient engagement and activation (Hibbard and Greene 2013; Hibbard et al. 2004). Other landmarks in this paradigm shift included Engel's proposal to "take into account the patient" (Engel 1977), Cassell's transcriptions of clinical encounters, which provided a basis to understand the doctor-patient relationship (Cassell 1985), and Kleinman's definitions of "disease" and "illness" as the patient's subjective experience of feeling ill (Kleinman 1988).

Personal Health Informatics can be traced back to the early twentieth century, where the U.S. Federal Children's Bureau served as a major source of health information for the public. Mothers could write to this federal agency, asking questions about normal child development, nutrition, and disease management. Written materials, such as letters and pamphlets served as the primary mechanism for delivering information that supported lay

people in their handling of health challenges. Patient education companies such as Krames would partner with organizations like the American Heart Association to provide general printed material on heart disease or with the American Cancer Society to provide information on cancer.

Personal Health Informatics applications followed a similar trend as patient-centered medicine with early applications in the 1950's and 1960's. Collen and colleagues at Kaiser Permanente created one of the earliest patient data collection applications--a health appraisal system that prompted for patient data and returned a systematic risk appraisal (Collen et al. 1964). Warner Slack and colleagues at the University of Wisconsin used a mainframe computer system as a health assessment tool. Patients sat at a cathode ray tube (CRT) terminal and responded to text questions, receiving a printed summary of their health appraisal at the end of the session (Slack et al. 1966). ■ Figure 11.1 shows an early example of the mainframe-based tool developed by Slack. At Massachusetts

General Hospital in the late 1950's, computer-driven telephone systems were used to conduct home-based follow-up with post-surgery cardiac patients, calling them daily to obtain pulse readings. This was followed by an era of interactive video systems that augmented delivery of information and helped patients understand the risks and benefits associated with treatment options, but also to help define their values for possible future health outcomes. The prime examples of this type of system originated with the Foundation for Informed Medical Decision Making. As early as 1973, Wennberg and others discovered that the rates of many expensive surgeries and other treatments would vary from location to location throughout the U.S. (Wennberg and Gittelsohn 1973). This variation seemed to occur for medical conditions where there were multiple viable treatment options and choices depended more on physician and resource availability than need or patient characteristics. Barry et al. focused on developing interactive video consumer decision aids that focused on these conditions (e.g., prostate cancer, breast cancer, back pain, etc.), discovering that patient preferences and priorities for possible health outcomes could vary dramatically from person to person, and could be critical to defining an optimal decision (Barry et al. 1995).

In the 1980s, clinicians and health educators capitalized on the increasingly common personal computers as vehicles for health education. As shown in ■ Fig. 11.2 The Body Awareness Resource Network (BARN), developed in the 1980s by Gustafson and colleagues at the University of Wisconsin, engaged adolescents in game-like interactions to help them learn about growth and development, develop healthy attitudes towards avoidance of risky behaviors, and rehearse strategies for negotiating the complex interpersonal world of adolescence (Bosworth et al. 1983).

Another influential early personal health informatics application was the Comprehensive Health Enhancement Support System (CHESS) developed by Gustafson and colleagues in 1989 at the University of Wisconsin (Gustafson et al. 2001). CHESS

■ Fig. 11.1 Early use of computing in consumer health informatics, here taking a medical history directly from a patient (Slack WV et al. (1966). *NEJM* with permission)

**Fig. 11.2** BARN topic index and use by teens (Bosworth et al. 1983). This picture shows teens interacting with a game on an early graphical computer. The figure on the left is the topic index as displayed on the screen. (With permission from Gustafson, D, personal communication)

provided women with breast cancer information through curated articles and directories of cancer services, decision-making through charts, decision aids, and action plans, and emotional support through online support groups. Ferguson was also heavily influential in the 1980's and 90's in creating and analyzing online social support groups for patients (Ferguson 1996).

As the Internet became more available in homes, Internet support groups gathered momentum. One such example, Hopkins Teen Central developed by Johnson et al. (2001), allowed otherwise isolated children with cystic fibrosis to meet virtually and to discuss health and developmental issues that impacted healthy decision making. The idea of the Internet support group became an active area

of development, continuing through today (Eysenbach et al. 2004). During this time, computer games also increased in uptake, and while time-consuming and expensive to build, they were relatively easy to disseminate, and were associated with measurable changes in knowledge (Lieberman 1988) and, in some cases, symptom management (Patel et al. 2006; Redd et al. 1987).

Some major areas of growth in personal health informatics over the past 20 years include home telehealth, mobile health, personal health records, and personal genomics. The growth of home telehealth technologies has grown rapidly over the past 20 years (see ▶ Chap. 20). Some notable randomized controlled trials include Informatics for Diabetes Education and Telemedicine

(IDEATel), the Telemonitoring Study for Chronic Obstructive Pulmonary Disease (COPD), and the Tele-ERA study. Large randomized controlled trials demonstrated improved effects of these interventions. Personal health records started in the late 1990s with the Patient-Centered Access to Secure Systems Online (PCASSO) portal (Masys and Baker 1997). Tethered personal health records, commonly referred to as patient portals, have been implemented by hundreds of institutions, with increasing adoption being driven by governmental policy such as the Affordable Care Act and Meaningful Use in the US, and the Power of Information strategy in the UK. There has been increasing literature demonstrating increased uptake and use of patient portals, and also improvement in patient satisfaction, communication, and outcomes (Ammenwerth et al. 2012; Goldzweig et al. 2012). With the advent of mobile technologies, such as smart phones and tablets, mobile health (mHealth) has exploded over the past 5 years (see ► Chap. 19). While significant work has been done in the U.S. utilizing this technology, a significant push of mHealth has occurred in low- and middle- income countries because of the ubiquitous nature and low cost of mobile phones as compared to other forms of technology. With the increased ability to record and review daily activities through mobile technologies, a movement called the Quantified Self has evolved (Appelboom et al. 2014). The Quantified Self movement, driven by the theory of patient engagement, is a fast growing practice of self-monitoring driven by technological advances and breakthroughs in miniaturization of wearable and environmental sensors. Personal genomics first became available in the early 2000s because of direct to consumer genetic testing. Companies like 23andMe, ► [Ancestry.com](http://Ancestry.com), and Pathway genomics provide the ability to test one's own genetic composition at home to discover genetic risk for diseases like breast cancer, ancestry, and pharmacogenomic information. Issues with regulatory bodies such as the Food and Drug Administration has prevented all information about genetic risk to be provided

to customers of these companies for concern about false information (see ► Chap. 28).

Patient-centered medicine and Personal Health Informatics have become and will continue to be a bigger and more important driving force in medicine. In 1998 the Institute of Medicine (IOM) established a major program on Quality of Health Care in America and placed patient-centered as one of the six aims in their landmark paper on improving the quality of health care, *Crossing the Quality Chasm* (Institute of Medicine (US) Committee on Quality of Health Care in America 2001). Many studies have demonstrated improvement in care using patient-centered medicine including classic medical outcomes (Epstein and Street Jr 2011), improved shared decision making (Golomb et al. 2007), and reducing unnecessary surgical operations.<sup>2</sup> Personal Health Informatics has also demonstrated important improvements in medical care (Gibbons et al. 2009). In a Medline search of “patient-centered care”, tens of thousands of articles have been published about patient centered medicine, with only 59 from 1950 to 1992. A similar search for “consumer health informatics” OR “personal health informatics” demonstrates hundreds of articles, with only 4 articles from 1950 to 1992. In recognition of the growth of scientific studies in this domain, in 2008 the MeSH term “Consumer Health Information” was introduced, defined as “information intended for potential users of medical and health care services” (Demiris 2016). As people increase their engagement in their health, and technologies improve their ability to do so, personal health informatics will become a bigger and more important part of biomedical informatics and the sub-disciplines within it.

■ Fig. 11.3 Analytic framework showing the interplay between social, cultural, and behavioral features and the opportunities for personal health informatics on outcomes

### 11.4 Important Concepts in Personal Health Informatics

In this section we review how social and cultural, economic and financial, education, language and literacy, environmental and behavior factors influence and mediate health outcomes for patients and consumers of health care. ■ Figure 11.3 shows a framework for thinking about how Personal Health Technology can influence outcomes from a variety of stakeholder’s points of view within a context of social and cultural factors (Jimison et al. 2008; Keselman et al. 2008).

Interactive consumer health technology applications have had an increasingly important role in health care. Work based on the IOM’s Crossing the Quality Chasm report (Institute of Medicine (US) Committee on Quality of Health Care in America 2001) focused on supporting self-management by encouraging providers to use education and other interventions to systematically increase patients’ skills, confidence, and empowerment in managing their health problems (Holman and Lorig 2004). Two specific initiatives include patient-centered care and informatics. As described in ► Sect. 13.2, patient-centered care aims to inform and involve patients and their families in decision making and self-

management, coordinate and integrate care, provide physical comfort and emotional support, understand patients’ concepts of illness and their cultural beliefs, and understand and apply principles of disease prevention and behavioral change appropriate for diverse populations. Informatics aims to communicate, manage knowledge, and support the use of information technology for decision making (Jimison et al. 2008). Examples of these informatics tools include home monitoring systems with interactive disease-management or self-management technology, educational or decision-aid software that is interactively customized to the patient’s needs, online patient support groups, tailored interactive health reminder systems where interactions are linked with electronic health records, and patient-physician electronic messaging. These types of tools may be implemented on a variety of platforms using Web/Internet technology, touch screen kiosks, mobiles phones, or combinations of these. The location where individuals access the information also widely varies – ranging from clinics, hospitals, home, workplace, or any mobile location. However, many factors relating to how the technology is deployed to the consumer or health system can influence access, usability, and effectiveness. Many studies have demonstrated health

outcome disparities related to race and ethnicity, income, and education. With the increasing availability and use of personal health technologies, we have an opportunity to reduce these disparities with appropriate targeted design choices. The following sections identify some of the design challenges.

### 11.4.1 Health Literacy and Numeracy

---

Literacy skills play an important role in navigating the healthcare system, in learning about health and medical concerns, and in using personal health technologies. Health literacy is defined as “the degree to which individuals can obtain, process, and understand the basic health information and services they need to make appropriate health decisions” (Berkman et al. 2011). Several skills are required for an individual to appropriately integrate healthcare information and function effectively in the healthcare environment. One must be able to understand written material (print literacy), understand graphs and numerical quantitative information (numeracy), and be able to both speak and listen effectively (oral literacy). Low health literacy is a significant problem in the United States. In 2003, approximately 80 million adults in the United States (36 percent) had limited health literacy. Certain population subgroups have higher rates of limited health literacy. For instance, rates are higher among older adults, minorities, individuals who have not completed high school, adults who spoke a language other than English before starting school, and people living in poverty. Highlighting the health impact of low health literacy, a 2004 systematic evidence review found a relationship between low health literacy and poor health outcomes (Berkman et al. 2011). Specifically, lower health literacy (measured by reading skills) was associated with lower health-related knowledge and comprehension, higher hospitalization rates, poor global health measures, and certain chronic diseases. There are important considerations that personal health informatics must address

to overcome these literacy issues such as adaptable interfaces and intuitive icons and graphics; however, designers need to give these considerations priority.

### 11.4.2 Digital Divide

---

Concerns about a “digital divide” between the “haves” and “have-nots” have long existed, mainly focused on economic access to the technology. And certainly, access to information technology is now seen as an important component to quality health care. Thus, disparity in access leads to disparity in health outcomes. However, there are many potential causes of a digital divide in addition to income. Studies have shown links to education, ethnicity, gender, urban/rural geography, age, and culture (Carr 2007; Ernest III et al. 2004; Kontos et al. 2014; Mossberger et al. 2006; Neter and Brainin 2012; Wensheng 2002). The terms “digital native” and “digital immigrant” are often used to characterize those generations of people who were born into a digital world, versus those who have experienced the migration from non-digital to digital information. Mobile phone and smartphone access has changed the digital divide trend somewhat recently with over 95% of the global population having access to a mobile phone (Fehske et al. 2011), and a rapidly growing number in all sectors having access to smartphones. Interestingly, in the U.S. the rate of smartphone adoption among Blacks and Hispanics outpaces that among Whites. With more personal health informatics systems using mobile phone interfaces, we may better address the digital divide issue in the future. The most challenging issues at this point relate to available mobile and smartphone bandwidth and education.

### 11.4.3 Chronic Conditions

---

Approximately 120 million Americans have one or more chronic illnesses, accounting for 70 to 80 percent of healthcare costs. Twenty-five percent of Medicare recipients have four or more chronic conditions, accounting for

two thirds of Medicare expenditures (Hoffman et al. 1996; Wagner 2001). Most patients with chronic conditions such as hypertension, diabetes, hyperlipidemia, congestive heart failure, asthma, and depression are not treated adequately, and the burden of chronic illness is magnified by the fact that chronic conditions often occur as comorbidities (Bodenheimer et al. 2002c; Wagner et al. 2001). One key element of systems-oriented chronic care models is support of patient self-management in the home environment (Bodenheimer et al. 2002b). Such self-management support can reduce hospitalizations, emergency department use, and overall managed care costs (Bodenheimer et al. 2002a; Coleman and Newton 2005; Lorig et al. 2001; Renders et al. 2001; Whitlock et al. 2000).

#### 11.4.4 Conditions Associated with Aging

---

A great many elderly persons receiving care have functional limitations, such as reduced sensory, cognitive, or motor capabilities and may require disease management for multiple chronic conditions. Although personal health informatics has the potential to empower patients to become more active in the care process, the elderly may be disadvantaged unless the designers of both software and hardware technology consider their needs explicitly (Demiris 2016). Usability and accessibility issues are important quality criteria for Web-based and mobile interventions (see ► Chap. 5), but often neglected by designers and evaluators (Eysenbach et al. 2002).

#### 11.4.5 Behavior Management

---

Many patients have believed in the concept of health prevention through wellness activities (active lifestyle development, stress reduction, weight control) long before healthcare professionals endorsed this mode of self-care. With the advent of preventive medicine and data supporting the role that wellness activities can

play in maintaining health, many of these tenets have become a part of the armamentarium for disease management and are an area of discovery supported by the Agency for Healthcare Research and Quality (AHRQ) and other Federal institutes.

A complete discussion of foundational models of behavior change is beyond the scope of this chapter, but key works are listed in ■ Table 11.1. Researchers and educators capitalize on these theories to reduce risky behaviors (e.g., cigarette smoking, unprotected sexual intercourse, and unhealthy eating) and to promote desirable health behaviors (i.e., referred to as behavior change).

Beginning in 2007, the Robert Wood Johnson Foundation, in the Project HealthDesign Initiative (Brennan et al. 2007), catalyzed the development of personal health applications, with the belief that a properly developed common platform would be essential to the spread of intelligent, interoperable and theoretically-based behavior change tools. This initiative demonstrated many tools that could help consumers with behavior change. These demonstrations leveraged the widespread adoption of “smart” phone technology across geographic and socioeconomic divides. This widespread adoption, coupled with easy to use software development environments, enables the development of personal health applications that operate as stand-alone or integrated tools available to most consumers.

### 11.5 The Impact of Personal Health Informatics on Biomedical Informatics

---

It is almost axiomatic in biomedical informatics that the introduction of a new discipline or information user category into the healthcare system induces change. Such is the case with the inclusion of person-centered care into biomedical informatics. The unique aspects of what distinguishes health system-generated, provider-generated, and person-generated data from each other permeate all aspects of biomedical informatics. These unique charac-

**Table 11.1** Models of health behavior change

Name and source	Summary
Self-efficacy [Bandura 1977]	An individual's impression of one's own knowledge and skill to perform any task, based on prior success, physical ability, and outside sources of persuasion. Predicts the amount of effort a person will expend to change behavior. It is a key component of other theories, such as the Theory of Planned Behavior.
Social cognitive theory [Bandura 1989]	Behavior change is determined by personal, environmental and behavioral elements, which are interdependent.
Theory of planned behavior [Ajzen 1985]	A link between attitudes and behavior. It asserts that behaviors viewed positively and supported by others (subjective norm) are more likely to have higher levels of motivation and more likely to be performed.
Transtheoretical/stages of change model [Prochaska 2005]	This model asserts that behavioral change is a 5-step process, between which a person may oscillate before achieving complete change.
Patient engagement/patient activation [Dentzer 2013; Hibbard 2004]	Patient engagement describes the actions one can take to achieve maximum benefits from the healthcare services available. Patient activation is a person's knowledge, confidence, and skills used to manage their health. Improved engagement and activation have been associated with improved healthcare outcomes

Early games targeted at behavior change (described above) attempted to remove the stigma (attitude) associated with engaging in healthy behaviors (such as taking medications to combat a chronic illness)

teristics impact both the development of methods to acquire and store data, as well as applications of these methods to impact care and discovery. To provide a frame of reference about the impact of person-centered care on the field, we will describe the magnitude of change using selected examples covered elsewhere in the book.

### 11.5.1 Data Science

The field of data science has been impacted greatly by personal health informatics methods and advances. This discipline, which is focused on the use of scientific processes, algorithms and systems to extract knowledge and insights from both structured and unstructured data, addresses a number of concerns inherent in so-called “big data” (Provost and Fawcett 2013). These data come in large amounts (volume), with often fast speeds of arrival and (velocity), varying formats (variety), varying timing (variability), unclear accuracy/validity (veracity), and significant risks to patient privacy (vulnerabil-

ity). Data collected by patients who may be less familiar with healthcare terminology add a layer of complexity to the variety, veracity, and vulnerability challenges inherent in these data. Data collected using commonly available sensor technologies add to the velocity and volume challenges, but also present new opportunities. These, and other new challenges imposed by the addition of personal data into the healthcare/discovery system are new opportunities for personal health informatics research.<sup>3</sup>

### 11.5.2 Precision Medicine

Perhaps no area has received greater attention in the last 10 years than precision medicine. The goal of precision medicine as noted

3 Technology OotNCfHI. Conceptualizing a Data Infrastructure for the Capture, Use, and Sharing of Patient-Generated Health Data in Care Delivery and Research through 2024, 2018. Available from: [https://www.healthit.gov/sites/default/files/onc\\_pghd\\_final\\_white\\_paper.pdf](https://www.healthit.gov/sites/default/files/onc_pghd_final_white_paper.pdf)

in the Mission statement of the NIH's *All of Us* initiative, is “to enable a new era of medicine through research, technology and policies that empower patients, researchers and providers to work together toward development of individualized treatments” (All of Us Research Program Investigators 2019) (► <https://obamawhitehouse.archives.gov/precision-medicine>) (see ► Chap. 28). Patient empowerment in this new era of medicine will take many forms, and will question how we help patients with concepts such as contributing personal data to empower discovery, understanding a radically new way to subcategorize diseases according to patient-specific attributes, learning a new “trust” model to understand why two patients with the same disease may have very different treatment plans, and even recognizing an expanding role for consumers in establishing and critiquing health policy (Adams and Petersen 2016; Juengst et al. 2012).

### 11.5.3 Ethical, Legal and Social Issues

---

As our understanding about the implications of adopting a person-centered care philosophy mature, so do the ways in which this philosophy should govern the treatment of the person and her data and information. This philosophy introduces new ethical, legal and social issues that are deserving of thought to maximize the effective and safe use of these data and applications (see ► Chap. 12). For example, concerns raised by the access to decision-making applications became the impetus for thoughtful discussion about the timing of FDA regulation of mHealth apps (Lye et al. 2018).

One of the most exciting, though potentially alarming consequences of our extensive use of the Web for shopping, communicating, and learning is that each of us leaves behind a profile of who we are, what we like or dislike, what we know or don't know, and what we want or already have. When combined with data mining and natural language processing techniques, it is possible to create highly targeted and predictive personal knowledge.

Search engines regularly exploit this opportunity to create a profile of each searcher and to improve the relevance of retrieved results (Frisse 1996). We can expect the use of these data to impact how medical care is personalized. Data created by consumers, coupled with ubiquitous computing, might provide just-in-time nutritional consults, over the counter medication advice, or advice that might prevent illnesses, such as convenient locations to receive a flu vaccine or when to begin medications for seasonal allergies (Guo et al. 2016; Pellegrini et al. 2018; Swendeman et al. 2015).

This technology, which is likely to improve the user experience and functionality available with consumer-facing technologies, also has significant downside risks to patient privacy. In particular, data from email, internet searches, support group chats, genome risk prediction sites, and mobile or cloud-based apps all may be directly identifiable, or may be combined with data from other sources to be identifiable. Together, they may be used to create a profile of an individual, his or her health status, the health status of related individuals, or other profiles, all of which may be useful for targeted advertising, insurance risk, employability, or other purposes. Biomedical informatics research in the person-centered care era focuses on such topics as the boundaries of HIPAA protection, genomic privacy, and re-identification risk.

A digital divide can lead to serious ethical issues. If technological interventions are only available or usable to a segment of the population, this imbalance can threaten the impact of these technologies on improving healthcare for all and increase healthcare disparities. Certain interventions, such as mHealth and the Internet of Things technologies, require a certain digital literacy. Installing and maintaining these devices with the tremendous amount of data they generate can be daunting to populations with lower literacy and numeracy as well as those with low proficiency levels for problem solving in technology-rich environments. Also, mobile phones made by different companies can have different capabilities. At the present time, Android phones are widely used by people with lower

socioeconomic status. If Apple iOS apps are shown to be more effective than Android, limited access may increase the disparities and effect of these interventions for many people. Finally, many mHealth apps are only available in English, which further increases the digital divide.

While the direction that personal health informatics will take in the future is at best, educated speculation, it is clear that as long as patient-provider partnerships are endorsed, technology will be a third partner in ensuring that activated people manage their health and disease effectively.

#### 11.5.4 Communication

Inherent in all aspects of information management is the recognition about the audience to whom information is being communicated. Perhaps no field has a larger gap between what is understood by its professionals and its consumers than health care. Numerous studies have demonstrated issues that persist with the age-old challenge of how to educate people about diseases. These challenges are magnified as the scope of consumer engagement broadens to include many of the topics listed above, and as we use data and evidence for care enters everyday discourse with patients (McCormack et al. 2013). Furthermore, the separation of information communication to and from medical professionals creates opportunities for misunderstanding at best, and inappropriate actions being taken by patients at worse (Isaacs and Creinin 2003; Morgan 2013). This is an area ripe for research and evaluation by biomedical informatics professionals, much of which is already underway in areas such as methods to circumvent literacy and numeracy challenges. It is clear that there is a correlation between health literacy and quality of life (Zheng et al. 2018), but also clear that more research needs to be done to understand how to communicate in the face of this reality (Newnham et al. 2017; Fisher et al. 2016).

#### 11.5.5 Mobile Health Care (mHealth)

Perhaps the most significant change in the landscape of personal health informatics has been the adoption of “smartphone” technology into society. Smartphones are mobile phones that perform many functions found on present-day computers. They typically contain a touch screen interface, camera, Internet access, short-range wireless interconnection technology, and an operating system capable of executing downloaded applications. Smartphone ownership has grown worldwide, with an estimated 81% ownership by adults in the United States.<sup>4</sup> When combined with a new generation of wireless or connected peripheral technologies (imaging tools, wearable sensors, monitoring systems, etc.) downloadable applications (apps) have revolutionized information collection and use by people, and have defined a new field called mobile health care (mHealth) (see ► Chap. 19) (Cameron et al. 2017).

One of the main byproducts of the mHealth era has been a radical improvement in consumer empowerment, coupled with information sharing that enables individual groups to make “informed” decisions about their care with or without the assistance of a healthcare professional. With these new capabilities come enormous opportunities for biomedical informatics to influence the entire healthcare system. Terms such as “quantified self” (Dudley et al. 2015) and “Internet of Things” (Dimitrov 2016) begin to characterize the potential of mHealth.

It is through the use of mHealth applications that the notion of personal health informatics has grown beyond the individual’s clinical needs to population-level care needs.

4 Pew Research Center. Smartphone ownership is growing rapidly around the world, but not always equally. Available from: ► <https://www.pewresearch.org/global/2019/02/05/smartphone-ownership-is-growing-rapidly-around-the-world-but-not-always-equally/>. Accessed November 9, 2019.

Indeed, innovations such as Apple's ResearchKit © and the explosion of wearable fitness trackers connected to social networks are designed for smartphones and mHealth technologies. These technologies also are being positioned improve the structure of healthcare delivery, through innovations such as appointment self-scheduling, direct-to-consumer e-consults, and peripheral devices that make home diagnoses commonplace (Topol 2015; Kawano et al. 2012).

Like any foundational change in biomedical informatics, the advent of mHealth creates new paradigms for concepts such as usability and usefulness. Unique characteristics of people (literacy, numeracy, language differences) must be kept in mind and considered, along with the capabilities of people and their living, working, and social environments. Research in user-centered design, usability assessment, failure modes and effects analysis, and other techniques to assure safe and effective use are increasingly critical to advances in mHealth (see ► Chap. 5) (Overdijkink et al. 2018; Matthew-Maich et al. 2016).

Another significant challenge for mHealth is integration into clinical workflows. If healthcare providers are not prescribing mHealth apps or using their data, patients may be less likely to use them if they cannot engage their provider in shared decision making. In other personal health informatics tools, such as patient portals, adoption and promotion of patient portal usage by providers leads to increased usage by patients (Cronin et al. 2015). It will be critical to improve usefulness of the vast amount of data generated by mHealth, aid provider and patients in choosing and using mHealth apps, and determine the appropriate touch points of these interventions between providers and patients, which will enable the potential of mHealth in the future.

### 11.5.6 Social Network Systems

Social network systems, epitomized by Facebook (► [www.facebook.com](http://www.facebook.com)), are online virtual communities where participants describe themselves with member-entered

attributes, establish or break connections to other members, communicate, and share information. This simple strategy creates a virtually unlimited method to connect similar people to one another, and has been shown to be an effective tool to connect people with specific health needs (Moorhead et al. 2013). The for-profit online health-related social networking community Patients Like Me has demonstrated that individuals with a severe chronic disease—amyotrophic lateral sclerosis—are highly willing, even without compensation, to contribute data and observations to a patient community (Frost and Massagli 2008) to accelerate learning about their disease. The site has no ties to the conventional healthcare system and short-circuits the traditional research enterprise, rewarding participants, not just researchers, with knowledge. The patient outcomes of diverse therapies are collected using crowd sourcing, where patients contribute their information to a common database that can be queried to obtain summaries of an aggregated experience of their peers.

Social networking Web sites share most or all of the features of electronic support groups, and even some data commonly provided through a portal (through creating an affiliation with a group who externalizes public or private information). Social networking platforms combined with personal health records provide a means for social network members to share and aggregate data obtained from the traditional health system, and to do so in a private manner (Eysenbach 2008; Weitzman et al. 2011a).

One of the features of health-related online social networks is the rapid dissemination of information across a network; however, there is great variability in the quality of discourse on health-related social networking sites. Conversations may be moderated, in certain cases by a health coach (Jimison et al. 2007). Conversations also may be unmoderated and commercial influences may enter the discourse without transparency. There are also concerns around privacy. Compared with the restrictive institutional consents and compacts with patients that limit use of data and specimens under federal regulations applica-

ble to much federally sponsored research, online social networks are generally governed by no more than a terms of use statement, often subject to change without notice in 30 days. These privacy policies may be difficult to find and not written in language accessible by a population with a broad range of health literacy (Weitzman et al. 2011b). Industry standards governing safety and privacy of online health-related social networking are yet to emerge.

### 11.5.7 Application Example: EHR Portals

As the electronic health record gains acceptance, its relevance to individual people also grows. Many hospitals and clinics have begun providing direct patient access to the clinical record. These portals are defined as person-facing systems tethered to electronic health records, allowing them views of clinical or claims data in institutional electronic health record systems or payer systems (Tang et al. 2006; Kim and Johnson 2002). Portals provide motivated people with a way to electronically access sections of their records to recall salient instructions or obtain results of tests. Some of the first such personal health portals were Columbia's PatCIS system (Cimino et al. 2002) and Beth Israel Deaconess's PatientSite, developed in 1999 (Weingart et al. 2006). Two of the most widely deployed portals are Epic's MyChart (Serrato et al. 2007) and MyHealthVet (Nazi and Woods 2008). Many of these portals provide capabilities besides simply viewing EHR information, such as secure physician-patient messaging, appointment scheduling, providing educational information, and viewing and managing medical bills. One of the more recent additions to this set of capabilities is the OpenNotes effort started by MyHealthVet, which exposes every progress note to patients, instead of exposing only discharge summaries. As new data types are provided to the healthcare system by people in support of their health, we can expect the data types exposed through EHR portals to

change, along with new EHR portal application capabilities.

### 11.5.8 Application Example: Personal Health Records

According to the Markle Foundation, a personal health record (PHR) is "an electronic application through which individuals can access, manage and share their health information, and that of others for whom they are authorized, in a private, secure, and confidential environment" Connecting for Health Personal Health Working Group (2003). Like the EHR portal, the PHR has become the foundation for developing tools to store data and to facilitate its reuse in ways people find engaging.

The idea of a personal repository for medical information is far from new. Families with infants have used an immunization record book for decades. The immunization blue book is a quintessential, efficient system with portable information that supports entry by multiple providers and storage by the patient. Clayton Christensen, who invented the concept of "disruptive innovation," summarizes the widely held promise of this technology in his book, the *Innovator's Prescription: A Disruptive Solution for Health Care* (Christensen et al. 2009). "We cannot overstate how important PHRs are to the efficient functioning of a low-cost, high quality healthcare system." PHRs enable users to acquire copies of their data from every site of care. In some ways, this model advances information flow far more than models requiring inter-institutional data sharing agreements. Data from two competing healthcare networks may reside in the same PHR without cumbersome agreements between those two networks. The patient asserts her claim to the data for each network independently. This model of data aggregation may promote data liquidity far more than competing approaches, such as health information exchanges, which require centralized management of data sharing agreements between networks and institutions (Adler-Milstein et al. 2008).

In part fueled by the knowledge gained during the Robert Wood Johnson Foundation's Project HealthDesign, various companies in the early 2000's developed commercially available personal health records. While some of these remain viable, many from that era were discontinued, largely due to the complex nature of establishing interoperability with external data sources, as well as unsustainable financial models.<sup>5</sup> Recently, however, as data liquidity and standards promoting interoperability have been mandated through Federal legislation, there has been a resurgence of activity to create PHRs from both small start-up companies and large EHR vendors. The future is still uncertain, but this suite of applications continues to be a likely foundation for more sophisticated services and applications used by people in support of their health or illness management (Staccini et al. 2018).

### 11.5.9 Application Example: Sensors for Home Monitoring and Tailored Health Interventions

With rapidly advancing technologies, sensors that measure and monitor are everywhere. We see an increasing population interested in monitoring their activity levels with wrist devices that now measure movement (converted into steps or calories burned), heart rate, and electrodermal activity (for stress level). There are wireless weight scales that are useful for weight management of everyone, and for fluid management of heart failure patients. Even smartphones have a myriad of embedded sensors useful for managing one's health (e.g., GPS for location context, motion for activity level, light and noise level for sleep

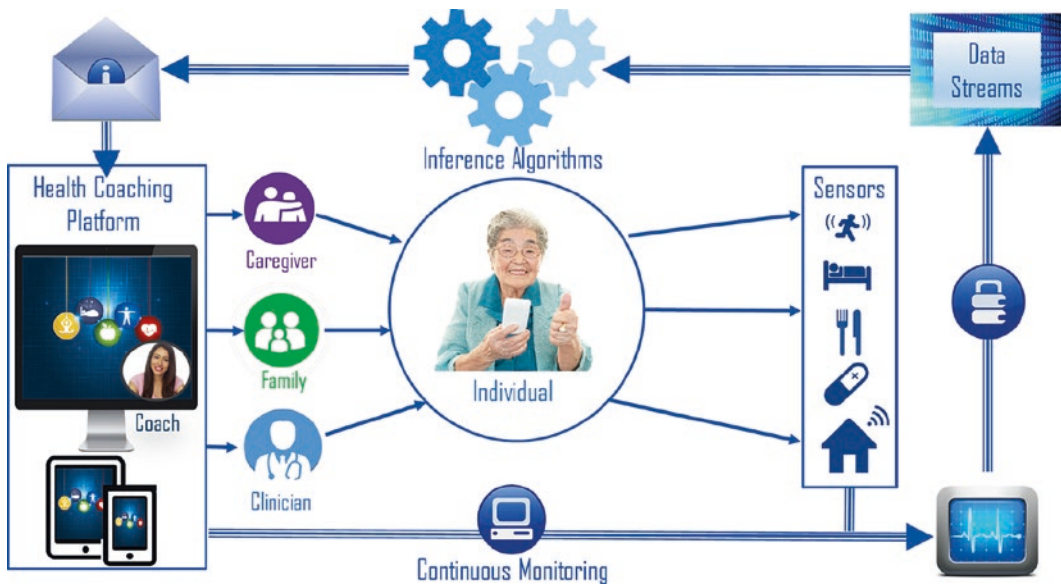

management, and voice statistics for mood management).

In health care there is an increasing need to manage chronic conditions more effectively by empowering patients and family caregivers with more active roles in self management. Sensors in the home and environment (including wearables) provide important input to algorithms that infer patient state and deliver tailored feedback and motivational messaging.

■ Figure 11.4 shows patient-generated sensor data being aggregated in a local device (typically a smartphone) and transferred with strict security protocols to a secure server. The inference algorithms in real time then generate messaging and summary content for the patient, as well as a health coach, clinician, and remote or local family caregiver (Pavel et al. 2015).

For disease management interventions typical sensors include wireless weight scales for fluid management, wireless blood pressure cuffs for cardiac disease, blood glucose meters for patients with diabetes, and peak flow meters for those with asthma. Additionally, many disease management protocols include weight management, physical exercise and medication management. ■ Figure 11.5a–c show examples of sensor technology used in home health settings. Motion sensors, as shown in ■ Fig. 11.5a, can be used to determine real-time patient location for inferring context as well as for measuring walking speed statistics (a useful cognitive indicator) (Hagler et al. 2010). Sleep quality can now be measured with varying accuracy with techniques ranging from accelerometers in wrist fitness trackers to pressure sensitive bed strips placed under the mattress that detect heart rate, heart rate variability (for stress recovery at night), respiration, as well as total sleep time and sleep efficiency. Another more complex approach to sensing in the home involves imaging, as shown with the interactive video exercise in ■ Fig. 11.5c. In this case, data from the Kinect camera is used to detect movement compared to goal state and provide just-in-time feedback to the user (Jimison et al. 2015; Obdrzalek et al. 2012; Ofli et al.

5 Google Official Blog. An update on Google Health and Google PowerMeter. Available at: ► <https://googleblog.blogspot.com/2011/06/update-on-google-health-and-google.html>. Accessed November 9, 2019.

**Fig. 11.4** This diagram shows how sensor data from the home or environment, generated by a patient who may have a chronic condition or an individual with an interest in improving health, can be used as input to a coaching platform to provide tailored motivation and feedback

**Fig. 11.5** This series of images shows examples of sensors and technology used to gain information about an individual’s state and provide tailored just-in-time feedback. **a** shows a motion sensor near the door, sensors on a smart cane, a presence lamp, wireless blood pressure cuff, and an Amazon Echo. **b** shows an individual interacting with a nurse care manager using a remote controlled Double Robot. **c** shows in-home chair exercises with real-time feedback using data from the Kinect camera. (With permission from the Consortium on Technology for Proactive Care at Northeastern University. Photo courtesy of Dr. Holly Jimison)

2016). Inferences on strength, flexibility, balance and endurance can be monitored over time and provided to both the user and clinician. Interactive voice messaging systems (e.g., Amazon Echo or Google Home) have an important role in home health interventions, both as communication devices, but also as sensors of voice affect. Finally, interactions with computers, tablets and smartphones provide valuable information on cognitive performance, both specifically with adaptive cognitive computer games (Hagler et al. 2014; Jimison et al. 2010), but also with indirect

measurements over time of motor speed, search time and cognitive load (Hagler et al. 2011, 2014).

The streaming data from a variety of sensors in the home and environment can be overwhelming from a clinical perspective. **Figure 11.6** shows a sample phone interface for coordinating information from a variety of sensors (Williamson 2015). This example shows a summary main screen for a patient or caregiver with feedback on calendar to-do’s, adherence to goals, medication taking (an issue in taking medications noted

■ **Fig. 11.6** This example shows a main screen for a patient or caregiver summary information. (Reprinted with permission of author, S. Williamson)

by a red “X”), level of socialization, cognitive function, and sleep quality (soft warning noted by an orange “!”). In this case, clicking on an icon opens a screen with further detail. The main goal of sensor-based systems for health is to facilitate health management and adherence to an individual’s health goals using known principles of health behavior change. This type of technology enables a scalable and potentially cost-effective approach to providing continuity of care. It addresses use of an often untapped resource of both patient and family caregiver participation as part of the care team.

## 11.6 Future Opportunities and Challenges

As is exemplified by the previous section, the opportunities for personal health informatics to improve health outcomes are plentiful.

Even worldwide, the access to mobile phones is becoming nearly ubiquitous, and the affordability of health sensors and devices for continuous monitoring and just-in-time intervention is also improving rapidly. However, we also see upcoming challenges in the areas of payment models and equity.

### 11.6.1 Reimbursement and Business Models

Many countries have global budgets for health care, usually managed at a regional level, where it is possible to allocate funds for cost-effective health interventions that personal health technologies may enable. However, medical care reimbursement in the United States is moving slowly towards value-based care. Healthcare systems in the U.S. require incentives and fairly short-term business model demonstrations to modify their workflow and hiring practices for a new model of value-based care. This model of care would bring healthcare consumers and family members as integral members of the care team, facilitated by personal health technologies.

### 11.6.2 Opportunities for Innovation

As health care moves from being clinic-centric and hospital-centric to person-centric and more proactive, there are many opportunities for new advances in personal health informatics to facilitate this change and improve health outcomes. As mentioned earlier in this chapter, advances in the assessment of person state through new always-on sensors and improved computational modeling will allow more tailored and timely messaging and interventions.

Virtual Reality and Augmented Reality are important innovations that can transform the way that individuals, especially older adults, are cared for. Artificial Intelligence innovations that could lead to more tailored messages for a person’s health and wellness could overcome barriers such as remembering to take their medications by targeting cues to improve care. Finally, fusing the information

from sensors could allow for improved assessment of people and their health.

Many of the innovations, however, will need to be social and protocol-based. For example, new workflow and hiring practices will be needed to compensate for the data and information these innovations will create. An increased emphasis on proactive person-centered care to improve outcomes and reduce costs will necessitate better use of community health workers and health behavior change coaches that interface with both the patient and the clinical team. One of the most exciting, though potentially alarming consequences of our extensive use of the Web for shopping, communicating, and learning is that each of us leaves behind a profile of who we are, what we like or dislike, what we know or don't know, and what we want or already have. When combined with data mining and natural language processing techniques, it is possible to create highly targeted and predictive personal knowledge. Data created by consumers, coupled with ubiquitous computing, might provide just-in-time nutritional consults, over the counter medication advice, or advice that might prevent illnesses, such as convenient locations to receive a flu vaccine or when to begin medications for seasonal allergies. We can expect the use of these massive data sets (also called "big data") to impact how medical care is personalized. While the direction that consumer health informatics will take in the future is at best, educated speculation, it is clear that as long as patient-provider partnerships are endorsed, technology will be a third partner in ensuring that activated consumers manage their health and disease effectively.

### Suggested Readings

Berwick, D. M. (2009). What 'patient-centered' should mean: confessions of an extremist. *Health Affairs*, 28(4), w555–ww65. This paper is written by Dr. Donald Berwick, an influential proponent of patient-centered health care and former administrator of the Centers for Medicare and Medicaid Services (CMS). The paper describes a number of maxims of patient-centered care.

Office of the Assistant Secretary for Planning and Evaluation, U.S. Department of Health & Human Services. Conceptualizing a data infrastructure for the capture and use of patient-generated health data. Available at: <https://aspe.hhs.gov/conceptualizing-data-infrastructure-capture-and-use-patient-generated-health-data>. Accessed 1 Nov 2019. This paper describes a project sponsored by the Office of the National Coordinator for Health Information Technology (ONC) regarding a data infrastructure for patients to share their data with caregivers, providers, researchers, and others according to their preferences.

Prey, J. E., Woollen, J., Wilcox, L., Sackeim, A. D., Hripcsak, G., Bakken, S., et al. (2014). Patient engagement in the inpatient setting: A systematic review. *Journal of the American Medical Informatics Association*, 21(4), 742–750. This paper reviews literature involving patient engagement in the hospital setting. The authors identify challenges such as inconsistent use of terminology and gaps in knowledge regarding impact on health outcomes and cost-effectiveness.

Topol, E. J. (2015). *The patient will see you now: The future of medicine is in your hands*. New York: Basic Books. This popular book describes the author's vision for medicine based on patient-centered health care, mobile health, and consumer health informatics.

### Questions for Discussion

1. What is the role of the health system in monitoring the quality of discourse on online social networks?
2. What is the optimal model for personal health records? Should personal health records display advertisements?
3. Which populations of consumers would be most likely to use personal health records?
4. Which consumer technologies do you think will be most influential in consumer-focused health informatics?
5. What is the right balance between privacy of personal health information and ready access to it? For example, for an unconscious patient in the emergency department?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- Why is ethics important to informatics?
- What are the leading ethical issues that arise in health care informatics?
- What are examples of appropriate and inappropriate uses and users for health-related software?
- Why does the establishment of standards touch on ethical issues?
- Why does system evaluation involve ethical issues?
- What challenges does informatics pose for patient and provider confidentiality?
- How can the tension between the obligation to protect confidentiality and that to share data be minimized?
- How might computational health care alter the traditional provider–patient relationship?
- What ethical issues arise at the intersection of informatics and managed care?
- What are the leading ethical and legal issues in the debate over governmental regulation of health care computing tools?

## 12.1 Ethical Issues in Biomedical and Health Informatics

- » More and more the tendency is towards the use of mechanical aids to diagnosis; nevertheless, the five senses of the doctor do still, and must always, play the preponderating part in the examination of the sick patient. Careful observation can never be replaced by the tests of the laboratory. The good physician now or in the future will never be a diagnostic robot. – Scottish surgeon Sir William Arbuthnot-Lane (Lane 1936)

Human values should govern research and practice in the health professions. Health informatics, like other health professions, encompasses issues of appropriate and inappropriate behavior, of honorable and disreputable actions and intentions, of right and wrong. Students and practitioners of the health sciences, including informatics, share

an important obligation to explore the moral underpinnings, ethical challenges and social issues related to their research and practice.

Ethical questions in medicine, nursing, human subjects research, psychology, social work, and affiliated fields continue to evolve and increase in number; nevertheless, the key issues are generally well known. Major questions in general bioethics have long been addressed in numerous professional, scholarly, and educational contexts. Ethical issues in health informatics are, for the most part, less familiar, even though certain of them have received attention for decades (Szolovits and Pauker 1979; Miller et al. 1985a; de Dombal 1987). Indeed, informatics now constitutes a source of some of the most important and interesting ethical debates in all the health professions. It has even been suggested that biomedical informatics raises so many such issues it could itself be used as the basis for a bioethics curriculum (Goodman 2017).

People often assume that the confidentiality of electronically stored patient information is the most important ethical issue in informatics. Although confidentiality and privacy are indeed of vital interest and significant concern, the field is rich with other ethical issues, including the appropriate selection and use of informatics tools in clinical settings; the determination of who should use such tools; the role of system evaluation; the obligations of system developers, maintainers, and vendors; the appropriate standards for interacting with industry; and the use of computers to track clinical outcomes to guide future practice. In addition, informatics engenders many important legal and regulatory questions.

To consider ethical issues in health care informatics is to explore a significant intersection among several professions—health care informatics per se, health care delivery and administration, applied computing and systems engineering, and ethics—each of which constitutes a vast field of inquiry. Fortunately, growing interest in bioethics and computation-related ethics has produced a starting point for such exploration. An initial ensemble of guiding principles, or ethical criteria, has emerged to orient decision making in health care informatics. These criteria are of practi-

cal utility to health informatics, and often have broader implications for all of biomedical informatics.

## 12.2 Health-Informatics Applications: Appropriate Use, Users, and Contexts

Application of computer-based technologies in the health professions can build on previous experience in adopting other devices, tools, and methods. Before clinicians perform most health-related interventions (e.g., diagnostic testing, prescription of medications, surgical and other therapeutic procedures), they generally evaluate appropriate evidence, standards, available technologies, presuppositions, and values. Indeed, the very evolution of the health professions entails the evolution of evidence, of standards, of available technologies, of presuppositions, and of values.

To answer the clinical question, “What should be done in this case?” one must pay attention to a number of subsidiary questions, such as:

1. What is the problem?
2. What resources are available and what am I competent to do?
3. What will maintain or improve this patient’s care?
4. What will otherwise produce the most desirable results (e.g., in public health)?
5. How strong are my beliefs in the accuracy of my answers to questions 1 through 4?

Similar considerations determine the appropriate use of informatics tools.

### 12.2.1 The Standard View of Appropriate Use

Excitement and enthusiasm often accompany initial use of new tools in clinical settings. Negative emotions are also common (Sittig et al. 2005). Based on the uncertainties that surround any new technology, scientific evidence counsels caution and prudence. As in other clinical areas, evidence and reason

determine the appropriate level of caution. For instance, there is considerable evidence that electronic laboratory information systems improve access to clinical data when compared with manual, paper-based test-result distribution methods. To the extent that such systems improve care at an acceptable cost in time and money, there is an obligation to use computers to store and retrieve clinical laboratory results. There is a small but growing body of evidence that existing **clinical expert systems** can improve patient care in a small number of practice environments at an acceptable cost in time and money (Kuperman and Gibson 2003). Nevertheless, such systems cannot yet uniformly improve care in typical, more general practice settings, at least not without careful attention to the full range of managerial as well as technical issues affecting the particular care delivery setting in which they are used (Kaplan and Harris-Salamone 2009; Holroyd-Leduc et al. 2011; Shih et al. 2011).

Clinical expert systems (see ► Chap. 24) attempt to provide decision support for diagnosis, therapy, and/or prognosis in a more detailed and sophisticated manner than do simple reminder systems (Duda and Shortliffe 1983). A necessary adjunction of expert systems – creation and maintenance of their related knowledge bases – still involves leading-edge research and development. Humans for the most part remain superior to electronic systems in understanding patients and their problems, in efficiently interacting with patients to ascertain pertinent past history and current symptoms across the spectrum of clinical practice, in the interpretation and representation of data, and in clinical synthesis. Humans might in the future however not hold the upper hand in these tasks, and claims of their superiority must continually be tested empirically (Blois 1980).

What has been called the “standard view” of computer-assisted clinical diagnosis (Miller 1990a; cf. Friedman 2009) holds in part that human cognitive processes, being more suited to the complex task of diagnosis than machine intelligence, should not be overridden or trumped by computers. The standard view states that when adequate (and even exem-

plary) decision-support tools are developed, they should be viewed and used as supplementary and subservient to human clinical judgment: They *support* decisions by human beings; they do not *make* decisions. Progress should be measured in terms of whether clinicians using a CDS tool perform better on specific tasks than the same clinicians without the tool (Miller 1990a; cf. Friedman 2009). These tools should assume subservient roles because the clinician caring for the patient knows and understands the patient's situation and can make compassionate judgments better than computer programs. Furthermore, clinicians, and not machine algorithms, are the entities which the state licenses, and specialty boards accredit, to practice medicine, surgery, nursing, pharmacy, and other health-related activities.

Corollaries of the standard view are that (1) practitioners have an obligation to use any computer-based tool responsibly, through adequate user training and by developing an understanding of the system's abilities and limitations; and (2) practitioners must not abrogate their clinical judgment reflexively when using computer-based decision aids.

The skills required for diagnosis are in many respects different from those required for the acquisition, storage, and retrieval of laboratory data. There is no contradiction in urging extensive use of efficient, non-burdensome laboratory information systems, and, for the time being, cautious deployment of expert diagnostic decision-support tools (i.e., not permitting their use in settings in which knowledgeable clinicians cannot immediately override faulty advice). Nevertheless, U.S. policy under the HITECH act of 2009 (as discussed in ► Chap. 29), led to widespread adoption of less-than ideal electronic health record systems. In many settings, those systems engendered less efficient, burdensome, error-prone care delivery and physician burn-out (cf. Halamka and Tripathi 2017).

More over, the standard view addresses a key aspect of the question, "How and when should computers be used in clinical practice?" by capturing important moral intuitions about error avoidance and evolving standards. Error avoidance and the benefits that follow

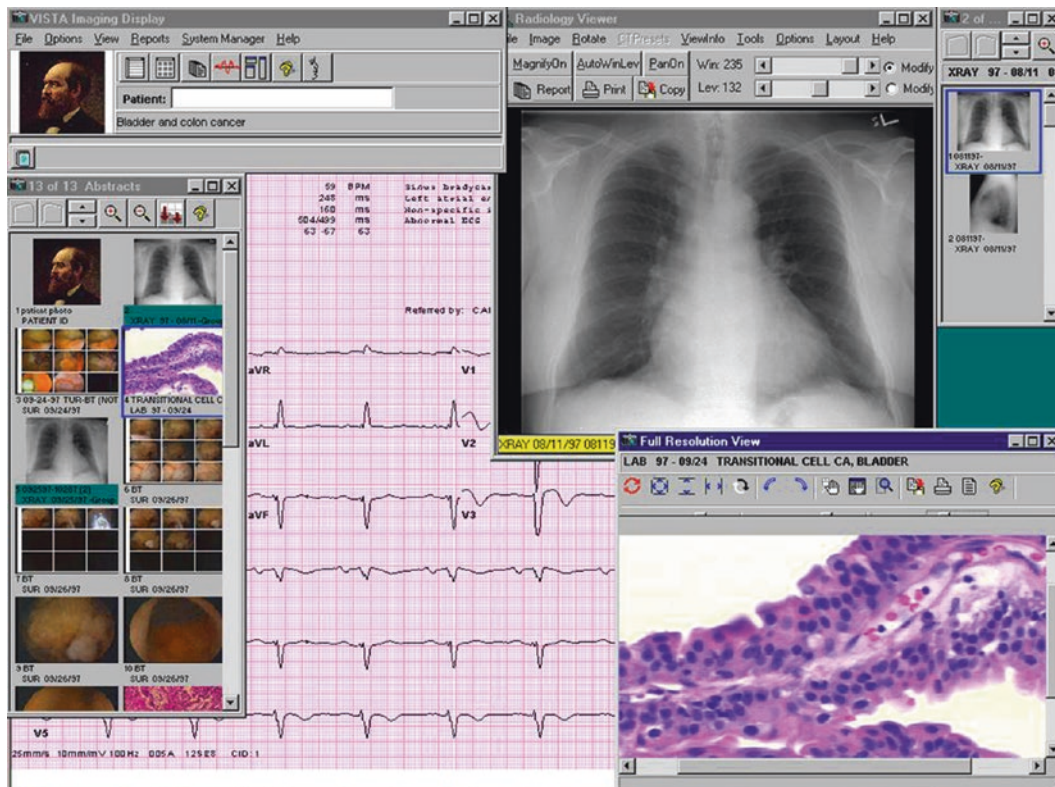

from it shape the obligations of practitioners. In computer-software use, as in all other areas of clinical practice, good intentions alone are insufficient to insulate recklessness from culpability. Thus, the standard view may be seen as a tool for both error avoidance and ethically optimized action.

Ethical software use, then, should be evaluated against a broad background of evidence for actions that produce favorable outcomes. Because informatics is a science in ongoing ferment, system improvements and evidence of such improvements are constantly emerging. Clinicians have an obligation to be familiar with this evidence after attaining minimal acceptable levels of familiarity with informatics in general and with the clinical systems they use in particular (■ Fig. 12.1).

### 12.2.2 Appropriate Users and Educational Standards

Efficient and effective use of health care informatics systems requires prior system evaluations demonstrating utility, education and training of new users, monitoring of experience, and appropriate, timely updating. Indeed, such requirements resemble those for other tools used in health care and in other domains. Inadequate preparation in the use of tools is an invitation to catastrophe. When the stakes are high and the domain large and complex—as is the case in the health professions—education and training take on moral significance.

Who should use a health care-related computer application? Consider expert decision-support systems as an example. An early paper on ethical issues in informatics noted that potential users of such systems include physicians, nurses, physicians' assistants, paramedical personnel, students of the health sciences, patients, and insurance and government evaluators (Miller et al. 1985a). Are members of all these groups appropriate users? One cannot answer the question until one precisely specifies the intended use for the system (i.e., the particular clinical questions the system will address). The appropriate level

**Fig. 12.1** The U.S. Department of Veterans Affairs in the 1970s developed the highly regarded “Veterans Health Information Systems and Technology Architecture” (VistA), once the largest electronic health record system in the United States. This fictitious screen shot

demonstrates some of the system’s functions and utilities. (Credit: Courtesy of U.S. Department of Veterans Affairs, Veterans Health Administration Office of Informatics and Analytics)

12

of training must be correlated with the question at hand. At one end of an appropriate-use spectrum, we can posit that medical and nursing students should employ decision-support systems for educational purposes; this assertion is relatively free of controversy once it has been verified that such tools convey accurately a sufficient quantity and quality of educational content. But it is less clear that patients, administrators, or insurance company gatekeepers, for example, should use expert decision-support systems for assistance in making diagnoses, in selecting therapies, or in evaluating the appropriateness of health professionals’ actions or determining their reimbursement. To the extent that some systems present general medical advice in generally understandable but sufficiently nuanced formats, such as once was the case with Dr.

Benjamin Spock’s 1950s era print-based child-care primer, one might condone system use by laypersons. There are additional legal concerns related to negligence and product liability, however, when health-related products are sold directly to patients rather than to licensed practitioners, and when such products give patient-specific counsel rather than general clinical advice (Miller et al. 1985a).

Suitable use of a software program that helps a user to suggest diagnoses, to select therapies, or to render prognoses must be plotted against an array of goals and best practices for achieving those goals, including consideration of the characteristics and requirements of individual patients. For example, the multiple, interconnected inferential strategies required for arriving at an accurate diagnosis depend on knowledge of facts;

experience with procedures; and familiarity with human behavior, motivation, and values. **Diagnosis** is a process rather than an event (Miller 1990a), so even well-validated diagnostic systems must be used appropriately in the overall context of patient care.

To use a **diagnostic decision-support system** (► Chap. 24), a clinician must be able to recognize when the computer program has erred, and, when it is accurate, what the output means and how it should be interpreted. This ability requires knowledge of both the diagnostic sciences and the software applications, and the strengths and limitations of each. After assigning a diagnostic label, the clinician must communicate the diagnosis, prognosis, and implications to a patient, and must do so in ways both appropriate to the patient's educational background and conducive to future treatment goals. It is not enough to be able to tell patients that they have cancer, human immunodeficiency virus (HIV), diabetes, or heart disease and then simply hand over a prescription. The care provider must also offer context when available, comfort when needed, and hope as appropriate. For instance, the reason many organizations have required counseling both before and after HIV and genetic testing is not to vex busy health professionals but to ensure that comprehensive, high-quality care, rather than mere diagnostic labeling, is delivered.

This discussion points to the following set of ethical principles for appropriate use of decision-support systems:

1. A computer program should be used in clinical practice only after appropriate evaluation of its efficacy and the documentation that it performs its intended task at an acceptable cost in time and money.
2. Users of most clinical systems should be health professionals who are qualified to address the question at hand on the basis of their licensure, clinical training, and experience. Software systems should be used to augment or supplement, rather than to replace or supplant, such individuals' decision making.
3. All uses of informatics tools, especially inpatient care, should be preceded by adequate training and instruction, which should include review of applicable product evaluations.

Such principles and claims should be viewed as analogous to other standards or rules in clinical medicine and nursing.

### 12.2.3 Obligations and Standards for System Developers and Maintainers

Users of clinical programs must rely on the work of other people who are often far removed from the context of use. As with all complex technologies, users depend on the developers and maintainers of a system and must trust evaluators who have validated a system for clinical use. Health care software applications are among the most complex tools in the technological armamentarium. Although this complexity imposes certain obligations on end users, it also commits a system's developers, designers, and maintainers to adhere to reasonable standards and, indeed, to acknowledge their moral responsibility for doing so.

#### 12.2.3.1 Ethics, Standards, and Scientific Progress

The very idea of a **standard of care** embodies a number of complex assumptions linking ethics, evidence, outcomes, and professional training. To say that nurses or physicians must adhere to a standard is to say, in part, that they ought not stray from procedures previously shown or generally believed to work better than alternatives. The difficulty lies in how to determine if a procedure or device "works better" than another. Such determinations in the health sciences constitute progress, and provide evidence that we now know more. Criteria for weighing such evidence, albeit short of proof in most cases, are applied. For example, evidence from well-designed randomized controlled trials merits greater trust than evidence derived from uncontrolled ret-

rospective studies (see ► Chap. 13). Typically, verification by independent investigators must occur before placing the most recent study results into common practice.

People who develop, maintain, and sell health care computing systems and their components have obligations that parallel those of system users. These obligations include holding patient care as the foremost value. The duty to limit or prevent harm to patients applies to system developers as well as to practitioners. Although this principle is easy to suggest and, generally, to defend, it invites subtle, and sometimes overt, resistance from people for whom profit or fame are primary motivators. (This is of course also true for other medical devices, processes and industries.) To be sure, quests for fame and fortune often produce good outcomes and improved care, at least eventually. Even so, some approaches fail to take into account the role of intention as a moral criterion (cf. Goodman et al. 2010).

In medicine, nursing, and psychology, a number of models of the **professional–patient relationship** place trust and advocacy at the apex of a hierarchy of values. Such a stance cannot be maintained if goals and intentions other than patient well-being are (generally) assigned primacy. The same principles apply to those who produce and attend to health care information systems. Because these systems are health care systems—and are not devices for accounting, entertainment, real estate, and so on—and because system underperformance can cause pain, disability, illness, and death, it is essential that the threads of trust run throughout the fabric of clinical system design and maintenance.

System purchasers, users, and patients must rely upon developers and maintainers to recognize the potentially grave consequences of errors or carelessness, trust them to care about the uses to which the systems will be put, and rely upon them to value the reduced suffering of other people at least as much as they value their own personal gain. This reliance emphatically does not entail that system designers and maintainers are blameworthy or unethical if they hope and strive to profit from

their diligence, creativity, and effort. Rather, it implies that no amount of financial benefit for a designer or builder can counterbalance bad outcomes or ill consequences that result from recklessness, avarice, or inattention to the needs of clinicians and their patients. Purchasers and users should require demonstrations that systems are worthy of such trust and reliance before placing patients at risk, and that safeguards (human and mechanical) are in place to detect, alert, and rectify situations in which systems underperform.

Quality standards should stimulate scientific progress and innovation while safeguarding against system error and abuse. These goals might seem incompatible, but they are not. Let us postulate a standard that requires timely updating and testing of knowledge bases that are used by decision-support systems. To the extent that database accuracy is needed to maximize the accuracy of inferential engines, it is trivially clear how such a standard will help to prevent or reduce decision-support mistakes. Furthermore, the standard should be seen to foster progress and innovation in the same way that any insistence on best possible accuracy helps to protect scientists and clinicians from pursuing false leads, or wasting time in testing poorly wrought hypotheses. It will not do for database maintainers to insist that they are busy doing the more productive or scientifically stimulating work of improving knowledge representation, say, or database design. Although such tasks are important, they do not supplant the tasks of updating and testing tools in their current configuration or structure. Put differently, scientific and technical standards are perfectly able to stimulate progress while taking a cautious or even conservative stance toward permissible risk in patient care.

This approach has been described as **progressive caution**: “Medical informatics is, happily, here to stay, but users and society have extensive responsibilities to ensure that we use our tools appropriately. This might cause us to move more deliberately or slowly than some would like” (Goodman 1998).

A more recent concern, with both ethical and legal implications, is the responsibility of software developers to design and implement

software programs that cannot easily be hacked by malicious code writers. This concern goes beyond privacy and confidentiality issues (discussed below), and includes the possibility that medical devices with embedded software might be nefariously “reprogrammed” in a manner that might cause harm to patients (see, for example, Pugh et al. 2018 and Sackner-Bernstein 2017). A more detailed discussion of this topic appears under the ► Sect. 12.5 below.

### 12.2.3.2 System Evaluation as an Ethical Imperative

Any move toward “best practices” in biomedical informatics is shallow and feckless if it does not include a way to measure whether a system performs as intended. This and related measurements provide the ground for quality control and, as such, are the obligations of system developers, maintainers, users, administrators, and perhaps other players (see ► Chap. 13).

» Medical computing is not merely about medicine or computing. It is about the introduction of new tools into environments with established social norms and practices. The effects of computing systems in health care are subject to analysis not only of accuracy and performance but of acceptance by users, of consequences for social and professional interaction, and of the context of use. We suggest that system evaluation can illuminate social and ethical issues in medical computing, and in so doing improve patient care. That being the case, there is an ethical imperative for such evaluation (Anderson and Aydin 1998).

To give a flavor of how a comprehensive evaluation program can ethically optimize implementation and use of an informatics system, consider these ten criteria for system scrutiny (Anderson and Aydin 1994):

1. Does the system work as designed?
2. Is it used as anticipated?
3. Does it produce the desired results?
4. Does it work better than the procedures it replaced?
5. Is it cost effective?

6. How well have individuals been trained to use it?
7. What are the anticipated long-term effects on how organizational units interact?
8. What are the long-term effects on the delivery of medical care?
9. Will the system have an impact on control in the organization?
10. To what extent do effects depend on practice setting?

Another way to make this important point is by emphasizing that *people* use computer systems. Even the finest system might be misused, misunderstood, or mistakenly allowed to alter or erode previously productive human relationships. Evaluation of health information systems in their contexts of use should be taken as a moral imperative. Such evaluations require consideration of a broader conceptualization of “what works best” and must look toward improving the overall health care delivery system rather than only that system’s technologically based components. These higher goals entail the creation of a corresponding mechanism for ensuring institutional oversight and responsibility (Miller and Gardner 1997a, b).

## 12.3 Privacy, Confidentiality, and Data Sharing

Some of the greatest challenges of the Information Age arise from placing computer applications in health care settings while upholding traditional principles and values. One challenge involves balancing two competing values: (1) free access to information, and (2) protection of patients’ privacy and confidentiality.

Only computers can efficiently manage the now-vast amount of information generated during clinical encounters and other health care transactions (see ► Chap. 2); at least in principle, such information should be easily available to health professionals and others involved in the administration of the care-delivery system, so that they can provide effective, efficient care for patients. Yet, making this information readily available creates

greater opportunities for inappropriate access. Such access may be available to curious health care workers who do not need the information to fulfill job-related responsibilities, and, even more worrisome, to other people who might use the information to harm patients physically, emotionally, or financially. Clinical system administrators must balance the goals of protecting confidentiality by restricting use of computer systems and improving care by assuring the integrity and availability of data. These objectives are not incompatible, but there are trade-offs that cannot be avoided.

### 12.3.1 Foundations of Health Privacy and Confidentiality

Privacy and confidentiality are necessary for people to evolve and mature as individuals, to form relationships, and to serve as functioning members of society. Imagine what would happen if the local newspaper or gossip blog produced a daily report detailing everyone's actions, meetings, and conversations. It is not that most people have terrible secrets to hide but rather that the concepts of solitude, intimacy, and the desire to be left alone make no sense without the expectation that at least some of our actions and utterances will be kept private or held in confidence among a limited set of persons.

The “average” sentiment about the appropriate sphere of private vs. public may vary considerably from culture to culture, and even from generation to generation within any particular culture; and it may differ widely among persons within a culture or generation, and evolve for any particular person over a lifetime. Even the “born digital” generation, for which social media are a fixture of everyday life, has – and ought to have – its boundaries (Palfrey and Gasser 2010).

The terms *privacy* and *confidentiality* are not synonymous. As commonly used, “privacy” generally applies to people, including their desire not to suffer eavesdropping, whereas “confidentiality” is best applied to information. One way to think of the difference is as follows. If someone follows you and spies on you entering an AIDS clinic, your

privacy is violated; if someone sneaks into the clinic without observing you in person and looks at your health care record, your record's confidentiality is breached. In discussions of the electronic health record, the term privacy may also refer to individuals' desire to restrict the disclosure of personal data (National Research Council 1997).

There are several important reasons to protect privacy and confidentiality. One is that privacy and confidentiality are widely regarded as rights of all people, and such protections help to accord them respect. On this account, people do not need to provide a justification for limiting access to their identifiable health data; privacy and confidentiality are entitlements that a person does not need to earn, to argue for, or to defend. Another reason is more practical: protecting privacy and confidentiality benefits both individuals and society. Patients who know that their identifiable health care information will not be shared inappropriately are more comfortable disclosing that information to clinicians. This trust is vital for the successful physician–patient, nurse–patient, or psychologist–patient relationship, and it helps practitioners to do their jobs. This insight is as old as the Hippocratic corpus.

Privacy and confidentiality protections also benefit public health. People who fear disclosure of personal information are less likely to seek out professional assistance, increasing the risks that contagion will be spread and maladies will go untreated. In addition, people still suffer discrimination, bias, and stigma when certain health data do fall into the wrong hands. Financial harm may occur if insurers are given unlimited access to family members' records, or access to patient data, because some insurers might be tempted to increase the price of insurance for individuals at higher risk of illness or discriminate in other ways if such price differentiation were forbidden by law. This is, in the United States, among the reasons the Patient Protection and Affordable Care Act of 2010 (U.S. Public Law 111-148), in prohibiting insurers from discrimination based on “pre-existing conditions,” was so important – and why subsequent efforts on ideological grounds to overturn the act are dangerously erosive.

The ancient idea that physicians should hold health care information in confidence is therefore applicable whether the data are written on paper or processed in silicon. The obligations to protect privacy and to keep confidences fall to system designers and maintainers, to administrators, and, ultimately, to the physicians, nurses, and others who elicit the information in the first place. The upshot for all of them is this: protection of privacy and confidentiality is not an option, a favor, or a helping hand offered to patients with embarrassing health problems; it is a duty, regardless of the malady or the medium in which information about it is stored.

Some sound clinical practice and public health traditions run counter to the idea of absolute confidentiality. When a patient is hospitalized, it is expected that all appropriate (and no inappropriate) employees or affiliates of the institution—primary physicians, consultants, nurses, therapists, and technicians—will have access to the patient’s medical records, when it is in the interest of the patient’s care to do so. In most communities of the United States, the contacts of patients who have active tuberculosis or certain sexually transmitted diseases are routinely identified and contacted by public health officials so that the contacts may receive proper medical attention. Such disclosures serve the public interest and are and should be legal because they decrease the likelihood that more widespread harm to other individuals might occur through transmission of an infection unknowingly.

A separate but important public health consideration (discussed in more detail below) involves the ability of health care researchers to anonymously pool data (i.e., pool by removing individual persons’ identifying information) from patient cases that meet specified conditions to determine the natural history of the disease and the effects of various treatments. Examples of benefits from such pooled data analyses range from the ongoing results generated by regional collaborative chemotherapy trials to the discovery, more than four decades ago, of the appropriateness of shorter lengths of stay for patients with myocardial infarction (McNeer et al. 1975). More recently, the need for robust

**syndromic surveillance** has been asserted as necessary for adequate bioterrorism preparedness, for earlier detection of naturally occurring disease outbreaks, and, most dramatically, in the Coronavirus pandemic of 2020 (Ienca and Vayena 2020; see also ► Chap. 18).

### 12.3.2 Electronic Clinical and Research Data

---

Access to electronic patient records holds extraordinary promise for clinicians and for other people who need timely, accurate patient data (see ► Chap. 14). Institutions that do not yet deploy electronic health record systems have fallen behind; this may become blameworthy. Failure to use such systems may also disqualify institutions for reimbursements from public and private insurance, making it effectively an organizational death sentence. Conversely, systems that make it easy for clinicians to access data also make it easier for people in general to access the data, and electronic systems generally magnify number of persons whose information becomes available when a system security breach occurs. Some would consider failure to prevent inappropriate access as at least as blameworthy as failure to provide adequate and appropriate access.

Nonetheless, there is no contradiction between the obligation to maintain a certain standard of care (in this case, regarding minimal levels of computer use) and ensuring that such a technical standard does not imperil the rights of patients. Threats to confidentiality and privacy are fairly well known. They include economic abuses, or discrimination by third-party payers, employers, and others who take advantage of the ever-burgeoning market in health data; insider abuse, or record snooping by hospital or clinic workers who are not directly involved in a patient’s care but examine a record out of curiosity, for instance; identity theft for insurance or other forms of financial fraud; and malevolent hackers, or people who, via networks or other means, copy, delete, or alter confidential information – or threaten to do so, a component of “ransomware” (see, e.g., Sittig and Singh

2016; and Slayton 2018). Moreover, widespread dissemination of information throughout the health care system often occurs without explicit patient consent. Health care providers, third-party payers, managers of pharmaceutical benefits programs, equipment suppliers, and oversight organizations collect large amounts of patient-identifiable health information for use in managing care, conducting quality and utilization reviews, processing claims, combating fraud, and analyzing markets for health products and services (National Research Council 1997).

The proper approach to such challenges is one that will ensure both that appropriate clinicians and other people have rapid, easy access to patient records and that others do not have access. Is that a contradictory burden? No. Is it easy to achieve both? No. There are many ways to restrict inappropriate access to electronic records, but all come with a cost. Sometimes the cost is explicit, as when it comes in the form of additional security software and hardware; sometimes it is implicit, as when procedures are required that increase the time commitment by system users.

A well-established standard way to view the landscape of protective measures is to divide it into technological methods and institutional or policy approaches (Alpert 1998):

### 12.3.2.1 Technological Methods

Computer systems per se can optimize some aspects of security. Typical systems verify that users are who they claim to be (“authenticating”) with passwords, tokens or biometrics. Other controls limit access to people with a professional “need to know.” Creating audit trails, or logs, to record who viewed confidential records enables authorized facility administrators, automated security auditing programs, and patients to later review who accessed what. Encryption can protect data in transit and at rest (in storage). These technical means are complemented by protecting the elements of the electronic infrastructure with physical barriers when operations allow it. Auditing works best when appropriately severe punishments are widely known to be policy, and when policy

breaches are uniformly punished in a semi-public manner.

Technological efforts to improve health system security have emerged as a kind of sub-specialty in health informatics, with system developers, computer scientists and others working to improve confidentiality protections. This often entails both better firewalls against intrusion and software to prevent re-identification of stored data with the individuals to whom the data apply (see, for example, Malin and Goodman 2018).

### 12.3.2.2 Policy Approaches

In its landmark report, the National Research Council (1997) recommended that hospitals and other health care organizations create security and confidentiality committees and establish education and training programs. These recommendations parallel an approach that had worked well elsewhere in hospitals for matters ranging from infection control to bioethics. The U.S. Health Insurance Portability and Accountability Act (HIPAA) requires the appointment of privacy and security officials, special policies, and the training of health care workforce members who have access to health information systems. The European Union’s General Data Protection Regulation (GDPR) requires new accountability and governance measures, standards for access by people to data and information about them, and rules for use of that data and information.

Such measures are all the more important when health data are accessible through networks. The rapid growth of **integrated delivery networks (IDNs)** (see ► Chap. 16) and Health Information Exchanges, for example, illustrate the need not to view health data as a well into which one drops a bucket but rather as an irrigation system that makes its contents available over a broad—sometimes an extremely broad—area. It is not yet clear whether privacy and confidentiality protections that are appropriate in hospitals will be fully effective in a ubiquitously networked environment, but it is a start. System developers, users, and administrators are obliged to identify appropriate measures in light of the particular risks associated with a given imple-

mentation. There is no excuse for failing to make this a top priority throughout the data storage and sharing environment.

### 12.3.2.3 Electronic Data and Human Subjects Research

The use of patient information for **clinical research** and for quality assessment raises interesting ethical challenges. The presumption of a right to confidentiality seems to include the idea that patient records are inextricably linked to patient names or to other identifying data. In an optimal environment, then, patients can monitor who is looking at their records. But if all unique identifiers have been stripped from the records, is there any sense in talking about confidentiality?

The benefits to **public health** loom large in considering record-based research (► Chap. 18). A valuable benefit of the electronic health record is the ability to access vast numbers of patient records to estimate the incidence and prevalence of various maladies, to track the efficacy of clinical interventions, and to plan efficient resource allocation (see ► Chap. 18). Such research and planning would, however, impose onerous or intractable burdens if informed, or valid consent had to be obtained from every patient whose record was represented in the sample. Using confidentiality to impede or forbid such research fails to benefit patients at the same time it sacrifices beneficial scientific investigations.

A more practical course is to establish safeguards that better balance the ethical obligations to privacy and confidentiality against the social goals of public health and systemic efficiency. This balancing can be pursued via a number of paths. The first is to establish mechanisms to **anonymize** the information in individual records or to decouple the data contained in the records from any unique patient identifier. This task is not always straightforward; it can be remarkably difficult to anonymize data such that, when coupled with other data sets, the individuals are not at risk of re-identification. A relatively rare disease diagnosis coupled with demographic data such as age and gender, or geographic data such as a postal code, may act as a surrogate unique identifier; that is, detailed infor-

mation can in combination serve as a data fingerprint that picks out an individual patient even though the patient's name, Social Security number, or other (official) unique identifiers have been removed from the record. Challenges and opportunities related to de-identifying and re-identifying data are among the most interesting, difficult and important in all health computing (Atreya et al. 2013; Benitez and Malin 2010; Malin and Sweeney 2004; Malin et al. 2011; Sweeney 1997; Tamersoy et al. 2012).

Such challenges point to a second means of balancing ethical goals in the context of database research: the use of institutional panels, such as **medical record committees** or **institutional review boards**. Submission of database research to appropriate institutional scrutiny is one way to make the best use of more or less anonymous electronic patient data. Competent panel members should be educated in the research potential of electronic health records, as well as in ethical issues in epidemiology and public health. Scrutiny by such committees can also give appropriate weight to competing ethical concerns in the context of internal research for quality control, outcomes monitoring, and so on (Goodman 1998; Miller and Gardner 1997a, b).

### 12.3.2.4 Challenges in Bioinformatics

Safeguards are increasingly likely to be challenged as genetic information makes its way into the health care record (see ► Chaps. 11 and 28). The risks of bias, discrimination, and social stigma increase dramatically as **genetic data** become available to clinicians and investigators. Indeed, genetic information “goes beyond the ordinary varieties of medical information in its predictive value” (Macklin 1992). Genetic data also may be valuable to people predicting outcomes, allocating resources, and the like. In addition, genetic data are rarely associated with only a single person; they may provide information about relatives, including relatives who do not want to know about their genetic risk factors or potential maladies, as well as relatives who would love dearly to know more about their kin's genome. There is still much work to be

done in sorting out and addressing the ethical issues related to electronic storage, sharing, and retrieval of genetic data (Goodman 1996, 2016a).

**Bioinformatics** or **computational biology** provides an exciting ensemble of new tools to increase our knowledge of genetics, genetic diseases, and public health. Use of these tools is accompanied by responsibilities to attend to the ethical issues raised by new methods, applications, and consequences (Goodman and Cava 2008). Identifying and analyzing these issues are among the key tasks of those who work at the intersection of ethics and health information technology. The future of genetics and genomics is utterly computational, with data storage and analysis posing some of greatest financial and scientific challenges. For instance:

- How, to what extent, and by whom should genomic databases be used for clinical or public health decision support?
- Are special rules needed to govern the study of information in digital genetic repositories (or are current human subjects research protection rules adequate)?
- Does data mining software present new challenges when applied to human genetic information?
- What policies are required to guide and inform the communication of patient-specific and incidental findings?
- Are special protections and precautions needed to address and transmit findings about population subgroups?

It might be that the tools and uses of computational biology will eventually offer ethical challenges—and opportunities—as important, interesting and compelling as any technology in the history of the health sciences. Significantly, this underscores the importance of arguments to the effect that attention to ethics must accompany attention to science. Victories of health science research and development will be undermined by any failures to address corresponding ethical challenges. We must strive to identify, analyze, and resolve or mitigate important ethical issues.

## 12.4 Social Challenges and Ethical Obligations

The expansion of **evidence-based medicine** and, in the United States, of managed care (now sometimes called **accountable care** since the passage of health reform legislation in 2010; see ► Chap. 29) places a high premium on the tools of health informatics. The need for data on clinical outcomes is driven by a number of important social and scientific factors. Perhaps the most important among these factors is the increasing unwillingness of governments and insurers to pay for interventions and therapies that do not work or that do not work well enough to justify their cost.

Health informatics helps clinicians, administrators, third-party payers, governments, researchers, and other parties to collect, store, retrieve, analyze, and scrutinize vast amounts of data—though the task of documenting this is itself a matter of research on what has come to be called “meaningful use.” The functions of health informatics might be undertaken not for the sake of any individual patient but rather for cost analysis and review, quality assessment, scientific research, and so forth. These functions are critical, and if computers can improve their quality or accuracy, then so much the better.

Challenges arise when intelligent applications are mistaken for decision-making surrogates or when institutional or public policy recommends or favors computer output over human cognition. This may be seen as a question or issue arising under the rubric of “appropriate uses and users.” That is, by whom, when, and under what constraints may we elicit and invoke computational analysis in shaping or applying public policy? The question whether an individual physician or multispecialty group, say, should be hired or retained or reimbursed or rewarded is information-intensive. The question that follows, however, is the key one: How should the decision-making skills of human and machine be used, and balanced (cf. Glaser 2010)?

### 12.4.1 Vendor Interactions

Motivated if not inspired by both technological necessity and financial opportunity, humble private practices and sprawling medical centers have—or should have—begun the transition from a paper patient record to an electronic one. The need to make such a transition is not in dispute: paper (and handwriting) are hard to store, find, read and analyze. **Electronic Health Records (EHR)** are not, or should not be. While there are important debates about the speed of the transition and regarding software quality, usability and ability to protect patient safety, it is widely agreed that the recording and storage of health information must be electronic.

Public policy has attempted to overcome some of the reluctance to make the change because of financial concerns. Notably, the U.S. Health Information Technology for Economic and Clinical Health (HITECH) Act, a part of the American Recovery and Reinvestment Act of 2009 (Blumenthal 2010), authorized some \$27 billion in incentives for EHR adoption. These incentives helped address but did not eliminate financial concerns in that they offset only some of the cost of converting to an e-system. Still, while a number of companies had previously found opportunity in developing hospital and other clinical information systems, HITECH accelerated the pace (see ► Chap. 29).

The firms that make and sell EHRs are not regulated in the same way as those that manufacture pharmaceutical products or medical devices (see ► Sect. 12.5.3). In an increasingly competitive environment, this has led to controversy about the nature of vendor interactions with the institutions that buy their products. An EHR system for a mid-sized hospital can cost upwards of \$100 million over time, including consulting services, hardware and training. It follows that it is reasonable to ask what values should guide such vendor interactions with clients, and whether they should be similar to or different from values that govern other free-market dealings.

While many or most contracts between vendors and hospitals are confidential, it has been reported that some HIT vendors require contract language that indemnifies system developers for personal injury claims or malpractice, even if the vendor is at fault; some vendors require system purchasers to agree not to disclose system errors except to the vendor (Koppel and Kreda 2009). Such provisions elicit concern to the extent they place or appear to place corporate interests ahead of patient safety and welfare. In this case, a working group chartered by AMIA, the society for informatics professionals (see ► Chap. 1), issued a report that provided guidance on a number of vendor interaction issues (Goodman et al. 2010). Importantly, the working group comprised industry representatives as well as scientists and other academics. The group's recommendations included these:

- Contracts should not contain language that prevents system users, including clinicians and others, from using their best judgment about what actions are necessary to protect patient safety. This includes freedom to disclose system errors or flaws, whether introduced or caused by the vendor, the client, or a third party. Disclosures made in good faith should not constitute violations of HIT contracts. This recommendation neither entails nor requires the disclosure of trade secrets or of intellectual property.
- Because vendors and their customers share responsibility for patient safety, contract provisions should not attempt to circumvent fault and should recognize that both vendors and purchasers share responsibility for successful implementation. For example, vendors should not be absolved from harm resulting from system defects, poor design or usability, or hard-to-detect errors. Similarly, purchasers should not be absolved from harm resulting from inadequate training and education, inadequate resourcing, customization, or inappropriate use.

While some of the debates that led to those conclusions were about political economy (regulation vs. free enterprise) as much as ethics (right vs. wrong), the opportunity for rapprochement in the service of a patient-centered approach may be seen as an affirmation of the utility of an applied ethics process in the evolution of health information technology.

### 12.4.2 Computational Prognosis

Consider the utility of **prognostic scoring systems** that use physiologic and mortality data to compare new critical-care patients with thousands of previous patients (Knaus et al. 1991). Such systems allow hospitals to track the performance of their critical-care units by, say, comparing the previous year's outcomes to this year's or by comparing one hospital to another. If, for instance, patients with a particular profile tend to survive longer than their predecessors, then it might be inferred that **critical care** has improved. Such scoring systems can be useful for internal research and for quality management (■ Fig. 12.2).

Now suppose that most previous patients with a particular physiologic profile have died in critical-care units; this information might be used to identify ways to improve care of such patients—or it might be used in support of arguments to contain costs by denying care to subsequent patients fitting the profile (since they are likely to die anyway).

An argument in support of such an application might be that decisions to withdraw or withhold care are often and customarily made on the basis of subjective and fragmented evidence; so it is preferable to make such decisions on the basis of objective data of the sort that otherwise underlie sound clinical practice. Such **outcomes data** are precisely what fuels the engines of managed care, wherein health professionals and institutions compete on the basis of cost and outcomes. Why should society, or a managed-care organization, or an insurance company pay for critical care when seemingly objective evidence exists that such care will not be efficacious? Contrarily, consider the effect on future scientific insights of denying care to such patients. Scientific progress is often made by noticing that cer-

12

■ Fig. 12.2 “Severity adjusted daily data” in fictitious APACHE® Outcomes screen shot. Using prognostic scoring systems, clinicians in critical-care units can monitor events and interventions and administrators can manage staffing based on patient acuity. Clinicians can also use such systems to predict mortality, raising a

number of ethical issues. This image shows 10 CCU patients. For the second one in the leftmost column, for instance, the “acute physiology score” is 128; the risk of hospital mortality is 96% and the risk of ICU mortality is 92%. (Credit: Courtesy of Cerner Corporation, with permission)

tain patients do better under certain circumstances, and investigation of such phenomena leads to better treatments. If all patients meeting certain criteria were denied therapy on the basis of a predictive tool, it would become a self-fulfilling prophecy for a much longer time that all such patients would not do well (Miller 1997).

Now consider use of a decision-support system to evaluate, review, or challenge decisions by human clinicians; indeed, imagine an insurance company using a diagnostic expert system to determine whether a physician should be reimbursed for a particular procedure. If the expert system has a track record for accuracy and reliability, and if the system “disagrees” with the human’s diagnosis or treatment plan, then the insurance company can contend that reimbursement for the procedure would be a mistake. Why pay for a procedure that is not indicated, at least according to a computational analysis?

In the two examples just offered (a prognostic scoring system is used to justify termination of treatment to conserve resources, and a diagnostic expert system is used to deny a physician reimbursement for procedures deemed inappropriate), there seems to be justification for adhering to the computer output. There are, however, three reasons why it is problematic to rely exclusively on clinical computer programs to guide policy or practice in these ways:

1. As we argued earlier with the standard view of computational diagnosis (and, by easy extension, prognosis), human cognition is, at least for a while longer, still superior to machine intelligence. Moreover, the act of rendering a diagnosis or prognosis is not merely a statistical or computational operation performed on uninterpreted data. Rather, identifying a malady and predicting its course requires understanding a complex ensemble of causal relations, interactions among a large number of variables, and having a store of salient background knowledge—considerations that have thus far failed to be grasped, assessed, and effectively blended into decisions made by computer programs.
2. Decisions about whether to treat a given patient are often value laden and must be made relative to treatment goals. In other words, it might be that a treatment will improve the quality of life but not extend life, or vice versa (Youngner 1988). Whether such treatment is appropriate cannot be determined scientifically or statistically (Brody 1989). The decisions ultimately depend on human preferences—those of the provider or, even more importantly, the patient.
3. Applying computational operations on aggregate data to individual patients runs the risk of including individuals in groups they resemble but to which they do not actually belong. Of course, human clinicians run this risk all the time—the challenge of inferring correctly that an individual is a member of a set, group, or class is one of the oldest problems in logic and in the philosophy of science. The point is that computers have not solved this problem, yet, and allowing policy to be guided by simple or unanalyzed correlations constitutes a conceptual error.

The idea is not that diagnostic or prognostic computers are always wrong—we know that they are not—but rather there are numerous instances in which we do not know whether they are right. It is one thing to allow aggregate data to guide policy; doing so is just using scientific evidence to maximize good outcomes. But it is altogether different to require that a policy disallow individual **clinical judgment** and expertise.

Informatics can contribute in many ways to health care reform. Indeed, computer-based tools can help to illuminate ways to reduce costs, to optimize clinical outcomes, and to improve care. Scientific research, quality assessment, and the like are, for the most part, no longer possible without computers. But it does not follow that the insights from such research apply in all instances to the myriad variety of actual clinical cases at which competent human clinicians excel.

The Coronavirus crisis of 2020 provided an opportunity to assess and review the use of

prognostic scoring systems to inform or guide triage and rationing. Controversy inherent in resource allocation under conditions of scarcity was magnified when decisions about ventilator allocation, for instance, were made based on a prognostic score rendered by utilities resident in electronic health records (Truog et al. 2020). Although a strong case can be made that such use was permissible during a crisis and in the absence of anything better, an equally strong case must be made that this opportunity to assess and review the use of prognostic scoring systems not be squandered. The *in situ* use of this informatics tool should be scrutinized and studied.

### 12.4.3 Effects of Informatics on Traditional Relationships

Patients are often frightened and vulnerable. Treating illness, easing fear, and respecting vulnerability are among the core obligations of physicians, nurses, and other clinicians. Health informatics has the potential to complement these traditional duties and the relationships that they entail. We have pointed out that medical decisions are shaped by non-scientific considerations. This point is important when we assess the effects of informatics on human relationships. Thus:

- » The practice of medicine or nursing is not exclusively and clearly scientific, statistical, or procedural, and hence is not, so far, computationally tractable. This is not to make a hoary appeal to the “art and science” of medicine; it is to say that the science is in many contexts inadequate or inapplicable: Many clinical decisions are not exclusively medical—they have social, personal, ethical, psychological, financial, familial, legal, and other components; even art might play a role. (Miller and Goodman 1998)

#### 12.4.3.1 Professional–Patient Relationships

If computers, databases, and networks can improve physician–patient or nurse–patient relationships, perhaps by improving communication, then we shall have achieved a happy

result. If reliance on computers impedes the abilities of health professionals to establish trust and to communicate compassionately, however, or further contributes to the dehumanization of patients (Shortliffe 1993, 1994), then we may have paid too dearly for our use of these machines.

Suppose that a physician uses a decision-support system to test a diagnostic hypothesis or to generate differential diagnoses, and suppose further that a decision to order a particular test or treatment is based on that system’s output. A physician who is not able to articulate the proper role of computational support in his decision to treat or test will risk alienating those patients who, for one reason or another, will be disappointed, angered, or confused by the use of computers in their care. To be sure, the physician might just withhold this information from patients, but such deception carries its own threats to trust in the relationship.

Patients are not completely ignorant about the processes that constitute human decision making. What they do understand, however, may be subverted when their doctors and nurses use machines to assist delicate cognitive functions. We must ask whether patients should be told the accuracy rate of decision support automata—when they have yet to be given comparable data for humans. Would such knowledge improve the informed-consent process, or would it “constitute another befuddling ratio that inspires doubt more than it informs rationality?” (Miller and Goodman 1998).

To raise such questions is consistent with promoting the responsible use of computers in clinical practice. The question whether computer use will alienate patients is an empirical one; it is a question for which, despite many initial studies, we lack conclusive data to answer. (For example, we cannot yet state definitively whether all categories of patients will respond well to all specific types of e-mail messages from their doctors. Nevertheless, as a moral principle discussed above, one should not convey a new diagnosis of a malignancy via email.) To address the question now anticipates potential future problems. We must ensure that the exciting

potential of health informatics is not subverted by our forgetting that the practice of medicine, nursing, and allied professions is deeply human and fundamentally intimate and personal.

### 12.4.3.2 Consumer Health Informatics

The growth of the World Wide Web and the commensurate evolution of clinical and health resources on the Internet also raise issues for professional–patient relationships. **Consumer health informatics**—technologies focused on patients as the primary users—makes vast amounts of information available to patients (see ► Chap. 11). There is also, however, misinformation—even outright falsehoods and quackery—posted on some sites. If physicians and nurses have not established relationships based on trust, the erosive potential of apparently authoritative Internet resources can be great. Physicians once accustomed to newspaper-inspired patient requests for drugs and treatments now face ever-increasing demands that are informed by Web browsing. Consequently, the following issues have gained in ethical importance for more than a decade:

- Peer review: How and by whom is the quality of a Web site to be evaluated? Who is responsible for the accuracy of information communicated to patients?
- Online consultations: There is no standard of care yet for online medical consultations. What risks do physicians and nurses run by giving advice to patients whom they have not met or examined in person? This question is especially important in the context of **telemedicine** or **remote-presence health care**, the use of video teleconferencing, image transmission, and other technologies that allow clinicians to evaluate and treat patients in other than face-to-face situations (see ► Chap. 20). Use of telehealth tools became ubiquitous during the Coronavirus pandemic of 2020. This too presents an opportunity to evaluate widespread adoption in context.
- Support groups: Internet support groups can provide succor and advice to the sick,

but there is a chance that someone who might benefit from seeing a physician will not do so because of anecdotes and information otherwise attained. How should this problem be addressed?

That a resource is touted as worthwhile does not make it so. We lack evidence to illuminate the utility of consumer health informatics and its effects on professional–patient relationships. Such resources cannot be ignored given their ubiquity, and they often are useful for improving health. But we insist that here—as with decision support, appropriate use and users, evaluation, and privacy and confidentiality—there is an ethical imperative to proceed with caution. Informatics, like other health technologies, will thrive if our enthusiasm is open to greater evidence and is wed to deep reflection on human values.

### 12.4.3.3 Personal Health Records

At the same time as institutions have moved to computer-based health records systems, the tools available to individuals to keep their own health records have been making a similar transition. Electronic **personal health record** (PHR) systems, whether designed for use on a decoupled storage device or accessible over the Web, are now available from a rapidly expanding set of organizations (see ► Chap. 11) (► Figs. 12.3 and 12.4). Indeed, increasingly many patients access aspects of their health and medical records through “portals” established by EHR vendors.

PHRs provide a storage base for data once kept on paper (or in the patient’s head) and repeatedly extracted with each institutional encounter for inclusion in that entity’s records system, typically:

- Allergies, current medications
- Current health status and major health issues (if any)
- Major past health episodes and the condition of oneself and (sometimes) relatives
- Vaccinations, surgeries and other treatments

All these data can be kept on something simple (and un-networked) like a flash drive. It is

becoming more common to store the data on a Web site, where PHR data can also be linked to other health information relevant to the person. The PHR data can also be linked via a portal to a health care provider institution's records, to allow updating in both directions, or be free of any such tie. A flash drive can be forgotten or lost, whereas a Web site can be centrally updated and uniformly available via any properly authenticated device on the Internet.

**Fig. 12.3** Project HealthDesign (Brennan et al. 2010) was a landmark program sponsored by the Robert Wood Johnson Foundation's Pioneer Portfolio and intended to foster development of personal health records. Here is a barcode scanner that recognizes medication labels. Designed by researchers at the University of Colorado at Denver, the "Colorado Care Tablet" allows elderly users to track prescriptions with such scanners and portable touch-screen tablets. (Credit: Courtesy of Project HealthDesign; Creative Commons Attribution 3.0 Unported License)

Traditional insurers and health care providers are duty-bound by privacy laws and regulations to protect the information under their control. PHRs have a somewhat shakier set of protections given their relatively short history. The legal obligations of institutions that provide PHRs, but do not fully manage the content of those records nor their use, as well as the obligations (if any) of the individuals who "manage" their own health records, remain to be resolved (Cushman et al. 2010).

PHRs are now commonly linked to so-called "personal health applications" (PHAs) which provide ways of moving beyond simple static storage of one's medical history. Most provide some sort of primitive decision support, if only in linking to additional information about a particular disease or condition. Others include more ambitious decision-support functionality. All the concerns about the accuracy of Web-based information recur in this context, with concerns about the reliability of decision support added to that. Compounding concerns about accuracy are the inherent limitations of the "owner-operator": If it can be difficult for trained health care providers to evaluate the quality of advice rendered by a decision support system, the challenges for patients will be commensurately greater.

Traditional health care institutions may see the PHR as a device for patient empowerment because it adds a way for persons to keep track of their own data; but they can also be

**Fig. 12.4** A portable blood glucose communicator is part of the personal health record system developed by the T.R.U.E. Research Foundation of Washington, DC. The diabetes management application analyzes, summarizes, displays and makes individualized recommendations on nutritional data, physical activity data, prescribed medications, continuous blood glucose data, and self-reported emotional state. (Credit: Courtesy of Project HealthDesign; Creative Commons Attribution 3.0 Unported License)

used as a way of preserving “loyalty” to a particular institution in the health care system. It has been proposed that PHRs be subject to standards allowing “interoperability”—in this case, easy movement from one type of PHR to another—to prevent leveraging it as an impediment to patients’ movements when they wish to change providers or other preferences change. Whether such standards will evolve enough to make it easy to move from one PHR to another remains to be seen, given economic incentives to impede patient movement (just in case a patient is financially desirable because of insurance status or personal wealth).

Whether PHRs will reach the majority of patients is uncertain. For persons who must chronically manage complex treatment regimens for themselves or for dependents, PHRs and their associated applications may be compelling. Persons who deal with less complex or transient conditions may prefer to leave records management to their providers. In the context of health care, PHRs have the potential to replicate the “digital divide,” exacerbating rather than reducing health disparities. Persons with higher levels of income and education may differentially benefit from PHRs by more readily making fuller use of them. In the absence of robust policy protections, some minors may be reluctant to use PHRs as long as parents or guardians retain access.

## 12.5 Legal and Regulatory Matters

The use of clinical computing systems in health care raises a number of interesting and important legal and regulatory questions.

### 12.5.1 Difference Between Law and Ethics

Ethical and legal issues often overlap. Ethical considerations apply in attempts to determine what is good or meritorious and which behaviors are desirable or correct in accordance with higher principles. Legal principles are generally derived from ethical ones but deal

with the practical regulation of morality or behaviors and activities. Many legal principles deal with the inadequacies and imperfections in human nature and the less-than-ideal behaviors of individuals or groups. Ethics offers conceptual tools to evaluate and guide moral decision making. Laws directly tell us how to behave (or not to behave) under various specific circumstances and prescribe remedies or punishments for individuals who do not comply with the law. Historical precedent, matters of definition, issues related to detectability and enforceability, and evolution of new circumstances affect legal practices more than they influence ethical requirements.

### 12.5.2 Legal Issues in Biomedical Informatics

Prominent legal issues related to the use of software applications in clinical practice and in biomedical research include liability under tort law; potential use of computer applications as expert witnesses in the courtroom; legislation governing privacy and confidentiality; and copyrights, patents, and intellectual property issues.

#### 12.5.2.1 Liability Under Tort Law

In the United States and in many other nations, principles of tort law govern situations in which harm or injuries result from the manufacture and sale of goods and services (Miller et al. 1985a). Because there are few, if any, U.S. legal precedents directly involving harm or injury to patients resulting from use of clinical software applications (as opposed to a small number of well-documented instances where software associated with medical devices has caused harm), the following discussion is hypothetical. The principles involved are, however, well established with voluminous legal precedents outside the realm of clinical software.

A key legal distinction is the difference between products and services. **Products** are physical objects, such as stethoscopes, that go through the processes of design, manufacture, distribution, sale, and subsequent use by pur-

chasers. **Services** are intangible activities provided to consumers at a price by (presumably) qualified individuals.

The practice of clinical medicine has been deemed a service through well-established legal precedents. On the other hand, clinical software applications can be viewed as either goods (“products”) (software programs designed, tested, debugged, placed on DVDs or other media, and distributed physically to purchasers) or services (applications that present data or provide advice to practitioners engaged in a service such as delivering health care). There are few legal precedents to determine unequivocally how software will be viewed by the courts, and it is possible that clinical software programs will be treated as goods under some circumstances and as services under others. It might be the case that that software purchased and running in a private office to handle patient records or billing would be deemed a product, but the same software mounted on shared, centralized computers and accessed over the Internet (and billed on a monthly basis) would be offering a service.

Three ideas from tort law potentially apply to the clinical use of software systems:

(1) **Harm by intention**—when a person injures another using a product or service to cause the damage, (2) the **negligence theory**, and (3) **strict product liability** (Miller et al. 1985a). Providers of goods and services are expected to uphold the standards of the community in producing goods and delivering services. When individuals suffer harm due to substandard goods or services, they may sue the service providers or goods manufacturers to recover damages. **Malpractice** litigation in health care is based on negligence theory.

Because the law views delivery of health care as a service (provided by clinicians), it is clear that negligence theory will provide the minimum legal standard for clinicians who use software during the delivery of care. Patients who are harmed by clinical practices based on imperfect software applications may sue the health care providers for negligence or malpractice, just as patients may sue attending physicians who rely on the imperfect advice of a human consultant (Miller et al.

1985a). Similarly, a patient might sue a practitioner who has not used a decision-support system when it can be shown that use of the decision-support system is part of the current standard of care, and that use of the program might have prevented the clinical error that occurred (Miller 1989). It is not clear whether the patients in such circumstances could also successfully sue the software manufacturers, as it is the responsibility of the licensed practitioner, and not of the software vendor, to uphold the standard of care in the community through exercising sound clinical judgment. Based on a successful malpractice suit against a clinician who used a clinical software system, it might be possible for the practitioner to sue the manufacturer or vendor for negligence in manufacturing a defective clinical software product, but cases of this sort have not yet been filed. If there were such suits, it might be difficult for a court to discriminate between instances of improper use of a blameless system and proper use of a less-than-perfect system.

In contrast to negligence, strict product liability applies only to harm caused by defective products and is not applicable to services. The primary purpose of strict product liability is to compensate the injured parties rather than to deter or punish negligent individuals (Miller et al. 1985a). For strict product liability to apply, three conditions must be met:

1. The product must be purchased and used by an individual.
2. The purchaser must suffer physical harm as a result of a design or manufacturing defect in the product.
3. The product must be shown in court to be “unreasonably dangerous” in a manner that is the demonstrable cause of the purchaser’s injury.

Note that negligence theory allows for adverse outcomes. Even when care is delivered in a competent, caring, and compassionate manner, some patients with some illnesses will not do well. Negligence theory protects providers from being held responsible for all individuals who suffer bad outcomes. As long as the quality of care has met the prevailing standards, a practitioner should not be found liable in a

malpractice case (Miller et al. 1985a). Strict product liability, on the other hand, is not as forgiving or understanding.

No matter how good or exemplary a manufacturer's designs and manufacturing processes might be, if even one in ten million products is defective, and that one product defect is the cause of a purchaser's injury, then the purchaser may collect damages (Miller et al. 1985a). The plaintiff needs to show only that the product was unreasonably dangerous and that its defect led to harm. In that sense, the standard of care for strict product liability is 100-percent perfection. To some extent, appropriate product labeling (e.g., "Do not use this metal ladder near electrical wiring") may protect manufacturers in certain strict product liability suits in that clear, visible labeling may educate the purchaser to avoid "unreasonably dangerous" circumstances. Appropriate labeling standards may similarly benefit users and manufacturers of clinical expert systems (Geissbuhler and Miller 1997).

Health care software programs sold to clinicians who use them as decision-support tools in their practices are likely to be treated under negligence theory as services. When advice-giving clinical programs are sold directly to patients, however, and there is less opportunity for intervention by a licensed practitioner, it is more likely that the courts will treat them as products, using strict product liability, because the purchaser of the program is more likely to be the individual who is injured if the product is defective. (As personal health records become more common, this legal theory may well be tested.)

A growing number of software "bugs" in medical devices have been reported to cause injury to patients (Majchrowski 2010; Levis 2014). The U.S. Food and Drug Administration (FDA) has traditionally viewed software embedded within medical devices, such as cardiac pacemakers and implantable insulin pumps, as part of the physical device, and so regulates such software as part of the device (FDA 2011). The courts are likely to view such software using principles of strict product liability (Miller and Miller 2007). Most recently, the FDA has contemplated wider regulatory scope (see ► Sect. 12.5.3).

Corresponding to potential strict product liability for faulty software embedded in medical devices is potential negligence liability if such software can easily be "hacked" (Robertson 2011). Malicious code writers might mimic external software-based "radio" controllers for pacemakers and insulin pumps and reprogram them to cause harm to patients. While such "hackers" should face criminal prosecution if they cause harm by intention, the device manufacturers have a responsibility to make it difficult to change the software code embedded in devices without proper authorization.

### 12.5.2.2 Privacy and Confidentiality

The ethical basis for privacy and confidentiality in health care is discussed in ► Sect. 12.3.1. For a long time, the legal state of affairs for privacy and confidentiality of electronic health records was chaotic (as it remains for written records, to some extent). This state of affairs in the U.S. had not significantly changed in the three decades since it was described in a classic *New England Journal of Medicine* article (Curran et al. 1969).

However, a key U.S. law, the Health Insurance Portability and Accountability Act (HIPAA), has prompted significant change. HIPAA's privacy standards became effective in 2003 for most health care entities, and its security standards followed 2 years later; a breach-notification rule was expanded in 2010 and HITECH provisions were incorporated in 2013. A major impetus for the law was that the process of "administrative simplification" via electronic recordkeeping, prized for its potential to increase efficiency and reduce costs, would also pose threats to patient privacy and confidentiality. Coming against a backdrop of a variety of noteworthy cases in which patient data were improperly—and often embarrassingly—disclosed, the law was also seen as a badly needed tool to restore confidence in the ability of health professionals to protect confidentiality. While the law has been accompanied by debate both on the adequacy of its measures and the question whether compliance was unnecessarily burdensome, it nevertheless established the first nationwide health privacy protections. At its

core, HIPAA embodies the idea that individuals should have access to their own health data, and more control over uses and disclosures of that health data by others. Among its provisions, the law requires that patients be informed about their privacy rights, including a right of access; that uses and disclosures of “protected health information” generally be limited to exchanges of the “minimum necessary”; that uses and disclosures for other than treatment, payment and health care operations be subject to patient authorization; and that all employees in “covered entities” (institutions that HIPAA legally affects) be educated about privacy and information security.

As noted above, the HITECH Act provided substantial encouragement for Electronic Health Record (EHR) development, particularly the encouragement of billions of dollars in federal subsidies for “meaningful use” of EHRs. However, HITECH also contained many changes to HIPAA privacy and security requirements, strengthening the regulations that affect the collection, use and disclosure of health information not only by covered entities, but also the “business associates” (contractors) of those covered entities, and other types of organizations engaged in health information exchange.

The Office of Civil Rights in the U.S. Department of Health and Human Services remains the entity primarily charged with HIPAA enforcement, but there is now a role for states’ attorneys general as well as other agencies such as the Federal Trade Commission. HITECH increases penalty levels under HIPAA and includes a mandate for investigations and periodic audits, shifting the enforcement balance away from voluntary compliance and remediation plans.

HITECH’s changes to HIPAA, those from other federal laws such as the Genetic Information Nondiscrimination Act of 2008 (GINA) and the Patient Safety and Quality Improvement Act of 2005, and the new attention to information privacy and security in most states’ laws, comprise significant changes to the legal-regulatory landscape for health information.

### 12.5.2.3 Copyright, Patents, and Intellectual Property

**Intellectual property** protection afforded to developers of software programs, biomedical knowledge bases, and World Wide Web pages remains an underdeveloped area of law. Although there are long traditions of copyright and patent protections for non-electronic media, their applicability to computer-based resources is not clear. **Copyright law** protects intellectual property from being copied verbatim, and **patents** protect specific methods of implementing or instantiating ideas. The number of lawsuits in which one company claimed that another copied the functionality of its copyrighted program (i.e., its “look and feel”) has grown, however, and it is clear that copyright law does not protect the “look and feel” of a program beyond certain limits. Consider, for example, the unsuccessful suit in the 1980s by Apple Computer, Inc., against Microsoft, Inc., over the “look and feel” of Microsoft Windows as compared with the Apple Macintosh interface (which itself resembled the earlier Xerox Alto interface).

It is not straightforward to obtain copyright protection for a list that is a compilation of existing names, data, facts, or objects (e.g., the telephone directory of a city), unless you can argue that the result of compiling the compendium creates a unique object (e.g., a new organizational scheme for the information) (Tysyer 1997). Even when the compilation is unique and copyrightable, the individual components, such as facts in a database, might not be copyrightable. That they are not copyrightable has implications for the ability of creators of biomedical databases to protect database content as intellectual property. How many individual, unprotected facts can someone copy from a copyright-protected database before legal protections prevent additional copying?

A related concern is the intellectual-property rights of the developers of materials made available through the World Wide Web. Usually, information made accessible to the public that does not contain copyright annotations is considered to be in the public domain. It is tempting to build from the work

of other people in placing material on the Web, but copyright protections must be respected. Similarly, if you develop potentially copyrightable material, the act of placing it on the Web, in the public domain, would allow other people to treat your material as not protected by copyright. Resolution of this and related questions may await workable commercial models for electronic publication on the World Wide Web, whereby authors could be compensated fairly when other people use or access their materials. Electronic commerce might eventually provide copyright protection (and perhaps revenue) similar to age-old models that now apply to paper-based print media; for instance, to use printed books and journals, you must generally borrow them from a library, purchase them or access them under Creative Commons or similar open-access platforms.

### 12.5.3 Regulation and Monitoring of Computer Applications in Health Care

In the mid-1990s, the U.S. Food and Drug Administration (FDA) held public meetings to discuss new methods and approaches to regulating clinical software systems as medical devices. In response, a consortium of professional organizations related to health care information (AMIA, the Center for Health Care Information Management, the Computer-Based Patient Record Institute, the American Health Information Management Association, the Medical Library Association, the Association of Academic Health Science Libraries, and the American Nurses Association) drafted a position paper published in both summary format and as a longer discussion with detailed background and explanation (Miller and Gardner 1997a, b). The position paper was subsequently endorsed by the boards of directors of all the organizations (except the Center for Health Care Information Management) and by the American College of Physicians Board of Regents.

The consortium recommended the following:

- Recognition of four categories of clinical system risks and four classes of monitoring and regulatory actions that can be applied based on the level of risk in a given setting.
- Local oversight of clinical software systems, whenever possible, through the creation of autonomous **software oversight committees**, in a manner partially analogous to the institutional review boards that are federally mandated to oversee protection of human subjects in biomedical research. Experience with prototypical software-oversight committees at pilot sites should be gained before any national dissemination.
- Adoption by health care-information system developers of a code of good business practices.
- Recognition that budgetary, logistic, and other constraints limit the type and number of systems that the FDA can regulate effectively.
- Concentration of FDA regulation on those systems posing highest clinical risk, with limited opportunities for competent human intervention, and FDA exemption of most other clinical software systems.

The recommendations for combined local and FDA monitoring are summarized in [Table 12.1](#). We do not yet know whether improved outcomes would occur if vendors were to give qualified (i.e., informatics-capable) institutional purchasers greater local control over system functionality.

Section 618 of the 2012 Food and Drug Administration Safety and Innovation Act (FDASIA), Public Law 112-144, mandated a new generation of oversight guidelines for clinical software. Pursuant to the legislation, the FDA, the Office of the National Coordinator for Health Information Technology, and the Federal Communications Commission held public hearings and conducted workshops. The ensuing April 2014 FDASIA Health IT report (FDASIA 2014)

**Table 12.1** Consortium recommendations for monitoring and regulating clinical software systems

Variable	Regulatory class			
	A	B	C	D
Supervision by FDA	Exempt from regulation	Excluded from regulation	Simple registration and postmarket surveillance required	Premarket approval and postmarket surveillance required
Local software oversight committee	Optional	Mandatory	Mandatory	Mandatory
Role of software oversight committee	Monitor locally	Monitor locally instead of monitoring by FDA	Monitor locally and report problems to FDA as appropriate	Assure adequate local monitoring without replicating FDA activity
Software risk category				
0: Informational or generic systems <sup>a</sup>	All software in category	–	–	–
1: Patient-specific systems that provide low-risk assistance with clinical problems <sup>b</sup>	–	All software in category	–	–
2: Patient-specific systems that provide intermediate-risk support on clinical problems <sup>c</sup>	–	Locally developed or locally modified systems	Commercially developed systems that are not modified locally	–
3: High-risk, patient-specific systems <sup>d</sup>	–	Locally developed, non commercial systems	–	Commercial systems

Reproduced with permission from Author(s). Miller and Gardner (1997a). ©American College of Physicians  
<sup>a</sup>Includes systems that provide factual content or simple, generic advice (such as “give flu vaccine to eligible patients in mid-autumn”) and generic programs, such as spreadsheets and databases  
<sup>b</sup>Systems that give simple advice (such as suggesting alternative diagnoses or therapies without stating preferences) and give ample opportunity for users to ignore or override suggestions  
<sup>c</sup>Systems that have higher clinical risk (such as those that generate diagnoses or therapies ranked by score) but allow users to ignore or override suggestions easily; net risk is therefore intermediate  
<sup>d</sup>Systems that have great clinical risk and give users little or no opportunity to intervene (such as a closed-loop system that automatically regulates ventilator settings)

12

met Congress’ requirements to propose “strategy and recommendations on an appropriate, risk-based regulatory framework pertaining to health-information technology, including mobile medical applications, that promotes innovation, protects patient safety, and avoids regulatory duplication.” The Report implemented many recommendations from the National Academy of Medicine’s 2012 report, “Health IT and Patient Safety: Building Safer Systems for Better Care” (IOM 2012a).

The FDASIA Health IT Report specified three categories of risk based on system functionality, rather than software product category or on implementation platform (FDASIA 2014). The functionality categories are:

1. Administrative health IT functions. Non-exhaustive examples given in the Report include billing and claims processing, inventory management, and scheduling. The FDASIA Report categorizes those

functions posing little or no risk to the patient, and exempt from additional oversight.

2. Health management IT functions. Non-exhaustive examples cited in the Report include encounter documentation, electronic access to clinical results, non-device-related clinical decision support, medication management, provider order entry, knowledge management, and electronic communication, including health information exchange. The FDASIA Report asserts that the actual safety risks posed by this category are for the most part outweighed by their potential benefits, and require limited national-level oversight. Whereas the FDA previously played a major regulatory and monitoring role for applications with this category of functionality, the FDASIA Report transfers responsibility for such oversight to a collaboration between ONC and commercial vendors.
3. Medical device health IT functions. Non-exhaustive examples listed in the Report include computer-assisted detection software, notification of real-time alarms from bedside monitors, and robotic surgery systems. The FDA will maintain oversight responsibility for device-related clinical software.

A given application or product may involve more than one of the functionality categories.

In concordance with the National Academy of Medicine 2012 recommendations (IOM 2012a), the FDASIA Report also created a public-private Health IT Safety Center, to be coordinated by ONC. It will promote innovations regarding patient safety and identify interventions to improve safety, including education about best practices.

#### 12.5.4 Software Certification and Accreditation

If, as above, (1) there is an ethical obligation to evaluate health information systems in the contexts in which they are being used, and if,

as we just saw, (2) there are good reasons to consider the adoption of software oversight committees or something similar, then it is worthwhile to consider the ethical utility of efforts to review and endorse medical software and systems.

Established in 2004, the Certification Commission for Health Information Technology, in collaboration with the Office of the National Coordinator for health information technology, assesses electronic health records according to an array of criteria, in part to determine their success in contributing to “meaningful use.” These criteria address matters ranging from electronic provider order entry and electronic problem lists to decision support and access control (cf. Classen et al. 2007; Wright et al. 2009). The criteria, tests and test methods are developed in concert with the National Institute of Standards and Technology. Practices and institutions that want to receive government incentive payments must adopt certified electronic health record technologies.

Conceived under the American Recovery and Reinvestment Act, these processes aim to improve outcomes, safety and privacy. Whether they can accomplish this—as opposed to celebrate technology for its own sake—is an excellent source of debate (Hartzband and Groopman 2008). What should be uncontroversial is that any system of regulation, review or certification must be based on and, as a matter of process emphasize, certain values. These might include, among others, patient-centeredness, ethically optimized data management practices, and what we have here commended as the “standard view,” that is, human beings and not machines practice medicine, nursing and psychology.

The move to certification has unfortunately engendered precious little in the way of ethical analysis, however. To make any system of regulation, review or certification ethically credible, government and industry leaders must eventually make explicit that attention to ethics is a core component of their efforts.

An ethical approach to certification of clinical applications should entail “in vivo”

(on the front lines of clinical care) as well as “in vitro” (laboratory-based) testing (IOM 2012a). As stated in ► Sect. 12.2.2, “A computer program should be used in clinical practice only after appropriate evaluation of its efficacy and the documentation that it performs its intended task at an acceptable cost in time and money.” Federal and other certification programs currently address, in vitro, whether certain pre-specified technical capabilities exist within a software application. They do not, however, determine whether a given software package will be usable at an affordable cost in time and money in vivo, post-installation.

Almost all vendors’ comprehensive, institutional-level clinical information systems now pass the minimal federal certification standards. Those certification standards test algorithmic functionality while neglecting to assess real-world clinical impacts post-installation. The 2012 National Academy of Medicine report on Health IT and Patient Safety noted, “poor usability ... is one of the single greatest threats to patient safety. ... Evaluation of the impact of health IT on usability and on cognitive workload is important to determine unintended consequences and the potential for distraction, delays in care, and increased workload in general. Usability guidelines and principles focused on improving safety need to be put into practice” (IOM 2012a, p. 81). The certification standards also do not fully evaluate the accuracy or completeness of systems’ underlying information/knowledge bases. Nor do they evaluate information/knowledge base accuracy and maintainability over time.

Many institutional-level systems are so expensive that they financially cripple the medical centers and clinicians’ offices that adopt them. Many sites experience substantial decreases in post-installation revenue (usually transient, lasting several months, but sometimes persistent). System-induced disruptions of workflows diminish the number of patients who can be seen, and impair (at least temporarily) charge capture for billable services. The FDASIA Report minimizing decision support oversight fits better with past implementations, when academic system

developers could directly and efficiently address local problems of system functionality. Present-day commercial systems are inflexible, opaque, and maintained by vendors from a distance. The high sticker price of such systems guarantees that, once purchased, institutions cannot afford to de-install and replace problematic systems. Government mandates to install such expensive, disruptive “certified” software systems appear to some as unethical. The certification process should be expanded to evaluate the pragmatic, local, post-installation aspects of system function “at an acceptable cost in time and money.”

The diminished patient-care workflows engendered by cumbersome clinical software systems potentially increase the time and money costs of delivering quality healthcare – costs borne by patients, third-party payors, and the government. Clinicians often pay a higher price – beyond lost revenues. In their 2017 commentary, “The HITECH Era in Retrospect,” Halamka and Tripathi stated, “we lost the hearts and minds of clinicians. ... We expected interoperability without first building the enabling tools. In a sense, we gave clinicians suboptimal cars, didn’t build roads, and then blamed them for not driving” (Halamka and Tripathi 2017). Vergese, Shah, and Harrington, in a 2018 *JAMA* Viewpoint, added: “The nationwide implementation of electronic medical records (EMRs) resulted in many unanticipated consequences ... the redundancy of the notes, the burden of alerts, and the overflowing inbox has contributed to ... physician reports of symptoms of burnout. ... Most EMRs serve their front-line users quite poorly” (Vergese et al. 2018).

Installation of vendors’ massive, complex, institutional clinical software products creates additional ethical dilemmas. Post-installation, clinicians lack a clear or deep understanding of how system functions affect their patients’ care and safety. Institutions no longer possess the level of control/autonomy to change their systems locally, as they did decades ago when many academic medical centers had home-grown systems that they could manage and “evolve” at will. Prior to the advent of such large, complex clinical systems, clinicians directly responsible for a patient’s care

personally knew and supervised all important, relevant decision-making. By contrast, after system installation, clinicians must obtain substantial system-related technical training and expertise to be able to access or alter the clinical knowledge underlying a vendor system's patient-specific recommendations.

Even more opaque are the hidden mechanisms for how specific knowledge is brought to bear during clinical decision support. For example, a system might have a "patient is pregnant" indicator. That indicator may trigger warnings when someone orders medications contra-indicated in pregnancy, or when physicians order radiological studies deemed unsafe for the condition. The ethical issue is that most vendor systems obscure the basis for how the "patient is pregnant" flag is set locally. For example, Hospital A might use the nurse's admission intake interview form to set the pregnancy flag. The underlying information gathered by the nurse in such a setting might be the patient's response to the question "Are you pregnant now?" The latter is inadequate for patient safety. Hospital B might use the result of a patient's beta-HCG test to set the pregnancy flag. While a more reliable indicator of pregnancy than hearsay from the patient, the beta-HCG test may not be ordered by every clinician in all relevant circumstances; hence, that mechanism may also be imperfect for decision support. A physician practicing at both Hospital A and Hospital B would be unlikely to know that the flags have different meanings at each site. Yet all the clinician can see is the status of the flag.

This ethical problem extends far beyond setting pregnancy flags. System vendors may claim to provide a wide range of patient-safety related decision support tools, but responsible care providers cannot trust system-generated advice when the triggers for decision support rules are potentially unreliable and inaccessible. Tort law requires clinician-providers to uphold the standard of care for their patients. Ignorance of the basis for important system-initiated clinical advice is inconsistent with upholding the standard of care. Certifying agencies should require that clinical system vendors make the basis for

each decision-support rule transparent. Such transparency should require that, without special training, a clinical user could easily (and on request during system use) determine the underlying logic and data supporting each instance of patient-specific advice. Systems should also enable display of the evidential basis for other, more general advice – information that might become outdated over time. Vendors must expose, in non-technical terms, how decision-support triggers are locally determined at each site.

## 12.6 Summary and Conclusions

Ethical issues are important in biomedical informatics, and especially so in the clinical arena. An initial ensemble of guiding principles, or ethical criteria, has emerged to orient decision making:

1. Specially trained human beings (e.g., licensed practitioners) remain, so far, best able to provide health care for other human beings. Computer software developers should strive to warn caregivers whenever it appears that a mistake is imminent. However, because clinical practice involves as many exceptions as rules, software systems should not be allowed to overrule a clinician's decision once a warning has been issued.
2. Practitioners who use informatics tools should be clinically qualified and adequately trained in using the software products.
3. The tools themselves should be carefully evaluated and validated, *in vitro* and *in vivo*.
4. Health informatics tools and applications should be evaluated not only in terms of performance, including efficacy, but also in terms of their influences on institutions, institutional cultures, and workplace social forces.
5. Ethical obligations should extend to system developers, maintainers, and supervisors as well as to clinician users.
6. Education programs and security measures should be considered essential for

protecting confidentiality and privacy while improving appropriate access to personal patient information.

7. Adequate oversight should be maintained to optimize ethical use of electronic patient information for scientific and institutional research.

New sciences and technologies always raise interesting and important ethical issues. Much the same is true for legal issues, although in the absence of precedent or legislation any legal analysis will remain vague. Similarly, important challenges confront people who are trying to determine the appropriate role for government in regulating health care software. The lack of clear public policy for such software underscores the importance of ethical insight and education as the exciting new tools of biomedical and health informatics become more common.

### Suggested Readings

Goodman, K. W. (2016b). *Ethics, medicine, and information technology: Intelligent machines and the transformation of health care*. Cambridge: Cambridge University Press. This volume contains material on informatics and human values, electronic health records, confidentiality and privacy, decision support, prognostic scoring systems, research, including the role of learning health systems, and governance of medical computer systems.

Goodman, K. W. (2020). *Ethics and health informatics*. *International Yearbook of Medical Informatics*. <https://doi.org/10.1055/s-0040-1701966>. This overview emphasizes issues raised by Big Data and Machine Learning/Artificial Intelligence.

Goodman, K. W., Berner, E. S., Dente, M. A., Kaplan, B., Koppel, R., Rucker, D., Sands, D. Z., & Winkelstein, P. (2011). Challenges in ethics, safety, best practices, and oversight regarding HIT vendors, their customers, and patients: a report of an AMIA special task force. *Journal of the American Medical Informatics Association*, 18(1), 77–81. This document is one of the first to examine issues related to the manufacturers and vendors of

electronic health records, including their relationships with hospitals.

IOM (Institute of Medicine). (2012b). *Health IT and patient safety: Building safer systems for better care*. Washington, DC: The National Academies Press. A key National Academy of Medicine report linking appropriate use of EHRs and patient safety.

Miller, R. A. (1990b). Why the standard view is standard: People, not machines, understand patients' problems. *Journal of Medicine and Philosophy*. 15, 581–591. This contribution lays out the standard view of health informatics. This view holds, in part, that because only humans have the diverse skills necessary to practice medicine or nursing, machine intelligence should never override human clinicians.

Miller, R. A., Schaffner, K. F., Meisel, A. (1985b). Ethical and legal issues related to the use of computer programs in clinical medicine. *Annals of Internal Medicine*. 102, 529–536. This article constitutes a major early effort to identify and address ethical issues in informatics. By emphasizing the questions of appropriate use, confidentiality, and validation, among others, it sets the stage for all subsequent work.

### Questions for Discussion

1. What is meant by the “standard view” of appropriate use of medical information systems? Identify three key criteria for determining whether a particular use or user is appropriate.
2. Can quality standards for system developers and maintainers simultaneously safeguard against error and abuse and stimulate scientific progress? Explain your answers. Why is there an ethical obligation to adhere to a standard of care?
3. Identify (a) two major threats to patient data confidentiality, and (b) policies or strategies that you propose for protecting confidentiality against these threats.
4. Many prognoses by human beings are subjective and are based on faulty memory or incomplete knowledge of previous cases. What are the two drawbacks

to using objective prognostic scoring systems to determine whether to allocate care to individual patients?

5. People who are educated about their illnesses tend to understand and to follow instructions, to ask insightful questions, and so on. How can the World Wide Web improve patient education? How, on the other hand, might Web access hurt traditional physician–patient and nurse–patient relationships?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- Why are empirical studies based on the methods of evaluation and technology assessment important to the successful implementation of information resources to improve health?
- What challenges make studies in informatics difficult to carry out? How are these challenges addressed in practice?
- Why can all evaluations be classified as empirical studies?
- What features do all evaluations have in common?
- What are the key factors to take into account as part of a process of deciding what are the most important questions to use to frame a study?
- What are the major assumptions underlying objectivist and subjectivist approaches to evaluation? What are the strengths and weaknesses of each approach?
- How does one distinguish measurement and demonstration aspects of objectivist studies, and why are both aspects necessary? In the demonstration aspect of objectivist studies, how are control strategies used to draw inferences?
- What steps are followed in objectivist and subjectivist studies? What techniques are employed by investigators to ensure rigor and credibility of their findings?
- Why is communication between investigators and stakeholders central to the success of any evaluation?

### 13.1 Introduction

Most people understand the term evaluation to mean an assessment of an organized, purposeful activity. Evaluations are usually conducted to answer questions or in anticipation of the need to make decisions (Wyatt and Spiegelhalter 1990; Ammenwerth 2015). Evaluations may be informal or formal, depending on the characteristics of the

decision to be made and, particularly, how much is at stake. But all activities labeled as evaluation involve the empirical process of collecting information that is relevant to the decision at hand. For example, when choosing a holiday destination, members of a family may informally ask friends which Hawaiian island they prefer and browse various websites including those that provide ratings of specific destinations. After factoring in costs and convenience, the family reaches a decision. More formally, when a health care organization faces the choice of a new electronic health record system, the leadership will develop a plan to collect comparable data about competing systems, analyze the data according to the plan, and ultimately, through a predetermined process, make a decision.

The field of biomedical and health informatics focuses on the collection, processing, and communication of health-related information and the implementation of **information resources**—usually consisting of digital technology designed to interact with people—to facilitate these activities.<sup>1</sup> These information resources can collect, store, and process data related to the health of individual persons (institutional or personal electronic health records), manage and reason about biomedical knowledge (knowledge acquisition tools, knowledge bases, decision-support systems, and intelligent tutoring systems), and support activities related to public health (disease registries and vital statistics, disease outbreak detection and tracking). Thus, there is a vast range of biomedical and health information resources that can be foci of evaluation.

Information resources have many different aspects that can be studied (Friedman and Wyatt 2005; Chap. 3). Where safety is an issue, as it often is, (Fox 1993; Black et al. 2011; Russ et al. 2014), we might focus on

1 In this chapter, we will use the terms “information resource” and “information system” generally as synonyms. However, “information system” applies more specifically to applications of digital technology whereas a “resource” is a broad term that could, for example, include informal collegial consultations.

inherent characteristics of the resource, asking such questions as, “Are the code and architecture compliant with current software engineering standards and practices?” or “Is the data structure the optimal choice for this type of application?” Clinicians and patients, however, might ask more pragmatic questions such as, “Is the knowledge in this system completely up-to-date?” or “Who can access this information besides me?” Executives and public officials might wish to understand the effects of these resources on individuals and populations, asking questions such as, “Has this resource improved the quality of care?” or “What effects will a patient portal have on working relationships between practitioners and patients?” Thus, evaluation methods in biomedical informatics must address a wide range of issues, from technical characteristics of specific systems to systems’ effects on people and organizations. The outcomes or effects attributable to the use of health information resources will almost always be a function of how individuals choose to use them, and the social, cultural, organizational, and economic context in which these uses take place (Lundsgaarde 1987).

For these reasons, there is no formula for designing and executing evaluations; every evaluation, to some significant degree, must be custom-designed. A major factor shaping the design of evaluations is the decisions the evaluation is expected to inform. In the end, choices about what evaluation questions to pursue and how to collect and analyze data to pursue them, are exquisitely sensitive to each study’s special circumstances and constrained by the resources that are available for it. Evaluation is very much the art of the possible. But neither is evaluation an exercise in alchemy, pure intuition, or black magic. There exist many methods for evaluation that have stood the test of time and proved useful in practice. There is a literature on what methods work and under specific circumstances, and there are numerous published examples of successful evaluation studies. In this chapter, we will introduce many of these methods, and present frameworks that guide the application of methods to specific decision problems and study settings.

## 13.2 Why Are Formal Evaluation Studies Needed?

### 13.2.1 Computing Artifacts Have Special Characteristics

Why are empirical studies of information resources needed at all? Why is it not possible, for example, to model (and thus predict) the performance of information resources and their impact on users, and thus save a lot of time and effort? The answer lies, to a great extent, in the complexity of computational artifacts and their use. For some disciplines, specification of the structure of an artifact allows one to predict how it will function, and engineers can even design new objects with known performance characteristics directly from functional requirements. Examples of such artifacts are elevators and conventional road bridges. The principles governing the behavior of materials and structures made of specific materials are sufficiently well understood that a new elevator can be designed to a set of performance characteristics with the expectation that it will perform exactly as predicted. Laboratory testing of models of these devices is rarely needed. Field testing of the artifact, once built, is conducted to reveal relatively minor anomalies, which can be rapidly remedied, or to tune or optimize performance. However, when the object concerned is a computer-based resource, not an elevator, the story is different (Littlejohns et al. 2003). Software designers and engineers have theories linking the structure to the function of only the most trivial computer-based resources (Somerville 2002). Because of the complexity of computer-based systems themselves, their position as part of a complex socio-technical system including the users and the organization in which they work, and the lack of a comprehensive theory connecting structure and function, there is no way to know exactly how an information resource will perform until it is built and tested (Murray et al. 2004); and similarly there is no way to know that any revisions will bring about the desired effect until the next version of the resource is tested. It is also impossible to predict how even a perfectly

functioning information resource will impact user decisions or actions.

In sum, the only practical way to determine if a reasonably complex body of computer code does what it is intended to do is to test it in the laboratory and in the field. This testing can take many shapes and forms. The informal design, test, and revise activity that characterizes the development of all computer software is one such form of testing and results in software that usually functions as expected *by the developers*. More formal and exhaustive approaches to software design, verification and testing using synthetic test cases (e.g., Scott et al. 2011) and other approaches help to guarantee that the software will do what it was designed to do. Even these approaches, however, do not guarantee the success of the software when put into the hands of the intended end-users. This requires more formal studies of the types that will be described in this chapter, which can be undertaken before, during, and after the initial development of an information resource. Such evaluation studies can guide further development; indicate if the resource is likely to be safe for use in real health care, public health, research, or educational settings; or elucidate if it has the potential to improve the professional performance of the resource users and the health of individuals and populations. Many stakeholders wish to know if the resource, as actually used in practice, has had the intended beneficial effects.

Many other writings elaborate on the points offered here. Some of the earliest include Spiegelhalter (1983) and Gaschnig et al. (1983) who discussed these phases of evaluation by drawing analogies from the evaluation of new drugs or the conventional software life cycle, respectively. Wasson et al. (1985) discussed the evaluation of clinical prediction rules together with some useful methodological standards that apply equally to information resources. Many other authors since then have described, with differing emphases, the evaluation of health care information resources, often focusing on decision-support tools, which pose some of the most extreme challenges. One relevant book (Friedman and Wyatt 2005) discusses the challenges posed by evaluation in biomedical informatics and offers a wide

range of methods described in considerable detail to help investigators explore and resolve these challenges. Other books have explored more technical, health technology assessment or organizational approaches to evaluation methods (Szczepura and Kankaanpaa 1996; van Gennip and Talmon 1995; Anderson et al. 1994; Brender 2005; Harasevich and Pickering 2017).

### 13.2.2 The Special Issue of Safety

Before disseminating any biomedical information resource that stores and communicates health data or knowledge and is designed to influence real-world practice or personal health decisions, it is important to verify that the resource is safe when used as intended. In the case of new drugs, European and US regulators have imposed a statutory duty on developers to perform extensive *in vitro* testing, and *in vivo* testing in animals, before any human receives a dose of the drug. Since 2000, the safety of biomedical information resources has come increasingly into the spotlight (Rigby et al. 2001; Koppel et al. 2005). Accordingly, testing of information resources is now being considered, with governmental agencies imposing risk-based regulatory frameworks and clearer classifications of medical devices (Slight and Bates 2014; FDASIA 2014; EU Regulatory Framework 2018). For biomedical information resources, safety tests analogous to those required for drugs would include assessment of the accuracy of the data stored and retrieved, measuring the accuracy of any risk estimate or advice from a decision support system, determining whether and how easily end-users can employ the resource for its intended purposes, and estimating how often the resource furnishes misleading or incorrect information (Eminovic et al. 2004). It may be necessary to repeat these assessments following any substantial modifications to the information resource, as the correction of safety-related problems may itself generate new problems or uncover previously unrecognized ones.

Determining if an information resource is safe and effective goes fundamentally to the

process of evaluation we address in this chapter. Almost all of the methodological issues we raise apply to safety assessments. Casual assessments that fail to address these issues will not resolve the safety question, and will not reveal safety defects that can be remedied. Many of these issues are issues of sampling that we introduce in ► Sect. 15.4.2. For example, the advice or other “output” generated by most information resources depends critically on the quality and quantity of data available to it and on the manner in which the resource is used by patients or practitioners. People or practitioners who are untrained, in a hurry, or exhausted at 3 A.M., are more likely to fail to enter key data that might lead to the resource generating misleading advice, or to fail to heed an alarm that is not adequately emphasized by the user interface. Coded data automatically entered into resources may be inaccurate, incomplete, or not coded in the manner anticipated by the resource. Thus, to generate valid results, functional tests must put the resources in actual users’ hands under the most realistic conditions possible, or in the hands of people with similar knowledge, skills and experience if samples of intended users are not available. For example, a Facebook advertisement for an app to help women detect when conception was likely from body temperature readings was withdrawn in the UK because the accuracy quoted in publicity materials related to ideal use rather than use in everyday practice.<sup>2</sup> [BBC news story 29-8-18].

Other safety issues are, from a methodological perspective, issues of measurement that we address in ► Sect. 13.4.2. For example, should “usability” of an information resource be determined by documenting that the resource development process followed best practices to inculcate usability, asking end-users if they believed the resource was usable, or by documenting and studying their “click streams” to determine if end-users actually navigated the resource as the designers intended? There is no single clear answer to this question (see Jakob

Nielsen’s invaluable resource on user testing<sup>3</sup>), but we will see that all measurement processes have features that make their results more or less dependable and useful. We will also see that the measurement processes built into evaluation studies can themselves be designed to make the results of the studies more helpful to all stakeholders, including those focused on safety.

### 13.3 Two Universals of Evaluation

#### 13.3.1 The Full Range of What Can Be Formally Studied

Deciding what to study is fundamentally a process of winnowing down from a universe of potential questions to a parsimonious set of questions that can be realistically addressed given the priorities, time, and resources available. This winnowing process can begin with the full range of what can potentially be studied. To both ensure that the most important questions do get “on the table” and to help eliminate the less important ones, it can be useful to start with a comprehensive list. While experienced evaluators do not typically begin study planning from this broadest perspective, it is always helpful to have a broad range of options in mind.

There are five major aspects of an information resource that can be studied:

1. Need for the resource: In advance of any development, investigators can study the status quo *absent* the resource, including the nature of problems the resource is intended to address and how frequently these problems arise. (When an information resource is already deployed, the “status quo” might be the currently deployed resource, and the resource under study is a proposed replacement for it or enhancement to it.)
2. Design and development process: Investigators study the skills of the devel-

2 ► <https://www.bbc.co.uk/news/technology-45328965> (Accessed 11.20.19).

3 ► <https://www.nngroup.com/articles/> (Accessed 11.20.19).

opment team, and the development methodologies employed by the team, to understand if the resulting resource is likely to function as intended.

3. **Resource static structure:** Here the focus of the evaluation includes specifications, flow charts, program code, and other representations of the resource that can be inspected without actually running it.
4. **Resource usability and dynamic functions:** The focus is on whether the resource has the potential to be beneficial: the degree to which intended end-users can navigate the resource and how it performs when it is used in pilots prior to full deployment.
5. **Resource use, effect and impact:** Finally, after deployment, the focus switches from the resource itself to the extent of its use and its effects on professional, patient or public users, and on health care organizations.

In a theoretically “complete” evaluation, sequential studies of a particular resource might address all of these aspects, over the life cycle of the resource. In the real world, however, it is difficult, and rarely necessary, to be so comprehensive. Over the course of its development and deployment, a resource may be studied many times, with the studies in their totality touching on many or most of these aspects. Some aspects of an information resource will be studied informally using anecdotal data collected via casual methods. Other aspects will be studied more formally in ways that are purposefully designed to inform specific development decisions and that involve systematic collection and analysis of data. Distinguishing those aspects that will be studied formally from those left for informal exploration is a challenging task facing all evaluators.

### 13.3.2 The Structure of All Evaluation Studies, Beginning with a Negotiation Phase

If the list offered in the previous section can be seen as the universe of what can be studied, **Fig. 13.1** can be used as a framework for planning all evaluation studies. The first stage in any study is negotiation between the “investigators” (or “evaluators”) who will be carrying out the study and the “stakeholders” who have interests in or otherwise will be concerned about the study results. Before a study can proceed, the key stakeholders who are supporting the study financially and providing other essential resources for it—such as the institution where the information resource is deployed—must be satisfied with the general plan. The negotiation phase identifies the broad aim and objectives of the study, what kinds of reports and other deliverables will result and by when, where the study personnel will be based, the resources available to conduct the study, and any constraints on what can be studied. When a study of an information resource is being conducted internally—that is, when all of the key stakeholders represent one organization that also employs the investigators—it is still very useful to have an internal negotiation to lay out details of the study.

The results of the negotiation phase are expressed in a document, generally known as a contract between the evaluators and the key stakeholders. The contract guides the planning and execution of the study and, in a very significant way, protects all parties from misunderstandings about intent and execution. Like any contract, an **evaluation contract** can be changed later with consent of all parties.

**Fig. 13.1** Generic structure of all evaluation studies

Following the negotiation process and its reflection in a contract, the planning of the evaluation proceeds in a sequence of logical steps, starting with the formulation of specific questions to be addressed, then the selection of the type(s) of study that will be used, the investigation that entails the collection and analysis of data, and ultimately the communication back to the stakeholders of the findings, which typically inform a range of decisions. Although  Fig. 13.1 portrays a one-way progression through this sequence of stages, in the real world of evaluation there are often detours and backtracks.

### 13.4 Deciding What to Study and What Type of Study to Do: Questions and Study Types

#### 13.4.1 The Importance of Identifying Questions

Once the study's objective, scope and other applicable "ground rules" have been established, the real work of study planning can begin. The next step, as suggested by  Fig. 13.1, is to convert the perspectives of the concerned parties, and what these individuals or groups want to know, into a finite, specific set of questions. It is important to recognize that, for any evaluation setting that is interesting enough to merit formal evaluation, the number of potential questions is infinite. This essential step of identifying a tractable number of questions has a number of benefits:

- It helps to crystallize thinking of both investigators and key members of the audience who are the stakeholders in the evaluation.
- It guides the investigators and stakeholders through the critical process of assigning priority to certain issues and thus productively narrowing the focus of a study.
- It converts broad statements of aim (e.g., "to evaluate a new order communications system") into specific questions that can potentially be answered (e.g., "What is the impact of the order communications system

on how clinical staff spend their time, the rate and severity of adverse drug events and the length of patient stay?").

- It allows different stakeholders in the evaluation process—patients, professional groups, managers – to see the extent to which their own concerns are being addressed, and to ensure that these feed into the evaluation process.
- Most important, perhaps, it is hard if not impossible to develop investigative methods without first identifying questions, or at least focused issues, for exploration. The choice of methods follows from the evaluation questions: not from the novel technology powering the information resource or the type of resource being studied. Unfortunately, some investigators choose to apply the same set of the methods to any study, irrespective of the questions to be addressed, or even to limit the evaluation questions addressed to those compatible with the methods they prefer. We do not endorse this limiting approach.

Consider the distinction made earlier between informal evaluations that people undertake continuously as they make choices as part of their everyday personal or professional lives, and more formal evaluations that are planned and then executed according to that plan. In short, formal evaluations are those that conform to the architecture of  Fig. 13.1. In these formal evaluations, the questions that actually get addressed survive a narrowing process that begins with a broad set of candidate questions. When starting a formal evaluation, therefore, a major decision is whom to consult to establish the questions that will get "on the table", how to log and analyze their views, and what weight to place on each of these views. There is always a wide range of potential players in any evaluation (see  Box 13.1) and there is no formula that defines whom to consult or in what order. Through this process, the investigators apply their common sense and, with experience, learn to follow their instincts. The only universal mistake is to fail to consult one or more of the key stakeholders, especially those paying for the study or those ultimately

making the key decisions to be informed by the evaluation. It is often useful to establish a group to advise and guide the evaluators, a group with broad representation that will help ensure that study remains true to the interests and preferences of the stakeholders.

Through discussions with various stakeholder groups, the hard decisions regarding the questions to be addressed in the study are made. A significant challenge for investigators is the risk of getting swamped by detail, resulting from the multiplicity of questions that can be asked in any study. To manage through the process, it is important to reflect on the major issues identified after each round of discussions with stakeholders, and then identify the questions that map to these issues. Where possible, keep questions at the same level of granularity.

It is critical that the specific questions serving as the beacon guiding the study be determined and endorsed by all key stakeholders, before any significant decisions about the detailed design of the study are made. We will see later that evaluation questions can, in many circumstances, change over the course of a study; but that fact does not obviate the need to specify a set of questions at the outset. ► Appendix A describes two evaluation scenarios, and suggests some evaluation questions that may be appropriate for each.

### Box 13.1 Some of the Potential Players in an Evaluation Study

- Those commissioning the evaluation study, who will typically have questions or decisions that rely on the data collected
- Those paying for the evaluation study
- Those paying for the development and/or deployment of the information resource
- End-users of the resource, who are often providers of data for the study
- Developers of the resource and their managers
- Care providers and their managers
- Staff responsible for resource implementation and user training

- Information technology staff and leaders in the organization where the resource is deployed
- Senior managers in the organization where the resource is deployed
- The patients whose care the resource may directly or indirectly influence
- Staff in ancillary services whose workload may be affected by resource deployment, for example laboratory or imaging departments following deployment of a diagnostic decision support system
- Quality improvement and safety professionals in the organization in which the resource is implemented

## 13.4.2 Selecting a Study Type

After developing the list of evaluation questions, the next step is to understand which study type(s) the evaluation questions naturally invoke. The study types we will introduce in this chapter are specific to the evaluation of information resources, and are particularly informative to the design of evaluation studies in biomedical informatics. These study types are described below and also summarized in ■ Table 13.1. The second column of ■ Table 13.1 links the study types to the aspect of the resource that is studied—as previously introduced in ► Sect. 13.3.1. Each study type is likely to appeal to certain interests of particular stakeholders, as suggested in the rightmost column of the table. A wide range of data collection and analysis methods, as discussed later in ► Sect. 13.5, can be used to answer the questions embraced by all nine study types. Choice of a study type typically does not constrain the methods that can be used to collect and analyze data. And we will see later in this chapter, and specifically in ► Sect. 13.5.2.2, that all of these study types are what can be called demonstration studies, in contrast to so-called measurement studies. Finally, a set of studies, exemplifying many of these study types, is introduced and described in ► Appendix B.

**Table 13.1** Classification of demonstration study types by broad study question and the stakeholders most concerned

Study type	Aspect studied	Broad study question	Audience/stakeholders primarily interested in results
1. Needs assessment	Need for the resource	What is the problem?	Resource developers, funders of the resource
2. Design validation	Design and development process	Is the development method in accord with accepted practices?	Funders of the resource; professional and governmental certification agencies e.g., Food and Drug Administration, Office of the National Coordinator for HIT
3. Structure validation	Resource static structure	Is the resource appropriately designed to function as intended?	Professional indemnity insurers, resource developers; professional and governmental certification agencies
4. Usability test	Resource dynamic usability and function	Can intended users navigate the resource so it carries out intended functions?	Resource developers, users, funders
5. Laboratory function study	Resource dynamic usability and function	Does the resource have the potential to be beneficial?	Resource developers, funders, users, academic community
6. Field function study	Resource dynamic usability and function	Does the resource have the potential to be beneficial in the real world?	Resource developers, funders, users
7. Lab user effect study	Resource effect and impact	Is the resource likely to change user behavior?	Resource developers and funders, users
8. Field user effect study	Resource effect and impact	Does the resource change actual user behavior in ways that are positive?	Resource users and stakeholders, resource purchasers and funders
9. Problem impact study	Resource effect and impact	Does the resource have a positive impact on the original problem?	The universe of stakeholders

13

1. **Needs assessment** studies seek to clarify the information problem the resource is intended to solve. These studies take place before the resource is designed—usually in the setting where the resource is to be deployed, although simulated settings may sometimes be used. Ideally, the potential users of the resource will be studied while they work with real problems or cases, to understand better how information is used and managed, and to identify the causes and consequences of inadequate information flows. The investigator seeks to understand users' skills, knowledge and attitudes, as well as how they make decisions or take actions. To ensure that developers have a clear model of how a proposed information resource will fit with working practices and structures, they may also need to study health care or research processes, team functioning, or relevant aspects of the larger organization in which work is done (Wyatt et al. 2010).
2. **Design validation** studies focus on the quality of the processes of information resource design and development, for example by asking experts to review these processes. The experts may review docu-

ments, interview the development team, compare the suitability of the software engineering methodology and programming tools used with others that are available, and generally apply their expertise to identify potential shortcomings in the approach used to develop the software, as well as constructively to suggest how these shortcomings might be corrected.

3. **Structure validation** studies address the static form of the software, usually after a first prototype has been developed. This type of study is most usefully performed by an expert or a team of experts with experience in developing software for the problem domain and concerned users. For these purposes, the investigators need access to both summary and detailed documentation about the system architecture, the structure and function of each module, and the interfaces among them. The expert might focus on the appropriateness of the algorithms that have been employed and check that they have been correctly implemented by examining the code and its documentation. Experts might also examine the data structures (e.g., whether they are appropriately normalized) and knowledge bases (e.g., whether they are evidence-based, up to date, and modelled in a format that will support the intended analyses or reasoning). Most of this will be done by inspection and discussion with the development team. Sometimes specialized software may be used to test the structure of the resource (Somerville 10th edition 2015).

*Note that the study types listed up to this point do not require a functioning information resource. However, beginning with usability testing below, the study types require the existence of at least a functioning prototype.*

4. **Usability testing** studies address whether intended users can actually operate or navigate the software, to determine whether the resource has the potential to be helpful to them (see also ► Chap. 5). In this type of study, testing of a prototype by typical users informs further develop-

ment and should improve its usability. Although usability testing can be performed by obtaining opinions of usability experts who “test drive” the resource, usability can also be tested by deploying the resource in a laboratory or classroom setting, introducing users to it, and then allowing them either to navigate at will and provide unstructured comments or to attempt to complete some scripted tasks (see extensive material by Nielsen, ► [www.useit.com](http://www.useit.com)). Data can be collected by the computer itself, from the user, by a live observer, via audio or video capture of users’ actions and statements, or by specialized instrumentation such as eye-tracking tools. Many software developers have usability testing labs equipped with sophisticated measurement systems, staffed by experts in human computer interaction to carry out these studies—an indication of the importance increasingly attached to this type of study (Zhang et al. 2003; Saitwal et al. 2010).

5. **Laboratory function studies** go beyond usability to explore more specific aspects of the information resource, such as the quality of data captured, the speed of communication, the validity of the calculations carried out, or the appropriateness of the results or advice given. These functions relate less to the basic usability of the resource and more to how the resource performs in relation to what it is trying to achieve for the user or the organization. When carrying out any kind of function testing, real or proxy users are employed. The study results depend crucially on what problems the users are asked to solve, so the “tasks” employed in these studies (eg. case scenarios) should correspond as closely as possible to those to which the resource will be applied in real working life. *Such tasks vary across a set of dimensions—for example, difficulty, problem domain, and urgency—so it is very important to employ in these studies a set of tasks that spans the range of these dimensions.*
6. **Field function studies** are a variant of laboratory function testing in which the

resource is “pseudo-deployed” in a real work place and employed by real users with real problems—but only up to a point. In field function tests, although the resource is used by real users with real tasks, the users have no immediate access to the output or results of their interaction with the resource that might influence their real decisions or actions, so no effects on these can occur. The output is recorded for later review by the investigators, and perhaps by the users themselves.

*Studies of the effect or impact of information resources on users and problems are in many ways the most demanding. As the focus of study moves from function testing, which is always hypothetical, to possible effects on health decisions or care processes, the conduct of research, or educational practice, there is often the need to establish cause and effect and to submit studies to external review.*

7. In **laboratory user effect studies**, simulated user decisions or actions are studied. Practitioners employ the resource in a laboratory setting and are asked what they “would do” with the results or advice the resource generates, but no action is taken. Laboratory user effect studies can be conducted with prototype or released versions of the resource, outside the practice environment. Although such studies involve individuals who are representative of the “end-user” population, the primary results of the study derive from simulated actions, so the care of patients or conduct of research is not affected by a study of this type. An example is a study in which junior physicians viewed realistic prescribing scenarios and interacted with a simulated prescribing tool while they were exposed to simulated prescribing alerts of various kinds and the rate of prescribing errors was measured (Scott et al. 2011).
8. In a **field user effect study**, the actual actions or decisions of the users of the resource are studied after the resource is formally deployed. This type of study provides an opportunity to test whether the resource is actually used by the intended users, whether they obtain accurate and useful information from it, and whether this use affects their decisions and actions in significant ways. In field user effect studies, the emphasis is on the behaviors and actions of users, and not the health outcomes or consequences of these behaviors. For example, one study examined the impact of SMS reminders on anti-retroviral medication adherence in Africans with HIV and showed a dramatic improvement (Lester et al. 2010).
9. **Problem impact studies** are similar to field user effect studies in many respects, but differ profoundly in the questions that are the focus of exploration. Problem impact studies examine the extent to which the original health problem that motivated creation or deployment of the information resource has been addressed. Often this requires investigation that looks beyond the actions of care providers, researchers, or patients to examine the consequences of these actions. In the Lester study of SMS alerts (Lester et al. 2010), increased adherence to antiretroviral therapy (a user action) was also accompanied by improved viral load suppression. However, user effects cannot be assumed to engender problem impacts. For example, an information resource designed to reduce medication errors may affect the behavior of clinicians who employ the resource relative to those who do not, but for a variety of reasons, the actual incidence of harmful medication episodes remains unchanged. In such an instance, clinical pharmacists who review orders may be catching and correcting these errors before patients are affected. In other examples, individuals may be motivated to exercise through interaction with a wearable information resource but fail to meet weight loss objectives because they cannot afford concomitant changes in their diets. In still other domains, an information resource may be widely used by researchers to access biomedical information, as determined by a user effect study, but a subsequent problem impact study may or may not reveal effects on scientific productivity.

New educational technology may change the ways students learn, but may or may not increase their performance on standardized examinations. Problem impact studies, as well as user effect studies, will be sensitive to unintended consequences. Sometimes, the solution to the target problem creates other, unintended and unanticipated problems that can affect perceptions of success. As electronic mail became an almost universal mode of communication, almost no one anticipated the problems of “spam” or “phishing”.

### 13.4.3 Factors Distinguishing the Nine Study Types

Table 13.2 further distinguishes the nine study types, as described above, using a set of key differentiating factors discussed in detail in the paragraphs that follow.

**The setting in which the study takes place** Studies of the design process, the resource structure, and many resource functions are typically conducted outside the active

Table 13.2 Factors distinguishing the nine demonstration study types

Study type	Study setting	Version of the resource	Sampled users	Sampled tasks	What is observed
1. Needs assessment	Field	None, or pre-existing resource to be replaced	Anticipated resource users	Actual tasks	User skills, knowledge, decisions or actions; care processes, costs, team function or organization; patient outcomes
2. Design validation	Development lab	None	None	None	Quality of design method or team
3. Structure validation	Lab	Prototype or released version	None	None	Quality of resource structure, components, architecture
4. Usability test	Lab	Prototype or released version	Proxy, real users	Simulated, abstracted	Speed of use, user comments, completion of sample tasks
5. Laboratory function study	Lab	Prototype or released version	Proxy, real users	Simulated, abstracted	Speed and quality of data collected or displayed; accuracy of advice given...
6. Field function study	Field	Prototype or released version	Proxy, real users	Real	Speed and quality of data collected or displayed; accuracy of advice given...
7. Lab user effect study	Lab	Prototype or released version	Real users	Abstracted, real	Impact on user knowledge, simulated/pretend decisions or actions
8. Field user effect study	Field	Released version	Real users	Real	Extent and nature of resource use. Impact on user knowledge, real decisions, real actions
9. Problem impact study	Field	Released version	Real users	Real	Impact on targeted health status

health care or decision environment, in a “laboratory” setting. Studies to elucidate the need for a resource and studies of its impact on users would usually take place in settings—known generically as the “field”—where health care practitioners, researchers, students, patients or administrators are making real choices in the real world. These studies can take place only in settings where the resource is available for use and where health care or health behavior activities occur and/or where other important decisions are made. To an investigator planning such studies, an important consideration that determines the kind of study possible is the degree of access to resource users in the field setting. If, as a practical matter, access to the field setting is very limited, then several study types listed in ■ Tables 13.1 and 13.2 are either not possible, or the validity of the field studies that are possible will be reduced.

**The version of the resource used** For some kinds of studies, a simulated or prototype version of the resource may be sufficient (Scott et al. 2011; Russ et al. 2014), whereas for studies in which the resource is employed by intended users to support real decisions and actions, a fully robust and reliable version is needed (e.g., Lester et al. 2010).

**The sampled resource users** Information resources nearly always function through interaction with one or more such “users” who bring to the interaction their own domain knowledge and knowledge of how to operate the resource. Exceptions might include closed loop control systems such as smart insulin pumps and pharmacy robots, but even in these cases, humans who set the parameters for the otherwise autonomous operations of these devices can be seen as a form of “users”. In some types of evaluation studies, the users of the resource are not the end users for whom the resource is ultimately designed, but are members of the development or evaluation teams, or other individuals who can be called “proxy users”, chosen because they are conveniently available or because they are affordable. (For example, senior medical students

can sometimes be used as proxies for more experienced physicians.) In other types of studies, the users are sampled from the end-users for whom the resource is ultimately designed. The type of users employed gives shape to a study and can affect its results profoundly. The usability of a resource is easily overestimated if the “users” in a study are those who designed or are otherwise familiar with the resource. As another example, volunteer users of a consumer-oriented resource such as a dieting app may be more motivated than the general population the resource is designed to benefit.

**The sampled tasks** For function, effect, and impact studies, the users included in the study actually interact with the resource. This requires tasks, often clinical or scientific decision problems, for the users to undertake. These tasks can be invented or simulated; they can be abstracted versions of real cases or problems, shortened to suit the specific purposes of the study; or they can be live cases or research problems as they present to resource users in their everyday work. Clearly, the kinds of tasks employed, and how they are sampled, in a study have serious implications for the study results and the conclusions that can be drawn from them.

**The observations that are made** All evaluation studies entail observations that generate data that are subsequently analyzed to generate the study results. As seen in ■ Table 13.2, many different kinds of observations can be made.

In the paragraphs above we have introduced the term “sampled” for both tasks and users. It is important to establish that in real evaluation studies, tasks and users are always sampled from some real or hypothetical population. Choosing appropriate methods to sample users and tasks is a major challenge in evaluation study design since it is never possible, practical, or desirable to study everyone doing everything possible with an information resource. Sampling issues are addressed later in this chapter.

## 13.5 Conducting Investigations: Collecting and Drawing Conclusions from Data

### 13.5.1 Two Grand Approaches to Study Design, Data Collection, and Analysis

Several authors have developed classifications, or **typologies**, of evaluation methods or approaches. Among the best is that developed in 1980 by Ernest House (1980). Even though it is somewhat old, a major advantage of House's typology is that each approach is linked elegantly to an underlying philosophical model, as detailed in his book. This classification divides current practice into eight discrete approaches, four of which may be viewed as **objectivist** and four of which may be viewed as **subjectivist**. While the distinctions between the eight approaches House describes are beyond the scope of this chapter, the grand distinction between objectivist and subjectivist approaches is very important. Note that these approaches are not entitled "objective" and "subjective", because those labels carry strong and fundamentally misleading connotations of scientific precision in the former case and of idiosyncratic imprecision in the latter. We will see in this section how both objectivist (often called quantitative) and subjectivist (often called qualitative) approaches find rigorous application across the range of study types described earlier.

To appreciate the fundamental difference between the approaches, it is necessary to address their very different philosophical roots. The objectivist approaches derive from a **logical-positivist** philosophical orientation—the same orientation that underlies the classic experimental sciences. The major premises underlying the objectivist approaches are as follows:

- In general, the attributes of interest are properties of the resource under study, or the people interacting with it. More specifically, this premise suggests that the merit and worth of an information resource—the attributes of most interest in evaluation—can in principle be mea-

sured, with all observations yielding the same result. It also assumes that an investigator can measure these attributes without affecting how the resource under study functions or is used.

- Rational persons can and should agree on what attributes of a resource are important to measure and what results of these measurements would be identified as the most desirable, correct, or positive outcome. In informatics, making this assertion is tantamount to stating that perfection in resource or user performance can always be identified and that all rational individuals can be brought to consensus on what "perfection" is.
- Because numerical measurement allows precise statistical analysis of performance over time or performance in comparison with some alternative, numerical measurement is *prima facie* superior to a verbal description. Verbal, descriptive data (generally known as qualitative data) are thus useful in only preliminary studies to identify hypotheses for subsequent, more precise analysis using quantitative methods.
- Through these kinds of comparisons, it is possible to demonstrate to a reasonable degree that a resource is or is not superior to what it replaced, or to a competing resource.

Contrast these assumptions with the set of assumptions that derives from an **intuitionist-pluralist** or de-constructivist philosophical position that spawns a set of subjectivist approaches to evaluation:

- What is observed about a resource invariably depends in fundamental ways on the observer. Different observers of the same resource might legitimately come to different conclusions. Both can be objective in their appraisals even if they do not agree; it is not necessary that one is right and the other wrong. Important insight can derive from both, and from their juxtaposition.
- Merit and worth must be explored in context. The value of a resource emerges through study of the resource as it

functions in a particular decision-making environment.

- Individuals and groups can legitimately hold different perspectives on what constitutes the most desirable outcome of introducing a resource into an environment. There is no reason to expect them to agree, and it may be counterproductive to even try to lead them to consensus. An important aspect of an evaluation would be to document the ways in which they disagree.
- Verbal description can be highly illuminating. Qualitative data are valuable, in and of themselves, and can lead to conclusions as convincing as those drawn from quantitative data. The value of qualitative data, therefore, goes far beyond that of identifying issues for later more “precise” exploration using quantitative methods.
- Evaluation should be viewed as an exercise in argument or rhetoric, rather than as a demonstration, because every study can “appear equivocal when subjected to serious scrutiny” (House 1980).

The approaches to evaluation that derive from this subjectivist philosophical perspective may seem strange, imprecise, and unscientific when considered for the first time. This perception stems in large part from the widespread acceptance of the objectivist worldview in biomedicine. Over the last two decades, however, thanks to some early high quality studies (e.g., Forsythe et al.

1992; Sheikh et al. 2011; Wright et al. 2015) the importance and utility of these subjectivist approaches in evaluation have been established within biomedical informatics. It is important for people trained in classic experimental methods at least to understand, and possibly even to embrace, the subjectivist worldview if they are to conduct fully informative evaluation studies.

### 13.5.2 Conduct of Objectivist Studies

Figure 15.2 expands the generic process for conducting evaluation studies to illustrate the steps involved in conducting an objectivist study.

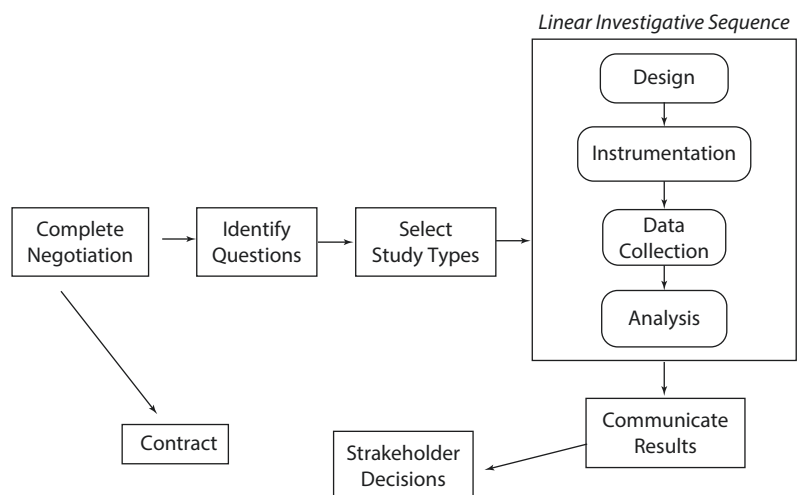

Figure 13.2 illustrates the linear sequence in which the investigation portion of an objectivist evaluation study is typically carried out. We will focus in this chapter on issues of study design that are most challenging in objectivist studies and we will further focus on that subset of objectivist study designs which are comparative in nature. More details on the other aspects of objectivist studies are available in standard references on experimental design (Campbell and Stanley 1963; Rothman et al. 2008).

#### 13.5.2.1 Structure and Terminology of Comparative Studies

Most objectivist evaluations performed in the world make a comparison of some type. For informatics, aspects of performance of

13

Fig. 13.2 Generic structure depicting an objectivist investigation

individuals, groups, or organizations *with* the information resource are often compared to those same aspects *without* the resource, with some alternative resource, or an alternate design of the same resource. After identifying a sample of participants for the study, the investigator assigns each participant, often randomly, to one or a set of conditions and some outcomes of interest are measured for each participant. The averaged values of these outcomes are then compared across the conditions. If all other factors are controlled, either directly through the design of the study or statistically through randomization, then any measured difference in the averaged outcomes can be attributed to the resource.

This relatively simple description of a comparative study belies the many issues that affect their design, execution, and ultimate usefulness. To understand these issues, we must first develop a precise terminology.

The **participants** in a study are the entities about which/whom data are collected. It is key to emphasize that participants are often people—for example, care providers or recipients—but also may be information resources, groups of people, or organizations. Because many of the activities in informatics are conducted in hierarchical settings with naturally occurring groups (a “physician’s patients”; the “researchers in a laboratory”), investigators must, for a particular study, define the participants carefully and consistently.

**Variables** are specific characteristics of the participants or the setting that either are measured purposefully by the investigator or are self-evident properties that do not require measurement. Some variables may take a continuous range of values while others have a discrete set of levels, corresponding to each of the possible measured values. For example, in a hospital setting, physician members of a ward team can be classified as residents, fellows, or attending physicians. In this case, the variable “physician’s level of qualification” is said to have three discrete “levels”.

The **dependent variables** are those variables in the study that capture the outcomes of interest to the investigator. (For this reason, dependent variables are also called **outcome variables**.) A study may have one or

more dependent variables. In a typical study, the dependent variables will be computed, for each participant, as an average over a number of tasks. For example, clinicians’ diagnostic performance may be measured over a set of cases, or “tasks”, that provide a range of diagnostic challenges.

The **independent variables** are included in a study to explain the measured values of the dependent variables. For example, whether an information resource is available, or not, to support certain clinical tasks could be the major independent variable in a study designed to evaluate the effects of that resource.

Measurement challenges almost always arise in the assessment of the outcome or dependent variable for a study. Often, for example, the dependent variable is some type of performance measure that invokes concerns about reliability (precision) and validity (accuracy) of measurement. The independent variables may also raise measurement challenges. When the independent variable is marital status, for example, the measurement problems are relatively straightforward. If the independent variable is an attitude or other “state of mind”, such as computer or health literacy, profound measurement challenges can arise.

### 13.5.2.2 Issues of Measurement

Measurement is the process of assigning a value corresponding to the presence, absence, or degree of a specific attribute in a specific object. When we speak specifically of measurement, it is customary to use the term “object” to refer to the entity on which measurements are made. Measurement usually results in either (1) the assignment of a numerical score representing the extent to which the attribute of interest is present in the object, or (2) the assignment of an object to a specific category. Taking and recording the temperature (attribute) of a person (object) is an example of the process of measurement.

From the premises underlying objectivist studies (see ► Sect. 13.5.1), it follows that proper execution of such studies requires careful and specific attention to methods of measurement. It can never be assumed that

attributes of interest are measured without error. Accurate and precise measurement must not be an afterthought and indeed, most scientific progress occurred once challenging measurement problems, such as measuring the speed of light or mass of an electron, were solved. Measurement is of particular importance in biomedical informatics because, as a relatively young field, informatics does not have a well-established tradition of “variables worth measuring” or proven instruments for measuring them. By and large, people planning studies in informatics are faced first with the task of deciding what to measure and then with that of developing their own measurement methods. For most researchers, these tasks prove to be harder and more time-consuming than initially anticipated.

We can underscore the importance of measurement by establishing a formal distinction between studies undertaken to develop methods for making measurements, which we call measurement studies, and the subsequent use of these methods to address questions of direct importance in informatics, which we call demonstration studies. **Measurement studies** seek to determine how accurately and precisely an attribute of interest can be measured in a population of objects. In an ideal objectivist measurement, which never actually occurs, all observers will agree on the result of the measurement. Any disagreement is therefore due to error, which should be minimized. The more agreement among observers or across observations, the better the measurement. Measurement procedures developed and validated through measurement studies provide researchers with the measurement instruments they need to conduct **demonstration studies** that directly address questions of substantive and practical concern to the stakeholders for an evaluation study. Once we know how accurately we can measure an attribute using a particular procedure and instrument, we can employ the measured values of this attribute as a variable in a demonstration study to draw inferences about the performance, perceptions, or effects of an information resource. For example, once measurement studies have determined how accurately and precisely the

usability of a class of information resources can be measured, using a specific measurement method, a subsequent demonstration study could explore which of two resources that are members of this class has greater usability.

A detailed discussion of measurement methods and issues is beyond the scope of this chapter but these topics are discussed in the Friedman and Wyatt textbook previously referenced. The bottom line is that investigators should know that their measurement methods will be adequate before they collect data for their studies. If the measures to be used do not have an established track record it is necessary to perform a measurement study, involving data collection on a small scale, to establish the adequacy of all measurement procedures (e.g., Ramnarayan et al. 2003; Demiris et al. 2000). Even if the measurement procedures of interest do have a track record in a particular setting, they may not perform equally well in a different environment, so a further measurement study may still be necessary. Researchers should always ask themselves, “How good are my measures in this particular setting?” whenever they are planning a study, before they proceed to the demonstration phase. The importance of measurement studies for informatics was first explained by Michaelis and co-workers (1990) and later expanded by Friedman and Abbas (2003). A study by Scott et al. (2019) documented that informatics studies continue to underappreciate the importance of measurement issues.

Whenever possible, investigators planning demonstration studies should employ established measurement methods with a “track record”, by re-using them, rather than by developing their own. Increasingly, compendia of measurement instruments specifically for health informatics are available on the Internet.<sup>4</sup>

4 Examples include: ► <https://www.gem-beta.org/public/home.aspx> and ► <https://healthit.ahrq.gov/health-it-tools-and-resources/evaluation-resources/health-it-survey-compendium-search> (Both accessed 11.20.18).

### 13.5.2.3 Sampling Strategies

#### ■ Selection of Participants

The participants selected for objectivist studies must resemble those to whom the evaluator and others responsible for the study wish to apply the results. For example, when attempting to quantify the likely impact of a clinical information resource on clinicians at large, there is no point in studying its effects on the clinicians who helped develop it, especially if they built it, as they are likely to be much more familiar with the resource than average practitioners. Characteristics of clinical participants that typically need to be taken into account include age, experience, role, type of work environment, attitude toward digital information resources, and extent of their involvement in the development of the resource. Analogous factors would apply to patients or health care consumers as participants.

#### ■ Volunteer Effect

A common bias in the selection of participants is the use of volunteers. It has been established in many areas that people who volunteer as participants, whether to complete questionnaires, participate in psychology experiments, or test-drive new cars or other technologies, are atypical of the population at large (e.g., Pinsky et al. 2007). Although evaluations are often the “art of the possible”, and all participants in studies are ultimately volunteers in the sense that no one can or should be coerced to participate, it is important to take steps to make the study participants as representative as possible of the resource’s ultimate user community. A systematic approach to participant selection would first identify the full population of users and then sample from that population either randomly or sometimes purposively to be sure the sample includes participants with characteristics seen as essential to a thorough test of the resource. Once a sample is selected, follow-up to invitation letters and other mechanisms can achieve as close to 100% recruitment of the selected sample as possible. Relatively

modest financial incentives can significantly boost participation rates.

#### ■ Number of Participants Needed

The financial investment required for an evaluation study depends critically on the number of participants needed. The required number in turn depends on the purpose and design of the study. In usability studies, discussed below, a great deal can be learned from a relatively small sample.<sup>5</sup> In subjectivist studies, participant selection can be a dynamic process where study participants identify other participants. In objectivist user effect or problem impact studies, sample sizes are directed by the precision of the answer required from the study and the risk investigators are willing to take of failing to detect a significant effect. (All other things being equal, the larger the sample size, the greater the likelihood of detecting an effect of a specified size using a predetermined criterion for statistical significance.) Statisticians can advise on this point and carry out power analyses that estimate the sample-size required. Sometimes, in order to recruit the required number of participants, an element of volunteer effect must be tolerated; often there is a trade-off between obtaining a sufficiently large sample and ensuring that the sample is representative. Also, the impact of sample size on effect detection is non-linear. The value of adding, say, 10 more representative participants to a sample of 100 is far less than that of adding 10 more participants to a sample of 30.

#### ■ Selection of Tasks

In the same way that participants must be carefully selected to resemble the people likely to use the information resource, any tasks the participants complete in the study must also resemble those that will generally be encountered where the information resource is deployed. Thus when evaluating a clinical order-entry system intended for general use, it would be unwise to use only complex cases from, for example, a pediatric intensive care setting. Although the order-entry

5 See ► <https://www.nngroup.com/articles/why-you-only-need-to-test-with-5-users/> (Accessed 11.20.18).

system might well be of considerable benefit in intensive care cases, it is inappropriate to generalize results from such a limited sample to the full range of cases seen in ambulatory pediatrics. An instructive example is provided by the study of Van Way et al. (1982) who developed a scoring system for diagnosing appendicitis and studied the resource's accuracy using exclusively patients who had undergone surgery for suspected appendicitis. Studying this group of patients had the benefit of allowing the true cause of the abdominal pain to be obtained with near certainty as a by-product of the surgery itself. However, in these patients who had all undergone surgery for suspected appendicitis the symptoms were more severe and the incidence of appendicitis was five to ten times higher than for the typical patient for whom such a scoring system would be used. Thus, the accuracy obtained with postsurgical patients would be a poor estimate of the system's accuracy in routine clinical use.

If the performance of an information resource is measured on a number of hand-picked tasks, the functions it performs may appear spuriously complete and its usability overestimated. This is especially likely if these cases are similar to, or even identical with, a "training" set of tasks used to develop or tune the information resource before the evaluation is carried out. When a statistical model that powers an information resource is carefully adjusted to achieve maximal performance on training data, this adjustment may worsen its accuracy on a fresh set of data due to a phenomenon called overfitting (Wasson 1985; Srivastava et al. 2014; Ravi et al. 2017). Thus, it is important to obtain a new set of tasks and evaluate performance on this new test set, a process called cross-validation. Sometimes developers omit tasks from a sample if they do not fall within the scope of the information resource, for example if the final diagnosis for a case is not represented in a diagnostic system's knowledge base. This practice violates the principle that a test set should be representative of all tasks in which the information resource will be used, and will overestimate its accuracy in the real world.

### 13.5.2.4 Control Strategies in Comparative Studies

One of the most challenging questions in quantitative comparative study design is how to obtain control (Liu et al. 2011). In the context of informatics, control mechanisms seek to account for all factors in a study environment that are not attributable to the information resource. In the following sections, we review a series of control strategies. We employ, as a running example of an information resource under study, a reminder system that prompts physicians to order prophylactic antibiotics for orthopedic patients to prevent postoperative infections. In this example, the intervention is the deployment of the reminder system; the participants are the physicians; and the tasks are the surgical cases. The dependent variables are physicians' ordering of antibiotics (a user effect measure) and the rate of postoperative infections (a problem impact measure). As such, this is an example of a study which straddles two of the types in ■ Table 13.1.

#### ■ Descriptive (Uncontrolled) Studies

In the simplest possible design, an uncontrolled or **descriptive study**, we deploy the reminder system and then make our measurements. There is no independent variable as such. Suppose that we discover that the overall postoperative infection rate is 5% and that physicians order prophylactic antibiotics in 60% of orthopedic cases. Although we have two measured dependent variables, it is hard to draw meaningful conclusions from these results. Although the results might be informative from a patient safety perspective, is not possible to draw any conclusions about the effect of the resource.

#### ■ Historically Controlled Experiments

As a first improvement to a descriptive study, from the perspective of control, consider a **historically controlled experiment**, sometimes called a **before–after study** (Wyatt & Wyatt 2003). The investigator makes baseline measurements of antibiotic ordering and postoperative infection rates before the information resource is installed, and then makes the same measurements after the information resource is in routine use. The independent variable is time and

has two levels: before and after resource installation. Let us say that, at baseline, the postoperative infection rates were 10% and physicians ordered prophylactic antibiotics in only 40% of cases; but the post-intervention figures are 5% and 60%, respectively (see Table 13.3).

The investigators may claim that the halving of the infection rate can be safely ascribed to the information resource, especially because it was accompanied by a substantial improvement in physicians' antibiotic prescribing. Many other factors might, however, have changed in the interim to cause these results, especially if there was a long interval between the baseline and post-intervention measurements. New staff could have been employed; the mix of patients could have changed; new prophylactic antibiotics may have been introduced; quality improvement meetings may have highlighted the infection problem and thus caused greater clinical awareness; and/or incentive programs may have been introduced to reward prescribing. Simply assuming that the reminder system alone caused the reduction in infection rates is naive.

#### ■ Simultaneous Nonrandomized Controls

To address some of the problems with historical controls, we might use **simultaneous controls**, which require additional measurements to be made with a new group of physicians and their patients who are not influenced by the prophylactic antibiotic reminder system—but who *are* subject to any other changes taking place in the environment.

This study design would be a parallel group comparative study with simultaneous controls; if the physicians are given the option to choose whether to use the

reminder system or not, it is a case control study. Table 13.4 gives hypothetical results of such a study, focusing on postoperative infection rates as a single outcome measure or dependent variable. The independent variables are time and group, both of which have two levels.

Table 13.4 illustrates improvement in the group where reminders were available, but no improvement—indeed a slight deterioration—where no reminders were available. This design provides suggestive evidence of an improvement that is most likely to be due to the reminder system.

However, even though the controls in this example are simultaneous, attribution of the effect to the information resources remains refutable because there may be some systematic, unknown difference between the clinicians and/or patients in the two groups. For example, if the two groups comprised the patients and clinicians in two adjacent wards, the difference in the infection rates could be attributable to differences between the wards. Perhaps hospital-staffing levels improved in some wards but not in others, or there was cross infection by a multiple-resistant organism only among the patients in the control ward. To overcome such criticisms, we could try to measure everything that happens to every patient in both wards and to build complete profiles of all staff to rule out systematic differences. Even then, attribution of the effect to the information resources would be vulnerable to the accusation that some variable that we did not measure—and did not even know about—explains the difference. An alternative strategy is to make the intervention and control groups statistically comparable by randomizing them.

■ **Table 13.3** Results from a hypothetical before-after study of the impact of reminders on post operative infection rates

	Prescribing rate (%)	Infection rate (%)
Baseline	40	10
Post-intervention	60	5

■ **Table 13.4** Results of a hypothetical non-randomized parallel group study of reminders and post op infection rates

	Reminder group (%)	Control group (%)
Baseline rate	10	10
Post-intervention rate	5	11

### ■ Simultaneous Randomized Controls

The crucial problem in the previous example is that, although the controls were simultaneous, there may have been systematic, unmeasured differences between them and the participants receiving the intervention (Liu and Wyatt 2011). A simple and effective way of removing systematic differences, whether due to known or unknown factors, is to randomly assign participants to control or intervention groups. Thus, we could randomly allocate one-half of the physicians to receive the antibiotic reminders and the remaining physicians to work as they did before. We would then measure and compare postoperative infection rates in patients managed by physicians in the reminder and control groups. Provided that the physicians care only for their assigned patients, any difference that is statistically “significant” (conventionally, a result that is statistically determined to have a probability of 0.05 or less of occurring by chance) can be attributed reliably to the reminders.

■ Table 13.5 shows the hypothetical results of such a study. The baseline infection rates in the patients managed by the two groups of physicians are similar, as we would expect, because the patients were allocated to the groups by chance. There is a greater reduction in infection rates in patients of reminder physicians compared with those of control physicians. Because strict random assignment means that there was no systematic difference in physician or patient characteristics between groups, the only systematic

difference between the two groups of patients is receipt of reminders by their physicians.

Provided that the number of patients is large enough to provide a sufficient number of events (post op infections) for these results to be statistically significant (about 250 infections observed overall), we would conclude with some confidence that providing physicians with reminders **caused** the reduction in infection rates. The small reduction, from baseline to installation, in infection rates in control cases is not unexpected, even in a perfectly randomized study. It could reflect changes in practice policy that affected both groups, some cross-talk among physicians who work in the same setting, or the Hawthorne Effect (whereby people’s performance often improves when it is studied). These phenomena occur in the real world of evaluation and should be expected. However, because the pre-post difference in the reminder group was larger, an effect due to the information resource is likely to have occurred.

#### 13.5.2.5 Drawing Conclusions from Observational Data: Real World Evidence

Demonstration studies using a planned, prospective data collection process share a number of challenges, including their cost, inevitable delays setting up the study and recruiting participants--and the concern that, because of the volunteer effect or other biases, the results will not confidently generalize to typical resource users, patients, or care settings. The use of so-called observational data from routinely generated patient care records--often linked to administrative or other data sources--could overcome many of these limitations and offer a more economical and faster method to address evaluation questions related to information resources. Ideally, such studies can be performed retrospectively with all necessary data drawn from existing data repositories and no further data collection required. These methods give rise to what is coming to be called Real World Evidence (RWE). As ever-increasing amounts of routinely collected data become available in coded digital forms, there is growing interest in RWE (Sherman et al. 2016).

RWE methods are increasingly important but also have important limitations. In the

■ **Table 13.5** Results of a hypothetical randomized controlled trial of the impact of reminders on post op infection rates

	Reminder physicians (%)	Control physicians (%)
Baseline infection rate	11	10
Post intervention infection rate	6	9
Difference in infection rate	-5	-1

absence of the kinds of controls described in the previous section of this chapter, it difficult to attribute any observed user effects or problem impacts to a specific cause. The analysis of observational data typically results in a pattern of correlations among the variables included in an analysis. This pattern of correlations must be interpreted with great care. For example, if Factor A (for example, extent of use of a decision support system) is correlated with outcome O (for example, fewer medication errors), A is not necessarily a direct cause of O. It may be the case that some Factor B (for example, clinical workload), which was not included in the study but which is correlated with A, is the true cause of O. There is, however, no way to know this, because Factor B was not included in the data set used for the study. This phenomenon is known as unmeasured confounding, and is the primary source of concern when putative causal conclusions are drawn from observational data.

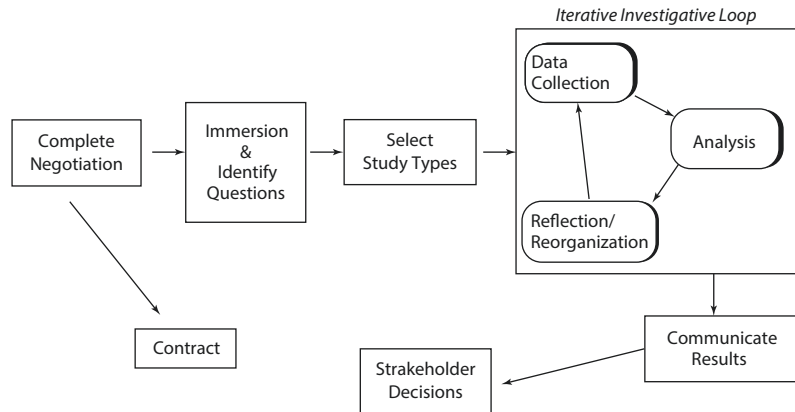

Other concerns arise with the quality of data drawn from documentation of routine care. Data entered by care providers themselves under pressure of time will not be expected to be as accurate and precise as data entered by an undistracted research assistant paid to be careful observer. Also, incompleteness in observational data may not be randomly distributed, so simply increasing the sample size or the range of included variables may make matters worse, not better. A further consideration is confounding by indication, in which the (usually unconscious) prejudice of clinicians leads to biased prescribing or recommendations to patients to use new, expensive or risky apps, online consultations or other digital services for those patients with the best – or the worst – prognosis. In these cases, a straightforward analysis will overestimate effectiveness, so a technique called propensity scoring is needed (McMurry et al. 2015).

Methods from the field of econometrics can be very helpful for establishing causal relationships between variables in observational studies. One approach is instrumental variable (IV) methods that attempt to identify an “instrument” that usually determines whether a treatment is given (Davey Smith et al. 2007). A clinical example might arise when trying to

estimate the benefit of bone marrow transplant (BMT) in acute myeloid leukemia in children without performing a randomized trial. It can be argued that one can compare mortality in this condition between children with and without a living sibling, since nearly all children with this leukemia and a live sibling will get a BMT and those without a sibling are much less likely to have a successful transplant. Since the presence of a living sibling is unrelated to whether a child has the disease, this kind of observational study might be almost as informative as a randomized trial for determining whether BMT is effective [3]. An informatics example would be if some diabetic patients are covered for online consultations by their health insurance while others are not. As long as we are satisfied that there are no systematic differences in disease severity or treatment adherence between the two patient groups, we could use the IV method to estimate the impact of online consultation on diabetes control and progression, assuming that those who are covered to use online consultations will usually take that option. However, the major challenge in designing an IV study is to identify an instrument that fulfils the following essential criteria: it usually dictates whether the intervention is given, does not affect the outcome except via the intervention, and is not correlated in any way with the outcome, or with other factors that cause it (Streeter et al. 2017; Gray et al. 2019).

In the age of “big data”, observational studies generating Real World Evidence will become increasingly important, but from the perspective of evaluation in informatics, they will apply only to field studies, and principally to user effect and problem impact studies. The seven other study types will remain largely reliant on prospective methods, although prospective studies too can benefit from the existence of data marts by incorporating already-available data whenever possible. As data quality improves, data marts become more comprehensive, and methods to establish causation gain increased sophistication, RWE methods will continue to mature. For studies addressing health outcomes--what this chapter refers to as problem impact studies--it is almost inevitable that Real World Evidence approaches will

**Fig. 13.3** Generic structure depicting a subjectivist investigation

assume an important place alongside randomized designs and in the best possible scenario, the two will complement each other.

### 13.5.3 Conduct of Subjectivist Studies

The objectivist comparative approaches to evaluation, described in the previous section, are useful for addressing some, but not all, of the interesting and important questions that challenge investigators in medical informatics. The subjectivist approaches described in this section address the problem of evaluation from a very different set of premises. They use different but equally rigorous methods. **Figure 13.3** expands the generic process for conducting evaluation studies to illustrate the stages involved in conducting a subjectivist study and emphasizes the “iterative loop” of data collection, analysis and reflection as the major distinguishing characteristic of a subjectivist investigation. Another distinctive feature of subjectivist studies is an immersion in the environment where the resource has been or will be deployed. Because subjectivist approaches may be less familiar to readers, we describe subjectivist studies in more detail than we did their objectivist counterparts.

#### 13.5.3.1 The Rationale for Subjectivist Studies

Subjectivist methods enable us to address the deeper questions that arise in informatics: the detailed, individualistic “whys”

and “according to whoms” in addition to the aggregate “whethers” and “whats.” Subjectivist approaches seek to represent the viewpoints of people who are users of the resource or are otherwise significant participants in the environment where the resource operates. The goal is illumination rather than judgment. The investigators seek to build an argument that promotes deeper understanding of the information resource or environment of which it is a part. The methods used derive largely from ethnography (Forsythe 1992; Ventres et al. 2006; Pope et al. 2013). The investigators immerse themselves physically in the environment (the “field”) where the information resource is or will be operational, and collect data primarily through observations, interviews, or reviews of documents. The designs—or data-collection plans—of these studies are not rigidly predetermined and do not unfold in a fixed sequence. They develop dynamically and nonlinearly, as the investigators’ experience in the field accumulates.

#### 13.5.3.2 A Rigorous, but Different, Methodology

These subjectivist approaches to evaluation, like their objectivist counterparts, are empirical methods. Although it is easy to focus only on their differences, these two broad classes of evaluation approaches share many features. In all empirical studies, for example, data are collected with great care; the investigators are always aware of what they are doing and why. The data are then compiled, interpreted, and ultimately reported.

Investigators keep records of their procedures, and these records are open to audit by the investigators themselves or by individuals outside the study team. The principal investigator or evaluation-team leader is under an almost sacred scientific obligation to report the study methods. Failure to do so will invalidate a study. Both classes of approaches also share a dependence on theories that guide investigators to explanations of the observed phenomena, as well as to a dependence on the pertinent literature such as published studies that address similar phenomena or similar settings. In both approaches, there are rules of good practice that are generally accepted; it is therefore possible to distinguish a “good” study from a bad one.

There are, however, fundamental differences between objectivist and subjectivist approaches. First, subjectivist studies are **emergent** in design. Objectivist studies typically begin with a set of hypotheses or specific questions, and with a plan for addressing each member of this set. The investigator assumes that, barring major unforeseen developments, the plan will be followed exactly. Deviation would be seen as a potential source of bias. For example, an objectivist investigator who sees negative results emerging from the exploration of a particular question or use of a particular measurement instrument might be inclined to change strategies in hope of obtaining more positive findings. In contrast, subjectivist studies typically begin with general orienting issues that stimulate the early stages of investigation. Through these initial investigations, the important questions for further study emerge. The subjectivist investigator is willing, at virtually any point, to adjust future aspects of the study in light of the most recent information obtained, while carefully recording that this had happened and why. Subjectivist investigators tend to be incrementalists; they thoughtfully change their plans as necessary from day-to-day and have a high tolerance for ambiguity and uncertainty. In this respect, they are much like good software developers. Also like software developers, subjectivist investigators must develop the ability to recognize when a project is finished, when further benefit can

be obtained only at too great a cost in time, money, or work.

A second feature of subjectivist studies is a **naturalistic** orientation: a reluctance to manipulate the setting of the study, which in informatics is typically the environment into which the information resource is introduced. Subjectivist studies do not alter the environment to study it. Control groups, placebos, purposeful altering of information resources to create contrasting interventions, and other techniques that are central to the construction of objectivist studies typically are not used. Subjectivist studies will, however, employ quantitative data for descriptive purposes and may offer quantitative comparisons when the research setting offers a “natural experiment” where such comparisons can be made without deliberate manipulation. For example, when physicians and nurses both use a clinical system to enter orders, the differing experiences of the two professional groups offer a natural basis for comparison. Subjectivist researchers are opportunists where pertinent information is concerned; they will use what they see as the best information available to illuminate a question under investigation.

A third important distinguishing feature of subjectivist studies is that their end product is a report written in narrative prose. While these reports may be lengthier than the statistical reports from objectivist studies, no technical understanding of quantitative research methodology is required to comprehend them. Results of subjectivist studies are therefore accessible—and may even be entertaining—to a broad community in a way that results of objectivist studies are not. Reports of subjectivist studies seek to engage their audience.

### 13.5.3.3 Natural History of a Subjectivist Study

■ Figure 13.3 illustrates the stages that characterize a subjectivist study (see also Chap. 9 in Friedman and Wyatt 2005). These stages constitute a general sequence, but, as we mentioned, subjectivist investigators must always be prepared to revise their thinking and possibly to return to earlier stages in light of new

data or insights resulting from its analysis. Backtracking is a legitimate step in this model.

1. *Negotiation of the ground rules of the study:* The understanding between the study team and the persons commissioning a study should embrace the general aims of the study; the kinds of methods to be used; access to various sources of information, including health care providers, patients, and various documents; and the format for interim and final reports. The aims of the study may be formulated in a set of initial **orienting questions**. Ideally, this understanding will be expressed in a memorandum of understanding, analogous to a contract.
2. *Immersion into the environment:* At this stage, the investigators begin spending time in the work environment. Their activities range from formal introductions to informal conversations, or to silent presence at meetings and other events. Investigators use the generic term **field** to refer to the setting, which may be multiple physical locations, where the work under study is carried out. Trust and openness between the investigators and the people in the field are essential elements of subjectivist studies to ensure full and candid exchange of information.

Even as immersion is taking place, the investigator is already collecting data to sharpen the initial questions or issues guiding the study. Early discussions with people in the field, and other activities primarily targeted toward immersion, inevitably begin to shape the investigators' views. Almost from the outset, the investigator is typically addressing several aspects of the study simultaneously.

3. *Iterative loop:* At this point, the procedural structure of the study becomes akin to an iterative loop, as the investigator engages in cycles of data collection, analysis and reflection, "member checking", and reorganization. Data collection involves interview, observation, document analysis, and other methods. Data are collected on planned occasions, as well as serendipitously and spontaneously. The data are recorded carefully and are interpreted in

the context of what is already known. Analysis and reflection entail the contemplation of the new findings during each cycle of the loop. Member checking is the sharing of the investigator's emerging thoughts and beliefs with the participants themselves. Reorganization results in a revised agenda for data collection in the next cycle of the loop.

Although each cycle within the iterative loop is depicted as unidirectional, this representation is misleading. Net progress through the loop is clockwise, as shown in  Fig. 13.3, but backward steps are natural and inevitable. They are not reflective of mistakes or errors. An investigator may, after conducting a series of interviews and studying what participants have said, decide to speak again with multiple participants to clarify their positions on a particular issue.

4. *Communicate results:* Subjectivist studies tend to have a multi-staged reporting and communication process. The first draft of the study report should itself be viewed as a research instrument. By sharing this report with a variety of individuals, the investigator obtains a major check on the validity of the findings. Typically, reactions to the preliminary report will generate useful clarifications and a general sharpening of the study findings. Because the report usually includes a prose narrative, it is vitally important that it be well written in language understandable by all intended audiences. Circulation of the report in draft, for comments by the intended recipients, can ensure that the final document communicates as intended. Use of anonymous quotations from interviews and documents makes a report highly vivid and meaningful to readers.

The final report, once completed, should be distributed as negotiated in the original memorandum of understanding. Distribution is often accompanied by "meet the investigator" sessions that allow interested persons to ask the author of the report to expand or explain what has been written.

### 13.5.3.4 Subjectivist Data-Collection and Data-Analysis Methods

What data-collection strategies are in the subjectivist researcher's tool kit? There are several, and they are typically used in combination. We shall discuss each one, assuming a typical setting for a subjectivist study in biomedical informatics: the introduction of an information resource into patient care activities in a hospital.

#### ■ Observation

The investigators typically immerse themselves into the setting under study in one of two ways. The investigator may act purely as a detached observer, becoming a trusted and unobtrusive feature of the environment but not a participant in the day-to-day work and thus reliant on multiple "informants" as sources of information. True to the naturalistic feature of this kind of study, great care is taken to diminish the possibility that the presence of the observer will skew any work activities or that the observer will be rejected outright by the team. An alternative approach is participant observation, where the investigator becomes a member of the work team. Participant observation is more difficult to engineer; it may require the investigator to have specialized training in the study domain. It is time consuming but can give the investigator a more vivid impression of life in the work environment. During both kinds of observation, data accrue continuously. These data are qualitative and may be of several varieties: statements by health care providers, patients, family members, administrative staff, and others; gestures and other nonverbal expressions of these same individuals; and characteristics of the physical setting that seem to affect the delivery of health care.

#### ■ Interviews

Subjectivist studies rely heavily on interviews. Formal interviews are occasions where both the investigator and interviewee are aware that the answers to questions are being recorded (on paper or digitally) for direct contribution to the evaluation study. Formal interviews vary in their degree of structure. At one extreme is the unstructured interview, where there

are no predetermined questions. Between the extremes is the semi structured interview, where the investigator specifies in advance a set of topics that he/she would like to address—but is flexible as to the order in which these topics are addressed, and is open to discussion of topics not on the pre-specified list. At the other extreme is the structured interview, with a schedule of questions that are always presented in the same words and in the same order. In general, the unstructured and semi structured interviews are preferred in subjectivist research. Informal interviews—spontaneous discussions between the investigators and members of a team that occur during routine observation—are also part of the data collection process. Informal interviews are invariably considered a source of important data. Group interviews, akin to focus groups, may also be employed (e.g., Haddow et al. 2011). Group interviews are very efficient ways to reach large numbers of participants, but investigators should not assume that individual participants will express in a group setting the same sentiments they will express if interviewed one-on-one.

Sampling also enters into the interview process. There are usually more participants to interview than resources to conduct them. Unlike in objectivist studies, where random sampling is a form of gold standard to inform statistical attributions of effects, subjectivist studies employ more purposeful sampling strategies. Investigators might actively seek interviewees they suspect to have unique or particularly insightful or influential opinions. They might remain in more frequent contact with key informants who, for various reasons, have the most insight into what is happening.

#### ■ Document and Artifact Analysis

Every project produces a trail of papers and other artifacts. These include patient charts, the various versions of an information resource and its documentation, memoranda prepared by the project team, perhaps a cartoon hung on an office door. Unlike the day-to-day events of health care, these artifacts do not change once created or introduced. With appropriate permissions negotiated in advance, they can be examined retrospectively

and referred to repeatedly, as necessary, over the course of a study. Also included under this heading are **unobtrusive measures**, which are the records accrued as part of the routine use of the information resource. They include, for example, user log files of an information resource. Data from these measures are often quantifiable and analyzed quantitatively even though the overall study design is qualitative in nature.

#### ■ Anything Else That Seems Useful

Subjectivist investigators are supreme opportunists. As questions of importance to a study emerge, the investigators will collect any information that they perceive as bearing on these questions. This data collection could include clinical chart reviews, questionnaires, tests, simulated patients, and other methods more commonly associated with the objectivist approaches.

When to end data collection is another challenge in otherwise open-ended subjectivist studies. “Saturation” is important principle to help investigators know when to stop. Stated simply, a data collection process is saturated when it becomes evident that, as more data are collected, no new findings or insights are emerging.

#### ■ Analysis of Subjectivist Data

There are many alternative procedures for analysis of qualitative data. In general terms, the investigator looks for insights, themes or trends emerging from several different sources. He/she collates individual statements and observations by theme, as well as by source. Investigators typically use software especially designed to facilitate analysis of qualitative data.<sup>6</sup> Because they allow electronic recording of the data while the investigator is “in the field”, tablets, smartphone Apps and other

hand-held devices are changing the way subjectivist research is carried out.

The subjectivist analysis process is fluid, with analytic goals shifting as the study matures. At an early stage, the goal is primarily to focus the questions that themselves will be the targets of further data elicitation. At the later stages of study, the primary goal is to organize data that address these questions into specific themes, interpretations, and explanations. Conclusions derive credibility from a process of “triangulation”, which is the degree to which information from different independent sources generate the same theme or point to the same conclusion. Subjectivist analysis also employs a strategy known as “member checking” whereby investigators take preliminary conclusions back to the persons in the setting under study, asking if these conclusions make sense, and if not, why not. In subjectivist investigation, unlike objectivist studies, the agenda is never completely closed. The investigator is constantly on the alert for new information that can require a significant reorganization of the findings and conclusions that have been drawn to date.

### 13.6 Communicating Evaluation Results

Once any study, qualitative or quantitative, is complete, the results need to be communicated to the stakeholders and others who might be interested. In many ways, communication of evaluation results, a term we prefer over “reporting”, is the most challenging aspect of evaluation. Elementary theory tells us that, in general, successful communication requires a sender, one or more recipients, and a channel linking them, along with a message that travels along this channel (Ong and Coiera 2011).

Seen from this perspective, successful communication of evaluation results is challenging in several respects. It requires that the recipient of the message actually receive it. That is, for evaluations, the recipient must read the written report or attend the meeting intended to convey evaluation results.

6 Examples include: Atlas.ti ► <https://atlasti.com/> (Accessed November 18, 2019) and NVivo ► <https://www.qsrinternational.com/nvivo/home> (Accessed November 18, 2019).

For this reason, the investigator is invariably challenged to create a report the stakeholders will want to read or to choreograph a meeting they will be motivated to attend. Successful communication also requires that the recipient understand the message, which challenges investigators to draft written documents at the right reading level, with audience-appropriate technical detail. Sometimes there must be several different forms of the written report to match several different audiences. Overall, we encourage investigators to recognize that their obligation to communicate does not end with the submission of a written document comprising their technical evaluation report. The report is one channel for communication, not an end in itself.

Depending on the nature, number, and location of the recipients—and permissions which have been obtained or written into evaluation agreements—many options exist for communicating the results of a study, including:

- Written reports
  - Document(s) prepared for specific audience(s)
  - Internal newsletter article
  - Published journal article, with appropriate permissions
  - Monograph, picture album, or book
- One-to-one or small group meetings
  - With stakeholders or specific stakeholder groups
  - With the general public, if appropriate
- Formal oral presentations
  - To groups of project stakeholders
  - Conference presentation with a poster or published paper in proceedings
  - To external meetings or seminars
- Internet
  - Project Web site or blog
  - Web “chat”, forum or Twitter feed to socialize results
  - Online preprint
  - Internet based journal
- Other
  - Video or podcast describing the study and information resource
  - Interview with a journalist on newspaper, TV, radio

A written, textual report is not the sole medium for communicating evaluation results. Verbal, graphical, or multimedia approaches can be helpful as ways to enhance communication with specific audiences. Another useful strategy is to hold a “town meeting” to discuss a traditional written report after it has been released. Photographs or videos can portray the work setting for a study, the people in the setting, and the people using the resource. If appropriate permissions are obtained, these images—whether included as part of a written report, shown at a town meeting, or placed on a Web site—can be worth many thousands of words. The same may be true for recorded statements of resource users. If made available, with permission, as part of a multimedia report, the voices of the participants can convey a feeling behind the words that can enhance the credibility of the investigator’s conclusions (■ Fig. 13.4).

In addition to the varying formats for communication described above, investigators have other decisions to make after the data collection and analysis phases of a study are complete. One key decision is what personal role they will adopt after the formal investigative aspects of the work are complete. They may elect only to communicate the results, but they may also choose to persuade stakeholders to take specific actions in response to the study results, and perhaps even assist in the implementation of these actions. This raises a key question: Is the role of an evaluator simply to record and communicate study findings and then to move on to the next study, or is it also to engage with the study stakeholders and help them change how they work as a result of the study?

To answer this question about the role of an evaluator, we need to understand that an evaluation study, particularly a successful one, has the potential to trigger a series of events, starting with the communication of study results, but then including interpretation, recommendation, and even implementation. Some evaluators—perhaps enthused by the clarity of their results and an opportunity to use them to improve health care, biomedical research, or education—prefer to go beyond

■ **Fig. 13.4** A picture is worth 1000 words: in the report of a study to establish the need for an electronic patient record, a casual photograph like this may prove much more persuasive than a table of data or paragraphs of prose

13

reporting the results and conclusions to making recommendations. The dilemma often faced by evaluators is whether to retain their scientific detachment and merely report the study results, or to stay engaged somewhat longer. Investigators who choose to remain may become engaged in helping the stakeholders interpret what the results mean, guiding them in reaching decisions and perhaps even in implementing the actions decided upon. The longer they stay, the greater the extent to which evaluators must leave behind their scientific detachment and take on a role more commonly associated with change agents (Lunenburg 2010). Some confounding of these roles is inevitable when the evaluation is performed by individuals within the organization that developed the information

resource under study. There is no hard-and-fast rule for deciding on the most appropriate role for the evaluator; the most important initial realization for investigators is that the different options exist and that a decision among them must inevitably be made.

### 13.7 Conclusion: Evaluation as an Ethical and Scientific Imperative

Evaluation takes place, either formally or informally, throughout the resource development cycle: from defining the need to monitoring the continuing impact of a resource once it is deployed (Stead et al. 1994). We have seen in this chapter that different issues are explored, at different degrees of intensity, at each stage of resource development. For meaningful evaluation to occur, adequate amounts must be allocated for these studies when time and money are budgeted for a development effort. Evaluation cannot be left to the end of a project. While formal evaluations, as we have described them here, are still seen as optional for resources of the types that are the foci of biomedical and health informatics, the increasing complexity and prevalence of these resources have raised concerns about their safety and effectiveness when used in the real world (e.g., Koppel et al. 2005). For the moment, we would argue that formal evaluations, using the range of methods described in this chapter, are mandated by the professional ethics of biomedical informatics as an applied scientific discipline (see ► Chap. 12).

Formal evaluations of biomedical information resources may someday be a statutory or regulatory requirement in many or all parts of the world, as they are already for new drugs or medical devices. If and when that day comes, the wide variety of questions to be addressed and the diversity of legitimate methods available to address those questions, as described in this chapter, will make it difficult to describe with exactitude how these studies should be done. There have been some published academic checklists or guidelines

describing things to study and report in such studies (Talmon et al. 2009), but this is a bridge to be crossed in the future. We express the hope that writers of such guidelines and regulations will not overprescribe the methods to be used, while insisting on rigor in drawing conclusions from data collected using study designs thoughtfully matched to carefully identified questions. We hope the reader has learned from this chapter that rigor in evaluation is achievable in many ways, that information resources raise unique challenges when they are the foci for evaluation, and that overly rigid prescription of evaluation methods, however well intentioned, could defeat their well-intentioned purpose. However, it is also clear that the intensity of the evaluation effort should be closely matched to the resource's maturity (Stead et al. 1994). The UK Medical Research Council's Framework for Complex Interventions (Campbell et al. 2000), or a more recent variation intended for digital interventions (Murray et al. 2016) point out that it is unwise to conduct an expensive user-effect field trial of an information resource that is barely complete, is still in prototype form, may evolve considerably before taking its final shape, or is so early in its development that it may fail because programing bugs have not been eliminated.

We believe that readers of this chapter will to varying degrees be critical appraisers of, participants in, and/or conductors of evaluation studies. In playing any or all of these roles, it is important to recognize that evaluation sits at the junction where the art of the possible, given the complexity of informatics interventions, meets the rigor of scientific method drawn from the objectivist and subjectivist traditions.

**Acknowledgment** The authors wish to acknowledge Nikolas Koscielniak for his multiple important contributions to this chapter. This chapter is adapted from material in an earlier edition of the textbook that was also co-authored by Douglas K. Owens.

## Appendices

### Appendix A: Two Evaluation Scenarios

Here we introduce two scenarios that collectively capture many of the dilemmas facing those planning and conducting evaluations in biomedical informatics:

1. A prototype information resource has been developed, but its usability and potential for benefit need to be assessed prior to deployment;
2. A commercial resource has been deployed across a large enterprise, and there is need to understand its impact on users as well as on the organization.

These scenarios do not address the full scope of evaluations in biomedical informatics, but they cover a lot of what people do. For each, we introduce sets of evaluation questions that frequently arise and examine the dilemmas that investigators face in the design and execution of evaluation studies.

#### ■ Scenario 1: A Prototype Information Resource Has Been Developed, but Its Usability and Potential for Benefit Need to Be Assessed Prior to Deployment

The primary evaluation issue here is the upcoming decision to continue with the development of the prototype information resource. Validation of the design and structure of the resource will have been conducted, either formally or informally, but not yet a usability study. If this looks promising, a laboratory evaluation of key functions is also advised before making the substantial investment required to turn a promising prototype into a system that is stable and likely to bring more benefits than problems to users in the field. Here, typical questions will include:

- Who are the target users, and what are their background skills and knowledge?
- Does the resource make sense to target users?

- Following a brief introduction, can target users navigate themselves around important parts of the resource?
- Can target users carry out a selection of relevant tasks using the resource, in reasonable time and with reasonable accuracy?
- What user characteristics correlate with the ability to use the resource and achieve fast, accurate performance with it?
- What other kinds of people can use it safely?
- How to improve the layout, design, wording, menus etc.
- Is there a long learning curve? What user training needs are there?
- How much on-going help will users require once they are initially trained?
- What concerns do users have about the system – e.g., accuracy, privacy, effect on their jobs, other side effects
- Based on the performance of prototypes in users' hands, does the resource have the potential to meet user needs?

These questions fall within the scope of the usability and laboratory function testing approaches listed in ■ Table 15.1. A wide range of techniques—borrowed from the human-computer interaction field and employing both objectivist and subjectivist approaches—can be used, including:

- Seeking the views of potential users after both a demonstration of the resource and a hands-on exploration. Methods such as focus groups may be very useful to identify not only immediate problems with the software and how it might be improved, but also potential broader concerns and unexpected issues that may include user privacy and long term issues around user training and working relationships.
- Studying users while they carry out a list of pre-designed tasks using the information resource. Methods for studying users includes watching over their shoulder, video observation (sometimes with several video cameras per user); think aloud

protocols (asking the user to verbalize their impressions as they navigate and use the system); and automatic logging of keystrokes, navigation paths, and time to complete tasks.

- Use of validated questionnaires to capture user impressions, often before and after an experience with the system, one example being the Telemedicine Preparedness questionnaire (Demiris et al. 2000).
- Specific techniques to explore how users might improve the layout or design of the software. For example, to help understand what users think of as a “logical” menu structure for an information resource, investigators can use a card sorting technique. This entails listing each function available on all the menus on a separate card and then asking users to sort these cards into several piles according to which function seems to go with which [► [www.useit.com](http://www.useit.com)].

Depending on the aim of a usability study, it may suffice to employ a small number of potential users. Nielsen has shown that, if the aim is to identify only major software faults, the proportion identified rises quickly up to about 5 or 6 users then much more slowly to plateau at about 15–20 users (Nielsen 1994). Five users will often identify 80% of software problems. However, investigators conducting such small studies, useful though they may be for software development, cannot then expect to publish them in a scientific journal. The achievement in this case is having found answers to a very specific question about a specific software prototype. This kind of local reality test is unlikely to appeal to the editors or readers of a journal. By contrast, the results of formal laboratory function studies, that typically employ more users, are more amenable to journal publication.

- **Scenario 2: A Commercial Resource Has Been Deployed Across a Large Enterprise, and There Is Need to Understand its**

### Impact on Users as Well as on the Organization

The type of evaluation questions that arise here include:

- In what fraction of occasions when the resource could have been used, was it actually used?
- Who uses it, why, are these the intended users, and are they satisfied with it?
- Does using the resource improve influence information/communication flows?
- Does using the resource influence their knowledge or skills?
- Does using the resource improve their work?
- For clinical information resources, does using the resource change outcomes for patients?
- How does the resource influence the whole organization and relevant sub units?
- Do the overall benefits and costs or risks differ for specific groups of users, departments, the whole organization?
- How much does the resource really cost the organization?
- Should the organization keep the resource as it is, improve it or replace it?
- How can the resource be improved, at what cost, and what benefits would result?

To each of the above questions, one can add: “Why, or why not?”, to get a broader understanding of what is happening as a result of use of the resource.

This evaluation scenario, suggesting a problem impact study, is often what people think of first when the concept of evaluation is introduced. However, we have seen in this chapter that it is one of many evaluation scenarios, arising relatively late in the life cycle of an information resource. When these impact-oriented evaluations are undertaken, they usually result from a realization by stakeholders, who have invested significantly in an information resource, that the benefits of the resource are uncertain and there is need to justify recurring costs. These stakeholders usually vary in the kind of evaluation methods that will convince them about the impacts that the resource is or is not having. Many such stakeholders will wish to see quantified indi-

ces of benefits or harms from the resource, for example the number of users and daily uses, the amount the resource improves productivity or reduces costs, or perhaps other benefits such as reduced waiting times to perform key tasks or procedures, lengths of hospital stay or occurrence of adverse events. Such data are collected through objectivist studies as discussed earlier. Other stakeholders may prefer to see evidence of perceived benefit and positive views of staff, in which case staff surveys, focus groups and unstructured interviews may prove the best evaluation methods. Often, a combination of many methods is necessary to extend the investigation from understanding what impact the resource has to why this impact occurs – or fails to occur.

If the investigator is pursuing objectivist methods, deciding which of the possible effect variables to include in an impact study and developing ways to measure them can be the most challenging aspect of an evaluation study design. (These and related issues receive the attention of five full chapters of a textbook by the authors of this chapter (Friedman and Wyatt 2005).) Investigators usually wish to limit the number of effect measures employed in a study for many reasons: limited evaluation resources, to minimize manipulation of the practice environment, and to avoid statistical analytical problems that result from a large number of measures.

Effect or impact studies can also use subjectivist approaches to allow the most relevant “effect” issues to emerge over time and with increasingly deep immersion into the study environment. This emergent feature of subjectivist work obviates the need to decide in advance which effect variables to explore, and is considered by proponents of subjectivist approaches to be among their major advantages.

In health care particularly, every intervention carries some risk, which must be judged in comparison to the risks of doing nothing or of providing an alternative intervention. It is difficult to decide whether an information resource is an improvement unless the performance of the current decision-takers is also measured in a comparison-based evaluation. For example, if physicians’ decisions are to

become more accurate following introduction of a decision-support tool, the resource needs to be “right” when the user would usually be “wrong” This could mean that the tool’s error rate is lower than that of the physician, or its errors are in different cases, or they should be of a different kind or less serious than those of the clinician, so as not to introduce new errors caused by the clinician following resource advice even when that advice is incorrect – “automation bias” (Goddard et al. 2012).

For effect studies, it is often important to know something about how the practitioners carry out their work prior to the introduction of the information resource. Suitable measures include the accuracy, timing, and confidence level of their decisions and the amount of information they require before making a decision. Although data for such a study can sometimes be collected by using abstracts of cases or problems in a laboratory setting (■ Fig. 15.2), these studies inevitably raise questions of generalization to the real world. We observe here one of many trade-offs that occur in the design of evaluation studies. Although control over the mix of cases possible in a laboratory study can lead to a more precise estimate of practitioner decision making, ultimately it may prove better to conduct a baseline study while the individuals are doing real work in a real practice setting. Often this audit of current decisions and actions provides useful input to the design of the information resource, and a reference against which resource performance may later be compared.

When conducting problem impact studies in health care settings, investigators can sometimes save themselves much time and effort without sacrificing validity by measuring effect in terms of certain health care processes rather than patient outcomes, in other words by employing a user effect study as a proxy for a problem impact study. For example, measuring the mortality or complication rate in patients with heart attacks requires data collection from hundreds of patients, as complications and death are (fortunately) rare events. However, as long as large, rigorous trials or meta-analyses have determined that a certain procedure (e.g., giving heart attack

patients streptokinase within 24 h) correlates closely with the desired patient outcome, it is perfectly valid to measure the rate of performing this procedure as a valid “surrogate” for the desired outcome. Mant and Hicks demonstrated that measuring the quality of care by quantifying a key process in this way may require one tenth as many patients as measuring outcomes (Mant and Hicks 1995).

## Appendix B: Exemplary Evaluation Studies

---

In this appendix, we briefly summarize studies that align with many of the study types described in ■ Tables 13.1 and 13.2.

**Usability Study** *Assessing Performance of an Electronic Health Record Using Cognitive Task Analysis.*

Saitwal et al. (2010) is a pure usability testing study that evaluates the Armed Forces Health Longitudinal Technology Application EHR using a cognitive task analysis approach, referred to as Goals, Operators, Methods, and Selection rules (GOMS). Specifically, authors evaluated the system response time and the complexity of the graphical user interface (GUI) when completing a set of 14 prototypical tasks using the EHR. Authors paid special attention to inter-rater reliability of the two evaluators using GOMS to analyze the GUI of the system through task completion. Each task was broken down into a series of steps, with the intent to determine the percent of steps classified as “mental operators”. Execution time was then calculated for each step and summed to obtain a total time for task completion.

**Lab Function Study** *Diagnostic inaccuracy of smartphone applications for melanoma detection.*

Wolf et al. (2013) conducted an evaluation study of smartphone applications capable of detecting melanoma and sought to determine the diagnostic inaccuracy. The study is exemplary of a lab function study and complements the Beaudoin et al. (2016) study

described below because study authors paid special attention to measuring application function in a lab setting using digital clinical images with a previous diagnosis obtained via histologic analysis by a dermatopathologist. Authors employed a comparative analysis between four different smartphone applications and assessed the sensitivity, positive predictive value, and negative predictive value of each application compared to histologic diagnosis. Rather than focus on the function in a real health care setting with real users, authors were interested in facilitating decision-making as to which applications performed best under controlled conditions.

**Field Function Study** *Evaluation of a machine learning capability for a clinical decision support system to enhance antimicrobial stewardship programs.*

Beaudoin et al. (2016) conducted an observational study to evaluate the function of a combined clinical decision support system (antimicrobial prescription surveillance system (APSS)) and a learning module for antimicrobial stewardship pharmacists in a Canadian university hospital system. Authors developed a rule-based machine learning module designed from expert pharmacist recommendations which triggers alerts for inappropriate prescribing of piperacillin–tazobactam. The combined system was deployed to pharmacists and outputs were studied prospectively over a five-week period within the hospital system. Analyses assessed accuracy, positive predictive value, and sensitivity of the combined system, the individual learning module, and the APSS compared to the pharmacist opinion. This is an exemplary field function study because authors are evaluating the ability of the combined rule-based learning module and APSS to detect inappropriate prescribing in the field with real patients.

**Lab User Effect Study** *Applying human factors principles to alert design increases efficiency and reduces prescribing errors in a scenario-based simulation.*

Russ et al. (2014) describe a study evaluating the redesign of alerts using human factors

principles and their influence on prescribing by providers. The study is exemplary of a lab user effect study because it analyzed frequency of prescribing errors by providers, and it was conducted in a simulated environment (the Human-Computer Interaction and Simulation Laboratory in a Veterans Affairs Medical Center). Authors were particularly interested in three types of alerts: drug-drug interactions, drug-allergy, and drug disease. Three scenarios were developed for this study that included 19 possible alerts. These alerts were intended to be familiar and unfamiliar to prescribers. Authors used a crossover design with a two-week “washout period” for participants to complete both original and redesigned alerts to reduce contamination in repeated measures. Special attention was paid to a repeated measures comparative analysis of the influence of original versus redesigned alerts on outcomes of perceived workload and prescribing errors. Authors also employed elements of usability testing during this study, such as assessing learnability, efficiency, satisfaction and usability errors.

**Field User Effect Study** *Reminders to physicians from an introspective computer medical record: A two-year randomized trial.*

McDonald et al. (1984) conducted a two-year randomized controlled trial to evaluate the effects of a computer-stored medical record system which reminds physicians about actions needed for patients prior to a patient encounter. This study most closely aligns with a field user effect study for the attention to behavior change in preventive care delivery associated with use of the information resource, and is exemplary because its rigorous design accounts for the hierarchical nature of clinicians working in teams without having to manipulate the practice environment. Randomization occurs at the clustered team level and analyses were performed at both the cluster and individual levels. The study did include problem impact metrics, however no significant changes were observed in these outcomes during the study.

**Field User Effect Study** *Electronic health records and health care quality over time in a federally qualified health center.*

Kern et al. (2015) conducted a three-year comparative study across six sites of a federally qualified health center in New York to analyze the association between post-implementation of an electronic health record (EHR) and quality of care delivery as measured by change in compliance with Stage 1 Meaningful Use quality measures. This study is an exemplary field user effect study for its attention to measures of clinician behavior in care delivery through test/screening ordering using the EHR and explicit use of statistical analysis techniques to account for repeated measures on patients over time. The study also includes two problem impact metrics (change in HbA1c and LDL cholesterol) analyzed over the study period; however, the study intent was primarily focused on clinician ordering behavior.

**Problem Impact Study** *Effects of a mobile phone short message service on antiretroviral treatment adherence in Kenya (WelTel Kenya1): A randomised trial.*

Lester et al. (2010) is an exemplar for problem impact studies. Authors conducted a randomized controlled trial to measure improvement in patient adherence to antiretroviral therapy (ART) and suppression of viral load following receipt of mobile phone communications with health care workers. The study randomized patients to the intervention group (receiving mobile phone messages from healthcare workers) or to the control group (standard care). Outcomes were clearly identified and focused on behavioral effects (drug adherence) and an overall intent to measure the extent that improvements in adherence influenced patient health status (viral load). The special attention to randomization and use of effect size metrics for analysis are critical components to measuring the overall impact of mobile phone communications on patient health.

### Suggested Reading

Ammenwerth, E., & Rigby, M. (Eds.). (2016). *Evidence-based health informatics.*

Amsterdam: IOS Press. This work includes an extensive exploration of evaluation methods pertinent to health informatics.

Anderson, J. G., & Aydin, C. E. (2005). *Evaluating the organizational impact of health care information systems.* New York: Springer. This is an excellent edited volume that covers a wide range of methodological and substantive approaches to evaluation in informatics.

Brender, J. (2006). *Handbook for evaluation for health informatics.* Burlington: Elsevier Academic Press. Along with the Friedman and Wyatt text cited below, one of few textbooks available that focuses on evaluation in health informatics.

Cohen, P. R. (1995). *Empirical methods for artificial intelligence.* Cambridge, MA: MIT Press. This is a nicely written, detailed book that is focused on evaluation of artificial intelligence applications, not necessarily those operating in medical domains. It emphasizes objectivist methods and could serve as a basic statistics course for computer science students.

Fink, A. (2004). *Evaluation fundamentals: Insights into the outcomes, effectiveness, and quality of health programs* (2nd ed.). Thousand Oaks: Sage Publications. A popular text that discusses evaluation in the general domain of health.

Friedman, C. P., & Wyatt, J. C. (2006). *Evaluation methods in biomedical informatics.* New York: Springer. This is the book on which the current chapter is based. It offers expanded discussion of almost all issues and concepts raised in the current chapter.

Jain, R. (1991). *The art of computer systems performance analysis: Techniques for experimental design, measurement, simulation, and modeling.* New York: Wiley. This work offers a technical discussion of a range of objectivist methods used to study computer systems. The scope is broader than Cohen's book (1995) described earlier. It contains many case studies and examples and assumes knowledge of basic statistics.

Lincoln, Y. S., & Guba, E. G. (1985). *Naturalistic inquiry.* Thousand Oaks: Sage Publications. This is a classic book on subjectivist methods. The work is very rigorous but also very easy to read. Because it does not focus on medical

domains or information systems, readers must make their own extrapolations.

Rossi, P. H., Lipsey, M. W., & Freeman, H. E. (2004). *Evaluation: A systematic approach* (7th ed.). Thousand Oaks: Sage Publications. This is a valuable textbook on evaluation, emphasizing objectivist methods, and is very well written. It is generic in scope, and the reader must relate the content to biomedical informatics. There are several excellent chapters addressing pragmatic issues of evaluation. These nicely complement the chapters on statistics and formal study designs.

### ? Questions for Discussion

1. Associate each of the following hypothetical evaluation scenarios with one or more of the nine types of studies listed in Table 13.1. Note that some scenarios may include more than one type of study.
  - (a) An order communication system is implemented in a small hospital. Changes in laboratory workload are assessed.
  - (b) The developers of the order communication system recruit five potential users to help them assess how readily each of the main functions can be accessed from the opening screen and how long it takes users to complete them.
  - (c) A study team performs a thorough analysis of the information required by psychiatrists to whom patients are referred by a community social worker.
  - (d) A biomedical informatics expert is asked for her opinion about a PhD project on a new bioinformatics algorithm. She requests copies of the student's code and documentation for review.
  - (e) A new intensive care unit system is implemented alongside manual paper charting for a month. At the end of this time, the quality of the computer-derived data and data recorded on the paper charts is compared. A panel of intensive care experts is asked to identify, independently, episodes of hypotension from each data set.
  - (f) A biomedical informatics professor is invited to join the steering group for a series of apps to support people living with diabetes. The only documentation available to critique at the first meeting is a statement of the project goal, description of the planned development method, and the advertisements and job descriptions for team members.
  - (g) Developers invite educationalists to test a prototype of a computer-aided learning system as part of a user-centered design workshop
  - (h) A program is devised that generates a predicted 24-h blood glucose profile using seven clinical parameters. Another program uses this profile and other patient data to advise on insulin dosages. Diabetologists are asked to prescribe insulin for a series of "paper patients" given the 24-h profile alone, and then again after seeing the computer-generated advice. They are also asked their opinion of the advice.
  - (i) A program to generate alerts to prevent drug interactions is installed in a geriatric clinic that already has a computer-based medical record system. Rates of clinically significant drug interactions are compared before and after installation of the alerting program.
2. Choose any alternative area of biomedicine (e.g., drug trials) as a point of comparison, and list at least four factors that make studies in biomedical informatics more difficult to conduct successfully than in that area. Given these difficulties, discuss whether it is worthwhile to conduct empirical studies in biomedical informatics or whether we should use intuition or the

- marketplace as the primary indicators of the value of an information resource.
3. Assume that you run a philanthropic organization that supports biomedical informatics. In investing the scarce resources of your organization, you have to choose between funding a new system or resource development, or funding empirical studies of resources already developed. What would you choose? How would you justify your decision?
  4. To what extent is it possible to be certain how effective a medical informatics resource really is? What are the most important criteria of effectiveness?
  5. Do you believe that independent, unbiased observers of the same behavior or outcome should agree on the quality of that outcome?
  6. Many of the evaluation approaches assert that a single unbiased observer is a legitimate source of information in an evaluation, even if that observer's data or judgments are unsubstantiated by other people. Give examples drawn from our society where we vest important decisions in a single experienced and presumed impartial individual.
  7. Do you agree with the statement that all evaluations appear equivocal when subjected to serious scrutiny? Explain your answer.

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What is the definition of an EHR?
- What are the functional components of an EHR?
- What are the benefits of an EHR?
- What are the some of the impediments to development, configuration, and use of an EHR?

## 14.1 What Is an Electronic Health Record?

The preceding chapters introduced the conceptual basis for the field of biomedical informatics, including the use of patient data in clinical practice and research. The chapters in this section cover the various technologies, systems, and approaches of biomedical informatics in practice. This chapter focuses on the **patient record** and associated systems, commonly referred to as the patient's chart, medical record, or health record. In particular, we define and examine the use of **electronic health records (EHRs)**,<sup>1</sup> discuss their purpose and functional components, potential benefits and costs, and describe current challenges and opportunities in their dissemination, optimal use, and innovation.

14

<sup>1</sup> The terms “electronic health record” (EHR) and “electronic health record system” (EHRS or EHR system) are often used interchangeably, with no generally agreed upon distinction. The terms “electronic medical record” (EMR) and “electronic medical record system” (EMRS or EMR system) have also been used but many have moved towards using the term “health” versus “medical” as these systems are being used broadly across the continuum of care by a multitude of roles; again, the distinctions between EMR and EMRS are not generally agreed upon. The term “computer-based record system” has also been used in the past. In this chapter, and throughout the book, we will use the term “electronic health record”, with the acronyms “EHR” and “EHRs” to designate the singular and plural forms, respectively.

### 14.1.1 Purpose of a Patient Record

Stanley Reiser (1991) wrote that the purpose of a patient record is “to recall observations, to inform others, to instruct students, to gain knowledge, to monitor performance, and to justify interventions.” The many uses described in this statement, although diverse, have a single goal—to leverage patient data and information within the record to care for patients and to further health sciences, including the conduct of research and public health activities that address population health. Traditionally, the patient record was on paper and almost exclusively used by providers, nurses, and other care team members to document and facilitate the care of patients. The paper record contained clinical notes documenting assessments, decision-making, and care rendered; paper charts also often contained diagnostic results (e.g., laboratory and imaging results); physiologic information (e.g., vital signs); and patient care orders. With the increased digitization of health care, modern EHRs have become increasingly ubiquitous; they are designed not only for patient care but also to facilitate broader value-added functions and views of patient information, providing much more than a static view of events.

### 14.1.2 EHR Overview

An EHR is an electronic repository of maintained information about an individual's health status and health care with functionality to enable provision of care and information stored in order to serve the multiple legitimate uses and users of the record. While traditional patient records have been illness-focused, health care is evolving to encourage health care providers to focus on the continuum of health and health care from wellness to illness and recovery.

As a result of this shift and increasing system inter-operability of EHRs, many anticipate that EHRs will increasingly carry a much

greater portion of a person's health-related information from a wide range of sources over their lifetime (e.g., diagnostic images, intensive care electrophysiologic monitoring, patient recorded biometrics, genomic information). Today, the Department of Veterans Affairs (VA) has already committed to keeping existing electronic patient data for 75 years. In many cases, EHRs incorporate or integrate with a range of additional multimedia sources, such as radiology images and echocardiographic video loops.

EHRs also often include active tools used to manage patient with a wide range of features. This includes information management tools to provide clinical reminders and alerts, dynamic tracking and trending which can often be personalized, linkages with knowledge sources for health care clinical decision support (CDS; see ► Chap. 26), and analysis of aggregate data both for care management and for research. The EHR also helps users organize, interpret, and react to patient data. Examples of tools provided in current EHRs are discussed in ► Sect. 14.3. As such, EHRs need to be able to provide different views and presentations of patient data to meet the needs of various user types and patient care contexts, along with associated functionality to serve patient care and various secondary EHR uses as described in ► Chap. 2.

EHRs can also analyze a patient's record, call attention to trends and dangerous conditions, and suggest corrective actions much like an airplane flight control information system. Another powerful aspect of EHRs is their ability to organize data at both the individual and population level such as a view to facilitate care for one patient or one for a population of patients to assist with care management decisions or answer epidemiologic questions.

One advantage of EHRs is the availability of information entry controls and capabilities. In addition to increased legibility compared to paper, EHRs can also increase the quality of data by applying validity checks as data is being entered like typographical errors checks and other checks (e.g., dosing ranges for medications). EHRs can require data entry in

specified fields, conditional on the value of other fields. As such, EHRs not only store data, but can also conditionally enforce the capture of certain data elements. This enforcement power should be used judiciously, however, and not *require* the entry of unavailable data (e.g., the age of an unidentified patient receiving care during an emergency trauma) especially during order entry, and potentially prevent the clinician from completing an important order needed for clinical care (Strom et al. 2010).

The degree to which a particular EHR achieves its intended value depends on several factors:

**Comprehensiveness of information** Does the system include information from all organizations and clinicians who participated in a patient's care and from all settings where care was delivered (e.g., office practice, hospital, homecare, care coordination, virtual care)? Does it include the full spectrum of clinical data, including clinical notes, laboratory test results, medication details, images, and patient reported outcomes, including those collected by validate patient self-assessments. Increasingly, genetic data (including both germline and somatic tumor data) will become key to clinical care and EHRs. Incorporation of genetic data (including its interpretation(s) and analysis model(s)) will bring important data management and knowledge management issues including data storage (e.g., 1100 patients for 1 year requiring 2 terabytes (Burykin 2011)) and evolving interpretation(s) of genetic data and computational analyses of this data (see ► Chap. 30).

**Duration of use and retention of data** EHRs gain value over time through accumulation of a greater proportion of the patients' medical history. A record system with 5 years of patient data will be more valuable than one with only the last month's records. Retention of medical records follow, at minimum, the statute of limitations for medical malpractice, which are state-based laws. EHR records can be archived on various systems or maintained for ongoing access.

**Degree of structure of data** Narrative notes stored in EHRs have the advantage over their paper predecessors as they can be searched by word or patterns. The success of such searches is limited by the sophistication of the EHR's text mining and search capabilities along with the quality of the user's search criteria particularly since there can often be language variability in expression of medical terms including the use of abbreviations.

A great deal of valuable information is contained in clinical notes mostly recorded in narrative. Though often time consuming and cumbersome, one way to obtain structured data with clinical notes is to ask the clinician to enter key information through structured forms which restrict data entry with a controlled vocabulary that is standards-based. Powerful automated techniques like natural language processing can also be increasingly leveraged to extract clinical data from notes (see ► Chap. 9).

**Ubiquity of access** With today's secure networks and other distributed technologies, clinicians and patients can access a patient's EHR from geographically distributed sites. Paper records have significant **inaccessibility** issues as they can only be in one place and with at most one user at any point in time. Previously, completing discharge summaries and signing orders with paper records or borrowing records for administrative or research purposes from medical record departments was logistically challenging. In contrast, EHRs are ubiquitously available to users for these and other purposes.

In some cases, the collective data about one patient from independent care systems can also be accessed through health information exchanges (see ► Chap. 17). Such availability can also support health care continuity during disasters. Brown et al. (2007) found a "stark contrast" between the care VA versus non-VA patients received after Hurricane Katrina, because appropriate and uninterrupted care were supported by nationwide access to the comprehensive VA EHRs. EHRs not only make data more accessible to autho-

rized users, but they also provide the benefit of greater control over data and user access and improved enforcement of applicable privacy regulations as required by the Health Insurance Portability and Accountability Act (HIPAA) (see ► Chap. 31).

System challenges can be experienced from several perspectives:

**Challenges with system use and training**

Physicians and other key personnel have to take time from their work to learn how to use the system. Furthermore, clinical workflows have to be re-designed in order to utilize the EHR effectively. It is increasingly appreciated that EHR usability needs to be improved so that clinicians can easily document and provide patient care.

**Readability of clinical notes** One of the advantages of EHRs is the ease with which text can be entered compared to paper notes. Unfortunately, this can result in something referred to as "note bloat", resulting from cutting and pasting text and inserting other results (► Sect. 14.3.1.2), resulting in voluminous documentation compared to paper records, making EHR notes often more difficult to review efficiently.

**System failures and ensuring adequate redundancy and security**

Computer-based systems have the potential for catastrophic failures that could cause extended unavailability of patients' computer records. To combat this, EHRs today often run across distributed technologies offering redundancy such as parallel operation at geographically separate sites and **hot fail over** with separate computer systems running synchronously with the primary system that can take over near instantaneously from the primary system if it were to fail. Yet, nothing provides complete protection; contingency plans with **downtime procedures** must be developed for handling brief (even planned) or longer system outages. Also, cybersecurity is increasingly a concern that health care systems are working to improve as attacks are of increasing sophistication and frequency (see ► Chap. 18).

## 14.2 Historical Perspective: Development of EHRs

The initial development of automated systems in health care was stimulated by regulatory and reimbursement requirements. Early health care systems in the inpatient setting provided charge capture functionality to meet billing requirements in a fee-for-service environment.

The Flexner report on medical education was the first formal statement made about the function and contents of the medical record (Flexner 1910). In advocating a scientific approach to medical education, the Flexner report also encouraged physicians to keep a patient-oriented medical record. Three years earlier, Dr. Henry Plummer initiated the “unit record” for the Mayo Clinic (including its St. Mary’s Hospital), placing all the patient’s visits and types of information in a single folder. This innovation represented the first longitudinal medical record (Melton 3rd 1996). The Presbyterian Hospital (New York) adopted the unit record for its inpatient and outpatient care in 1916, studying the effect of the unit record on length of stay and quality of care (Openchowski 1925) and writing a series of letters and books about the unit record that disseminated the approach around the nation (Lamb 1955).

The first record we could find of a computer-based medical record was a short newspaper article describing a new “electronic brain” – to replace punched and file index cards and to track hospital and medical records by the Michigan Hospital Service (Brain 1956). The first, operational EHRs emerged in the early 1970’s. Some started an outpatient systems, including Costar from Massachusetts General Hospital (Grossman et al. 1973; Barnett et al. 1979; Barnett 1984), RMRS from the Regenstrief Institute (McDonald 1973; McDonald et al. 1975; McDonald et al. 1999), Duke University (Stead 1977; Stead & Hammond 1988), STOR (Simborg and Whiting-O’Keefe III 1981), and others (see outpatient EHR review by Kuhn et al. 1984). Other systems began on the inpatient side including HELP (Warner 1972) and

Lockheed’s hospital information system (HIS) at El Camino Hospital, which became operational in 1971 (Coffey 1979).

Weed’s problem-oriented medical record book (POMR) (1968) shaped medical thinking about both manual and automated medical records. His computer-based inpatient system followed (Schultz et al. 1971). Morris Collen, who also pioneered the multiphasic screening system (1969), wrote a readable 500-page history of medical informatics (1995) that provides rich details about these early medical records systems, as does a three-decade summary of computer-based medical record research projects from the U.S. Agency for Health Care Policy and Research (AHCPR) (Fitzmaurice et al. 2002).

EHRs can provide Clinical Decision Support (CDS) by suggesting needed action based on the patient data it carries. A few early systems: HELP (Warner 1972; Pryor 1988) the RMRS (McDonald 1973, 1976) offered CDS as part of their initial design. Other early EHRs added CDS capability as they grew: the Columbia University system (Johnson et al. 1991; Hripcsak et al. 1999), the CCC (Center for Clinical Computing) system at Beth Israel Deaconess Medical Center (Rind et al. 1994; Slack and Bleich 1999; Bleich et al. 1985; Halamka and Safran 1998), and others (Giuse and Mickish 1996; Teich et al. 1999; Cheung et al. 2001; Duncan et al. 2001; Brown et al. 2003).

Since those early years, hundreds of commercial vendors have emerged to supply outpatient practice computer systems and a few dozen offered for inpatient systems. However, as hospital systems merged into ever-larger aggregations and pulled office practices through acquisitions, the boundaries between outpatient and inpatient computer systems have blurred and the number of health care system EHR vendors has shrunk considerably. However, specialized clinical information systems that cover the special needs within large and complex health care systems including medical and imaging areas continue. Today, a majority of health systems in the US use a select few EHRs provided by major health information technology (IT) vendors.

### 14.3 Functional Components of an EHR

An EHR is not simply a recording of the patient's clinical state but also has linkages and functional tools to facilitate communication and decision-making. We summarize the components of a comprehensive EHR and illustrate functionality with examples from systems currently in use. The functional components are:

1. Patient data capture, aggregation, and review
2. Computerized provider order entry
3. Clinical decision support
4. Access to knowledge resources
5. Care team and patient communication
6. Billing and coding

Increasingly, requirements around certified Health IT for EHRs are resulting in systems with specific functionality and system behavior. Certified Health IT system requirements have led to EHRs being more standards-based, and interoperable (2015 Edition Certification Regulations – 170.315<sup>2</sup>).

#### 14.3.1 Patient Data Capture, Aggregation, and Review

Providing an integrated view of relevant patient data and having functionality to enter and supplement patient data are overarching EHR goals. However, EHRs may miss certain patient data, including (1) patient data existing only on old paper records, (2) data from care provided outside of the current organization (e.g., unconnected office practices, free-standing radiology centers, home-health agencies, nursing homes), and (3) differences in data representation despite electronic and organizational links, the latter of which can be a result of different EHR vendors, different implementations of a given vendor's system at

different institutions, and by unwillingness to share data. Though some progress has been made in sharing EHR data among institutions especially when institutions have a common EHR vendor, sharing of EHR data remains challenging. For example, institutions may choose different sets of functionality from vendors and employ different business rules and use different codes for identifying tests, measurements and treatment.

##### 14.3.1.1 Data Integration and Standards

An integrated, mature EHR accommodates a broad spectrum of data types ranging from text to numbers and from signals (e.g., EKG waveform) to images as well as increasingly audio and video. More complex data such as radiology images are usually delivered for human viewing — via the DICOM<sup>3</sup> standard or general commercial imaging standards such as JPEG<sup>4</sup> or motion JPEG used for cardiac echocardiograms (see ► Chap. 12).

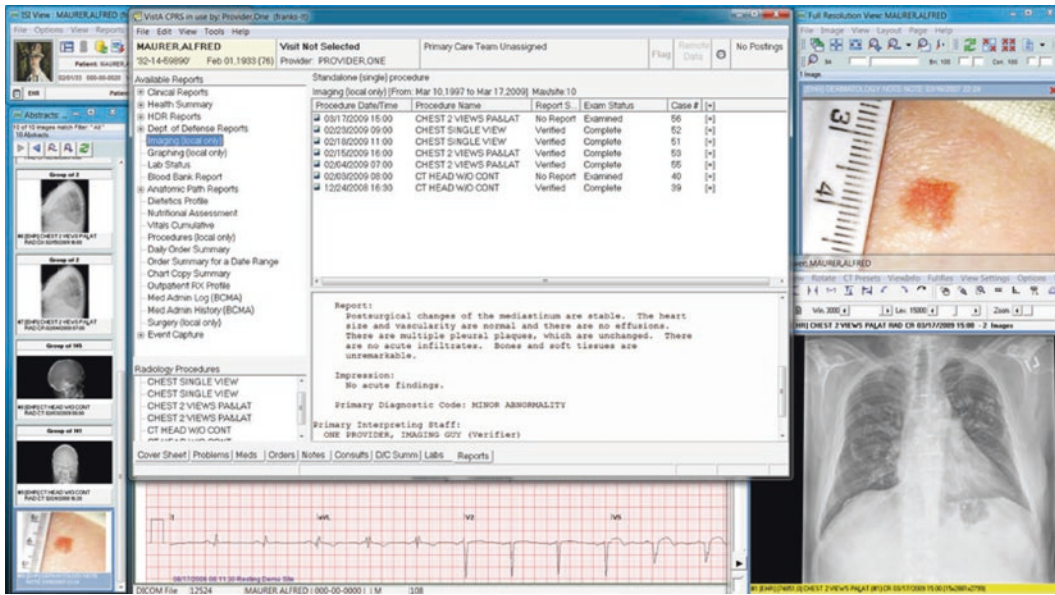

■ Figure 14.1 shows an example screenshot of WorldVista CPRS EHR, which integrates a variety of text data and images into a patient report data screen including: demographics, a detailed list of the patient's procedures, a DICOM chest x-ray image, and JPG photo of a skin lesion. Other tabs in the system provide links to problems, medications, orders, notes, consults, discharge summary, and labs.

In addition to challenges with EHR clinical data exchange, another important challenge in the US to the construction of an integrated view of patient data between systems is the lack of a national patient identifier. Because each organization assigns its own medical record number, a receiving organization cannot directly map a local medical record number from an external care organization to its own. Linking algorithms for identity management of patients are typically

**Fig. 14.1** A screenshot of the combined WorldVista Computer Based Patient Record System (CPRS) and ISI Imaging system. These systems are derived from the Department of Veterans Affairs VistA and VistA Imaging systems ([http://www.va.gov/vista\\_monograph/](http://www.va.gov/vista_monograph/)). The

figure shows how clinical images can be presented with laboratory test results, medications, notes and other relevant clinical information in a single longitudinal medical record. (Source: Courtesy of WorldVista ([worldvista.org](http://worldvista.org)) and II Group ([www.isig.com](http://www.isig.com)), 2012)

based on name, birth date, and other patient characteristics such as address and employment. The performance of these algorithms must be monitored for data integrity issues and errors and associated processes created to manage patient identity for cases where algorithms are not sufficient to adjudicate potential matches (Just et al. 2016; Zech et al. 2016).

One of the more significant barriers today to the integration of health record data from different organizations are the local and idiosyncratic identifiers used to label observations and coded observation values — recapitulating the Babel story. However, those barriers are shrinking as Health IT regulations<sup>5</sup> and institutions adopt terminology standards, including LOINC<sup>6</sup> for observations, questions,

variables, and assessments (McDonald et al. 2003; Vreeman et al. 2010); SNOMED CT<sup>7</sup> (Wang et al. 2002) for diagnoses, symptoms, findings, organisms and answers; UCUM<sup>8</sup> for computable units of measure; and RxNorm<sup>9,10</sup> for clinical drug names, ingredients, and orderable drug names for various purposes (see also ► Chaps. 8 and 31). Supporting this trend are laboratory instrument vendors, which are beginning to specify LOINC codes to use for each of the tests results that their instruments generate.<sup>11</sup>

As healthcare providers consolidate and bring together EHR data or implement a new

■ **Fig. 14.2** A block diagram of multiple-source-data systems that contribute patient data, which ultimately reside in a computerized patient record (CPR). The database interface, commonly called an interface engine, performs a number of functions. It may simply be a

router of information to the central database. It may also provide more intelligent filtering, translating, and alerting functions, as it does at Columbia University Medical Center. (Source: Courtesy of Columbia University Medical Center, New York)

EHR, organizations have used a number of approaches to load EHRs with pre-existing patient data. One approach is to interface the EHR from the available electronic source (e.g., dictation service, pharmacy system, and laboratory information system) and load data from these sources for a pre-specified length of time (e.g., 12 months). A second approach is to abstract select data (e.g., key laboratory results, the problem lists, and active medications) and either automatically or hand enter those data into the new EHR prior to each patient's visit for a period of time. The third approach is to scan and store 1–2 years of the old paper records or to produce electronic “printout” versions (e.g., as Portable Document Format [PDF]) of content stored in by preceding EHR. This approach can be applied to any kind of document, including handwritten records that predate the EHR installation. **Optical Character Recognition (OCR)** capability is built into most document scanners today, and converts typed text within scanned documents to computer understandable text with 98–99% character accuracy, which can make this content potentially searchable.

Today, most clinical data sources and EHRs can send and receive clinical content as version 2.x **Health Level 7 (HL7)**<sup>12</sup> messages. Most organizations use interface engines for HL7 messages and integration platforms (either part of the integration engine or separate technology platform) that can support other data formats to send, receive, and, when necessary, translate the format of and the codes within exchanged data (see ► Chap. 17); ■ Fig. 14.2 shows an example of architecture to integrate data from multiple source systems. The Columbia University Medical Center computerized patient record (CPR) interface depicted in this diagram not only provides message-handling capability but can also automatically translate codes from the external source to the preferred codes of the receiving EHR. And although many vendors now offer single systems that serve “all” needs, they never escape the need for standards-based data exchange from ancillary systems (e.g., EKG carts, cardiol-

12 Health Level Seven International, ► <http://www.hl7.org/> (Accessed 6/4/2020).

ogy systems, radiology imaging systems, anesthesia systems, off-site laboratories, community pharmacies and external collaborating health systems). At least one high-capability open-source interface engine, NextGen Connect (formerly Mirth Connect),<sup>13,14</sup> is available and used relatively widely for data exchange.

**HL7 Fast Healthcare Interoperability Resources (FHIR)** is an elegant application-programming interface for exchanging clinical data (see ► Chap. 17) with a recognizable heritage from V2. In 2018, it was embraced by a surge of large organizations including Apple, (Apple Health), Microsoft and Google (Mandl et al. 2019), many federal agencies (CMS, ONC, the Veterans Administration), major EHR vendors, and health insurance companies. Most of them are also using the related, SMART on FHIR App specification (Mandel et al. 2016), with which users can develop Apps designed to access data within EHRs from outside of that EHR.

#### 14.3.1.2 Clinician Data Entry

Clinical data may be entered as narrative free-text, as codes, or as a combination of the two. Trade-offs exist between the use of codes and narrative text. The major advantage of structured data is that it makes the data “understandable” to the computer and thus enables selective retrieval, clinical research, quality improvement, and clinical operations management. The coding of diagnoses, allergies, problems, orders, and medications is of particular importance for these purposes.

Because of the chance of errors with the hand entry of data, EHRs apply **validity checks** scrupulously. A number of different kinds of checks apply to clinical data (Schwartz et al. 1985). **Range checks** can detect or prevent entry of values that are out of range (e.g., a serum potassium level of 50.0 mmol/L—which is impossibly outside the normal range of 3.5–5.0 mol/L). **Pattern checks** for including regular

expressions can verify that the entered data have a required pattern (e.g., the three digits, hyphen, and four digits of a local telephone number). Range and pattern checks (among others can be implemented using standard browser features). **Computed checks** can verify that values have the correct mathematical relationship (e.g., white blood cell differential counts, reported as percentages, must sum to 100). **Consistency checks** can detect errors by comparing entered data (e.g., the recording of cancer of the prostate as the diagnosis for a female patient). Software for accomplishing this is embedded in standard web browser). **Delta checks** warn of large and unlikely differences between the values of a new result and of the previous observations (e.g., a recorded weight that changes by 100 lbs. in 2 weeks). **Spelling checks** verify the spelling of individual words.

Clinician-gathered patient information requires special comment because it presents one of the most difficult challenge to EHR developers and users. Physicians spend at least 20% of their time documenting the clinical encounter (Gottschalk and Flocke 2005; Hollingsworth et al. 1998). The burden has risen over time for several reasons (Poissant et al. 2005). EHRs tend to require far more data entry than the pre-existing manual systems. Many studies suggests that the EHR functions taken together may consume up to 1–2 hours of the physician’s free time per clinic day (Sinsky et al. 2016; McDonald et al. 2014). In one study, the computer system was a primary cause of clinician dissatisfaction (Edgar 2009) and their reason for leaving military medicine. In addition, EHR documentation requirements have been repeatedly been cited as a significant cause of physician burnout (Gardner et al. 2019). EHRs tend to forbid simple narrative text responses; so providers have to dig through menus to find the coded term that expresses their intended meaning. Billing requirements and fear of malpractice have fueled the demand for ever more data entry. Adding to provider’ data entry pain is the fact that EHR user interfaces can be clumsy and non-intuitive.

The requirement that providers enter all of their findings, impressions and plans into their note and orders into the computer comes from a dictum that says the person who cre-

13 ► <https://github.com/nextgenhealthcare> (Accessed 6/4/2020).

14 NextGen Connect Integration Engine. ► <https://www.nextgen.com/products-and-services/integration-engine> and ► <https://github.com/nextgenhealthcare> (Both accessed 6/4/2020).

ates the content should enter it. This dictum often makes sense for prescriptions, orders, and perhaps diagnoses and procedure orders, because immediate provider entry during the course of care makes diagnostic testing, treatments and check out more efficient and provides crucial grist for CDS. The justification for direct entry of visit notes by clinicians is weaker because of its time cost to physicians is high and the information is not a prerequisite to the checkout process.

Today, clinical notes can be entered into the EHR via one of three general mechanisms: (1) transcription or use of speech recognition systems to convert spoken word to dictated or written notes, (2) clinic staff (scribes) who transfer text or codes of providers written or spoken content into the computer system, and (3) direct data entry by physicians themselves (potentially facilitated by electronic templates or macros).

Free-form narrative entry—by typing, dictation, or speech recognition—allows clinicians to express important clinical information in the most natural manner. When clinicians communicate in narrative, they naturally prioritize findings and leave much information implicit. For example, an experienced clinician often leaves out “pertinent negatives” (i.e., findings that the patient does not have but that nevertheless inform the decision-making process) knowing that the clinician who reads the record will interpret them properly to be absent. The result is usually a more concise history with a high signal-to-noise ratio that not only shortens the data capture time but also lessens the cognitive burden on the reading clinician. Weir and colleagues present compelling evidence about these advantages, especially when narrative is focused and vivid, and emphasize that too much information interferes with inter-provider communication (Weir et al. 2011).

Most EHRs let physicians cut and paste notes from previous visits and other sources or even have automated functionality to “bring forward” content from previous visits. For example, a physician can cut and paste parts of a visit note into a letter to a referring physician and into an admission note, a most appropriate use of this capability. However, when over-used, this can cause ‘note bloat.’ In addition, without

proper attention to detail, users may copy information that is no longer pertinent or true or possibly lose context especially with time expressions (e.g., “yesterday”). Studies note high rates of text duplicated from previous notes of over 50% (Wrenn et al. 2010; Zhang et al. 2014).

Dictation with **transcription** has been common historically for entering narrative information into EHRs. Transcriptionists are often able to maintain a degree of structure in the transcribed document via section headers, and the structure can also be delivered as an HL7 CDA document (Ferranti et al. 2006). **Speech recognition** software offers an approach to “dictating” without the cost or delay of transcription by translating clinician speech to text automatically. Historically, these systems resulted in errors that required significant time to find and correct misunderstood words. Increasingly, these solutions have improved speech recognition algorithms, and companies can reach accuracies better than 99% without training. Skeptical readers can try it themselves.<sup>15</sup>

In addition, some dictation services use speech recognition to generate a draft transcription, which the transcriptionist corrects while listening to the audio dictation, thus saving transcriptionist time. Natural-language processing (NLP) (see ► Chap. 9) offers hope for automatic encoding of narrative text (Nadkarni et al. 2011). Some companies are exploring the use of NLP to auto-encode transcribed text, and employ the transcriptionist to correct any NLP coding errors (see ► Chap. 9).

Some practices have **scribes** (a variant on the stenographers of old) to do much of the physicians’ data entry work (Koshy et al. 2010; Misra-Hebert et al. 2016). Scribes typically work alongside the care provider in the examination room, or remotely through an audiovisual connection or recording. The Joint Commission is agnostic about the use of scribes, but provides guidelines for their use (The Joint Commission 2018<sup>16</sup>).

15 ► <https://cloud.google.com/speech-to-text/>

16 The Joint Commission: Documentation assistance provided by scribes. ► <https://www.jointcommission.org/en/standards/standard-faqs/nursing-care-center/record-of-care-treatment-and-services-rc/000002210> (Accessed 6/4/2020).

Another data-entry method is to have clinicians record information on a **structured form**, from which data and associated documentation are created (Downs et al. 2006; Hagen et al. 1998). One system, called CHICA (Anand et al. 2018), originally generated a patient specific and scannable paper document and used optical character and mark recognition to capture the recoded data in a two-step process. Today, data can be data captured from a handheld electronic tablet or via a webpage (Anand et al. 2017). In addition to a child-spe-

cific data-capture form completed by the child's family in the waiting room (■ Fig. 14.3a), the CHICA computer uses the entered data to generate a physician encounter form with a tailored agenda for the encounter (■ Fig. 14.3b). The CHICA system generates a prose version of associated form responses which can be incorporated into and used to help generate a clinical note.

The third alternative is the structured, coded entry of data by clinicians. A major issue associated with direct physician entry is

The screenshot shows a mobile application interface for a 'Pre-Screener' form. At the top, there is a dark header with 'Español' on the left, 'Pre-Screener: Patient' in the center, and a 'Quit' button on the right. Below the header, the form is titled 'a' and 'Patient'. The form contains five questions, each with three radio button options: 'Yes', 'No', and 'N/A'. The 'No' option is selected for all questions. The questions are: 'Has Ima ever had epilepsy or more than one seizure with stiffness or jerking?', 'Does Ima have a brother or sister with autism?', 'Has Ima had hard, large stools for more than 2 weeks?', 'Do you have concerns about Ima's development?', and 'Does Ima have sickle cell disease?'. At the bottom of the form is a large blue 'Next' button.

■ **Fig. 14.3** **a** The family completes the first form with questions tailored to patient's age and other factors. Form can be displayed on a tablet or printed on a tailored paper form that is scanned by an OCR system that passes the content to the EHR. **b** The computer generates a physician encounter form based on the contents of the first form and adds reminders. The form is dis-

played as a web form in the EHR or printed on paper that an OCR system interprets. Coded results are stored in the computer and a prose version is returned by the system to be incorporated in the physician's note. (Source: Courtesy of Prof Stephen M Downs, Indiana University, Indianapolis, IN)

Fig. 14.3 (continued)

the physician time cost. Studies document that structured data entry consumes more clinician time than the traditional record keeping (Chaudhry et al. 2006), as much as 20 seconds per SNOMED CT coded diagnosis (Fung et al. 2011). On the other hand, this option has the advantage that the computer can immediately check the entry for consis-

tency with previously stored information and can ask for additional detail or dimensions conditional on the information just entered. Some of these data will be entered into fields, with menu selection. For ease of entry, such menus should not be very long, require scrolling, or impose a rigid hierarchy (Kuhn et al. 1984). Using a process called auto complete,

clinicians can code items by typing in a few letters of an item name, then choose the item they need from the list of items that match the string they entered. In some cases this process can be fast and efficient, but critics have described it as “death by a thousand clicks” (Fry and Schulte 2019).

The use of templates and menus can speed note entry, but they can also generate excessive boilerplate and discourages specificity (i.e., it is easier to pick an available menu option than to describe a finding or event in detail). Notes written via templates may not convey as clear, or as accurate, a picture of the patient’s state as a provider note written in narrative. Developers can develop separate data capture forms using APIs specific to the manufacturer resulting in forms that are relatively easier to use and often can adapt to various form factors.

Among its many other capabilities, FHIR has developed specifications for web data capture forms. Questionnaire<sup>17</sup> is FHIR’s data capture resource. Questionnaire supports skip logic, nesting and repeating groups of questions and many simple data validation checks. It also supports nested, and repeating, groups of questions and thus can accommodate complicated forms such as the surgeon general is family history (see ■ Fig. 14.4a). FHIR has developed an enhanced version of Questionnaire called Structured Data Capture (SDC)<sup>18</sup> in STU4 trial use. It adds many capabilities to Questionnaire, including arithmetic and logical calculations (see ■ Fig. 14.4b – BMI and ■ Fig. 14.4c – Apgar score) and mechanisms for pre-populating forms with existing patient data from an EHR. It also includes regular expressions for validation of data entry along with mechanisms for storing form content data into designated FHIR resources. Finally, SDC supports adaptive (CAT) survey instruments such as PROMIS<sup>19</sup> patient reported outcomes.

The long-term solution for effective data capture of information generated by clinicians is still evolving. Semi-structured data entry combines the use of narrative text fields amenable to natural language processing combined with structured data entry fields where needed. With time and better input devices, acquisition of data will become faster and easier. In addition, direct entry of some data by patients could reduce the data entry burden for clinicians (Janamanchi et al. 2009).

### 14.3.1.3 Data Display

Once stored in the computer, EHRs can present patient data in different formats for different purposes. These systems can also present content in novel formats. Clinicians need more than just integrated access to patient data; they also need various views of these data: in chronologic order as flowsheets or graphs to highlight changes over time, and as snapshots that show a computer view of the patients’ current status and their most important observations.

### Timeline Graphs

A graphical presentation can help the physician to assimilate and draw conclusions from the information quickly and draw conclusions (Fafchamps et al. 1991; Tang and Patel 1994; Starren and Johnson 2000). An anesthesia system vendor provides an especially good example of the use of numbers and graphics in a timeline to convey the patient’s state in form that can be digested at a glance (Vigoda and Lubarsky 2006). Sparklines – “small, high resolution graphics embedded in a context of words, numbers, images” (Tuft 2006), which today’s browsers and spreadsheets can easily generate – provide a way to embed graphic timelines into any report. One study found that with sparklines, “physicians were able to assess laboratory data faster”. Sparklines enable more information to be presented more compactly in a single view and thus reduce the need to scroll or flip between screens” (Bauer et al. 2010).

**Fig. 14.4 a** A FHIR questionnaire with the same content as the Surgeon General’s Family History, rendered by the NLM FHIR Questionnaire App. The questionnaire asks questions about the proband and about each disease the proband experienced and when it occurred. These two questions repeat for each such disease the proband has experienced. Then it asks almost the same set of questions about each of the proband’s relatives as it asked about the proband, and this whole set of questions repeats for as many relatives as the user wants to enter. The same pair of questions about disease and age range also repeat within each set of questions about relatives. See FHIR definition for such forms at <http://hl7.org/fhir/uv/sdc/2019May/>. **b** An SDC form rendered by the NLM FHIR Questionnaire App that captures height and weight (among other things) and automatically computes BMI as soon as these data elements are available via a FHIRpath expression. More information about FHIRpath can be found here: <https://github.com/lhncbc/fhirpath.js>. Try it live on the Demo URL (<https://lhcfirms.nlm.nih.gov/sdc/>). **c** A rendered SDC form for the Apgar instrument to rate the health of a newborn. The answer to each question has an associated pre-defined score. This SDC form computes the overall Apgar score by adding the answers’ scores as the user selects them. The overall score appears at the bottom of the form. See demo URL (<https://lhcfirms.nlm.nih.gov/48334-7>). You can click on the gears to change the input control

The screenshot displays the 'US Surgeon General family health portrait' form. It is divided into several sections:

- My health history:** A table with columns 'Name', 'Value', and 'Units'. Fields include Name (Jack Lannon), Gender (Male), Birth Date (06/04/2009), Twin (No), Adopted (No), Parents related (No), Body height (47), Weight (23.1 kg), Race (White), and Ethnicity (Unknown/No answer).
- Diseases history panels:** Three expandable panels (1.1, 1.2, 1.3). Panel 1.1 shows 'Chickenpox (Varicella)' with onset age 'Infancy'. Panel 1.2 shows 'Asthma' with onset age 'Childhood'. Panel 1.3 is currently empty with search and age range options.
- Family member health history:** A section for relatives, starting with '1' for the first family member. Fields include Relationship to patient (NTH. Mother), Name (Donelle Kamu), Gender (Female), Living? (Yes), Date of Birth (07/21/1980), Current Age, Twin (No), Adopted (Yes), Race (White), and Ethnicity (Unknown/No answer). It also has expandable disease history panels (1.1, 1.2). Panel 1.1 shows 'Epilepsy' with onset age 'Adolescence'. Panel 1.2 is empty.
- Family member health history:** A second section for another family member, starting with '2'. Fields are mostly empty or set to 'Select one'.

Red callout boxes highlight expandable options: 'Can enter as many diseases as needed' points to the '+ Add another "Diseases history panel"' button, and 'Can enter as many family members as needed' points to the '+ Add another "Family member health history"' button.

**Timeline Flowsheets**

Figure 14.5 shows an integrated view of a flowsheet of the radiology impressions with the rows representing different kinds of radiology examinations and the columns representing study dates. Clicking on the radiology image icon brings up the radiology images.

Figure 14.6 shows the previously highly popular pocket rounds report that provides laboratory and nursing measurements as a

very compact flowsheet that fits in a white coat pocket (Simonaitis et al. 2006).

Flowsheets and other formats can be specialized for management of a particular problem. For example, a flowsheet used to monitor patients who have hypertension (high blood pressure) and might contain values for weight, blood pressure, heart rate, and medications that control hypertension with doses as well as results of laboratory tests that monitor

Fig. 14.5 A flow sheet of radiology reports. The rows all report one kind of study and the columns report one date. Each cell shows the impression part of the radiology report as a quick summary of the content of that report. The cells include two icons. Clicking on the report icon provides the full radiology report. Clicking

on the radiology image icon provides the images. (Source: Courtesy of Regenstrief Institute, Indianapolis, IN). The CareWeb program from Regenstrief, which generated this flowsheet, presents cross-institutional patient flowsheets from the Indiana HIE to office practices today

14

complications of hypertension, or the medications used to treat it. Physicians at the University of Wisconsin and University of Texas-Southwestern have developed tables of mappings from problem categories (e.g., renal failure, ischemic heart disease) to observations, and to medications, with mappings developed through a multi-institutional consensus process with universal code specifications that use SNOMED CT or ICD (for defining problem classes), LOINC for observations, and RxNorm for medications (Fig. 14.7) (Buchanan 2017; Willett et al. 2018). Physicians at the University of Wisconsin and University of Texas-Southwestern have developed Problem Concept Maps that

will be available for free download<sup>20,21</sup> under a LOINC-like agreement (Fig. 14.7). In this example of a *Problem Oriented View*, displays medications and lab results relevant to the problem of acute systolic heart failure. If a user chose a different problem in the panel on the left, it would display content relevant to that problem.

**POCKET SUPER ROUND for SIMONAITIS, LINDA (09 FEB 2000 - 09 51AM)**

**Fig. 14.6** The Pocket rounds report—so called because when folded from top to bottom, it fits in the clinician’s white coat pocket as a booklet. It is a dense report (12 lines per inch, 36 characters per inch), printed in landscape mode on one 8 1/2 × 11 in. page), and

includes the all active orders (including medications), recent laboratory results, vital signs and the summary impressions of radiology, endoscopy, and cardiology reports. (Source: Courtesy of L. Simonaitis, Regenstrief Institute, Indianapolis, IN)

The LHC Flowsheet on FHIR app (named for the NLM’s Lister Hill Center), is an open source web app (<https://lhcfloowsheet.nlm.nih.gov/>) that generates clinical flowsheets from any FHIR server with LOINC coded observation identifiers (Fig. 14.8a, b). It can display very large datasets (the example presents a patient with more than 20 thousand observations), can scroll quickly in the X and Y-axis and show or hide selected groups of variables. This app can also provide a problem-focused flowsheet as well as time axis (column) compression, variable (row) axis compression and units’ conversion according to user preferences. It can also convert observations with mixed units of measure into a

preferred unit of measure using LHC’s unit validation/converter (UCUM).<sup>22</sup>

**Summaries and Snapshots**

EHRs can highlight important components (e.g., active allergies, active problems, active treatments, and recent observations) in clinical summaries or snapshots (Tang et al. 1999). Figure 14.9 shows an example from the Epic EHR where active patient problems, active medications, allergies, health maintenance reminders, and other relevant sum-

chose a different problems in the panel on the left, it would display content relevant to that problem. (© 2019 Epic Systems Corporation. Used with permission)

14

mary information are summarized. These views are automatically updated and kept current as new data arrives. In the future, we can expect more sophisticated summarizing and surveillance strategies, such as automated detection of adverse events (Bates et al. 2003) or automated time-series events (e.g., cancer chemotherapy cycles). We may also see patient data views that distinguish abnormal changes that have been explained, or treated, from those that have not, and displays that dynamically organize the supporting evidence for existing problems (Tang and Patel 1994; Tang et al. 1994a; Buchanan 2017). Ultimately, computers should be able to produce concise and flowing summary reports that are like an experienced physi-

cian’s hospital hand crafted discharge summary.

Researchers are developing increasingly sophisticated summaries. The HARVEST system (Hirsch et al. 2015), for example, processes all of a patient’s notes, extracts unique concepts, ranks them in importance for the patient, and displays them in a word cloud. Clicking a word reveals the notes that support the concept, and clicking the individual note reveals the relevant snippet(s) of text. The user can pick a subset of the patient’s timeline. The system reveals information that the user may not know to ask for and has been found to be especially useful for emergency department doctors and quality assurance nurses.

**Fig. 14.8** LHC Flowsheet on FHIR app presenting the content of a large, (more than 15,000 observations) de-identified medical records. The dates and values within the dataset have been slightly shifted from their original values and salted with additional data using random methods. In this display, the user may choose to collapse columns to one value per quarter to facilitate user interpretation. Out of range results are flagged as

high (red up arrow) or low (blue down arrow) using HL7 interpretation codes and normal value ranges. A sparkline appears graphing all of the values in a row, appears to the right of each observation name. In **a**, values for each observation have separate rows, whereas **b** all of the values for within one equivalence class are folded into a single row after converting all values with any molar or mass unit into a common, but configurable, mass unit

### Dynamic On-Demand Data Views

Anyone who has reviewed a patient's chart knows how hard it can be to find a particular piece of information. From 10% (Fries 1974)

to 81% (Tang et al. 1994) of the time, when looking in the paper record, physicians did not find important patient information that was present in that record. Furthermore, the ques-

The screenshot displays the EpicCare Summary Record for a patient named Male, 55 y.o., 12/15/1996. The patient's active medical problems include Diabetes mellitus - Type 2, Essential hypertension, Obesity, and Hyperlipidemia. The chief complaint is Diabetes Follow-up. Medications listed include hydrochlorothiazide (HYDROCHLORAL) 25 MG tablet, metformin (GLUCOPHAGE-ER) 500 MG 24 hr tablet, lisinopril (PRINIVL/ZESTRAL) 5 MG tablet, and simvastatin (ZOCOR) 10 MG tablet. Allergies include PENICILLINS and Rash. Immunizations/Injections include Influenza (10/17/2011, 11/30/1998, 10/22/1997, ...), PPV23 (Pneumococcal polysaccharide) 8/24/2001, and Tetanus/Diphtheria (1/17/1992). Health Maintenance includes Colonoscopy (12/15/2008), Hgb A1c (Q 3mo) (3/14/2012), Influenza Vaccine (10/17/2012), and Tetanus Immunization (12/16/2018). The Care Team and Communications section lists Dr. Drew Walker, M.D. as the Referring Provider, and other team members like Pally Ching, M.D. (Endocrinologist) and Lisa Connelly, RN-NCM (Diabetes Educator).

■ **Fig. 14.9** Summary record. The patient's active medical problems, current medications, and drug allergies are among the core data that physicians must keep in mind when making any decision on patient care. This

one-page screen provides an instant display of core clinical data elements as well as reminders about required preventive care. (Source: Courtesy of Epic Systems, Madison, WI)

tions clinicians routinely ask are often the ones that are difficult to answer from perusal of a typical medical record. Common questions include whether a specific test has ever been performed, what kinds of medications have been tried, and how the patient has responded to particular treatments (e.g., a class of medications) in the past. Physicians constantly ask these questions as they flip back and forth in the chart searching for the facts needed to support or refute a given hypotheses as their thinking about the patient evolves. On demand search tools help clinicians locate and then organize relevant patient data, into flowsheets, problem oriented displays (see section “► **Timeline Flowsheets**”) or graphs (Fafchamps et al. 1991; Tang et al. 1994a; Starren and Johnson 2000) to facilitate provider assimilation of the relevant facts.

### 14.3.2 Computerized Provider Order Entry

One of the most important components of an EHR is computerized provider order entry

(CPOE), where clinicians make and act upon therapeutic and diagnostic decisions by entering orders. CPOE systems can reduce errors and costs compared to paper systems, in which orders are transcribed manually from one paper form (e.g., the orders section of the paper chart) to another (e.g., the nurse's work list, a laboratory request form), or faxed to a receiving area for fulfillment (e.g., transportation services, pharmacy). CPOE orders pass electronically from the decision-maker to the order filler with minimal to no manual labor. Order entry systems also provide opportunities to deliver CDS when providers are entering orders and making clinical decisions. Most existing CPOEs provide alerts about drug interactions, allergies, and dosing adjustments for renal insufficiency when new drug orders are entered. However, EHR implementers should be selective about which alerts to evoke and be parsimonious with the use of interruptive alerts to avoid wasting provider time on trivial or low-likelihood outcomes (Miller et al. 2005a; Phansalkar et al. 2012a, b). We discuss this capability in more fully in the next section.

■ **Fig. 14.10** Neonatal Intensive Care Unit (NICU) Total Parenteral Nutrition (TPN) Advisor provides information about complex interactive advice and performs various calculations in response to the

provider's prescribed goal for amount of fluid, calories, nutrition, and special additives. (Source: Miller et al. (2005b). Elsevier Reprint License No. 2800411402464)

Order entry systems can also remind providers about important orders, which might otherwise be forgotten. Very intelligently designed order entry systems can shrink the work of entering complicated orders such as declining dosing of prednisone, intravenous fluid orders, and total parenteral nutrition (TPN) orders the last of which require entry of many additives and calculations to avoid dangerous mixtures and to reach specified targets for calories each additives. ■ Figure 14.10 shows an example of a TPN order entry screen from Vanderbilt (Miller et al. 2005b). However, with some order entry systems, entry of intravenous and declining dose orders can be more difficult than with the manual alternative.

When a CPOE system is operational, simply changing the default drug or dosing based on the latest scientific evidence can shift ordering behavior toward the optimum standard of

care, with benefits to quality and costs. Because of these advantages, health care organizations have adopted CPOE widely and federal regulations for certified health IT require core CPOE functionality for medications, laboratories, diagnostic imaging, and EHRs, which include checking for drug-drug and drug-allergy interactions<sup>23</sup>—though some question the wisdom of those interaction requirements (Khajouei and Jaspers 2010) and, in one study, the use of these checks with alerts had no effect in the rate of adverse drug reactions (Nebeker et al. 2005).

23 Certification of Health IT, Testing Process & Test Methods, 2015 Edition Test Method. 2015 Edition Certification Regulations – 170.315(a) (1, 2, 3, 4): Computerized Provider Order Entry and Drug-drug and Drug-allergy checks for CPOE ► <https://www.healthit.gov/topic/certification-ehrs/2015-edition-test-method> (Accessed 6/4/2020).

### 14.3.3 Clinical Decision Support

Clinical trials have shown that certain reminders from CDS can improve care processes (McDonald 1976; Haynes 2011; Damiani et al. 2010; Schedlbauer et al. 2009; Ranta et al. 2015; Clyne et al. 2012; Tajmir et al. 2017) but the efficacy of CDS broadly is mixed (Delvaux et al. 2017; Parshuram et al. 2018; Muth et al. 2018; Fried et al. 2017). EHRs can deliver CDS in batch mode at intervals across a whole practice population to identify patients who are not reaching to treatment targets or are past due for immunizations, cancer screening, or have missed their recent appointments, to cite a few examples. In batch mode, clinical practices can utilize lists of patients generated by CDS to contact the patient and encourage him or her to reach a goal or to schedule an appointment for the delivery of suggested care and can reach patients who have not kept scheduled appointments.

Decision support—especially for preventive care—is most efficiently delivered in the course of routine care while the patient and provider are together. Suggestions can be delivered during the physician order entry process, which in some cases can be the best point in the workflow at which to discourage or countermand an order that might be dangerous or wasteful. It is also a convenient point to offer reminders about needed tests or treatments, which can easily be initiated during that order session.

One of the best ways for CDS systems to remind providers about tests or treatments is by presenting pre-constructed order(s) to the provider who can confirm or reject the order(s) with a single keystroke or mouse click. It is best to annotate such suggestions with their rationale (e.g., “the patient is due for his pneumonia vaccine because he has emphysema and is over 65”) so that the provider understands the rationale for the suggestion (Mamlin et al. 2007).

■ Figure 14.11 shows some suggestions from a sophisticated inpatient CDS system developed by Intermountain Health Care. This system used a wide range of clinical information to recommend antibiotic choice,

dose, and duration of treatment from the system improved clinical outcomes and reduced costs of infections among patients managed with the assistance of this system (Evans et al. 1998; Pestotnik 2005). Vanderbilt’s inpatient “WizOrder” CPOE system also addressed antibiotic orders, as shown in ■ Fig. 14.12; it suggests the use of Cefepine rather than Ceftazidime, and provides choices of dosing by indication.

Clinical alerts attached to a laboratory test result can include suggestions for appropriate follow up or treatments for some abnormalities (Ozdas et al. 2008; Rosenbloom et al. 2005). Also, CPOE functionality can warn the physician about allergies (■ Fig. 14.13a) and drug interactions (■ Fig. 14.13b) before the provider completes a medication order, as exemplified by screenshots from Partner’s outpatient medical record orders.

Reminders and alerts are employed widely in outpatient care. Indeed, the outpatient setting is where the first study of clinical reminders and the first randomized trial of medical informatics systems, was performed (McDonald 1976) and remains the setting for the majority of such studies (Garg et al. 2005). Reminders to physicians in outpatient settings quadrupled the use of recommended vaccines in eligible patients compared with those who did not receive reminders (McDonald et al. 2014; McPhee et al. 1991; Hunt et al. 1998; Teich et al. 2000). Reminder systems can also suggest needed tests and treatments for eligible patients (Overhage 1997). ■ Figure 14.14 shows an Epic system screen with reminders to consider ordering a cardiac echocardiogram and starting an ACE inhibitor—in an outpatient patient with a diagnosis of heart failure but no record of a cardiac echocardiogram or treatment with one of the most beneficial drugs for heart failure.

Though the outpatient setting is the primary setting for preventive care reminders, preventive reminders have also been applied effectively in the hospital setting (Dexter et al. 2001). Furthermore, reminders directed to inpatient nurses improve preventive care even more than reminders directed to physicians (Dexter et al. 2004).

### 14.3.4 Access to Knowledge Resources

Many clinical questions, whether addressed to a colleague or answered by searching through textbooks and published papers, are asked in the context of a specific patient (Covell et al. 1985). Thus, one appropriate time to offer knowledge resources to clinicians is while they are writing notes or entering orders for a specific patient. Clinicians

typically have access to a selection of knowledge sources, which can be accessed from a web browser at any point in time today. Some are from public sources, such as the National Library of Medicine's (NLM) PubMed and MedlinePlus, Centers for Disease Control and Prevention's (CDC) vaccines and international travel information, and Agency for Healthcare Research and Quality's (AHRQ) National Guideline Clearinghouse. Others come from commercial vendors like

Fig. 14.12 User ordered an antibiotic for which the Vanderbilt’s former inpatient “WizOrder” CPOE system, based on their Pharmaceuticals and Therapeutics (P and T) Committee input, recommended a substitution. This educational advisor guided clinician

through ordering an alternative antibiotic. Links to “package inserts” (via buttons) detailed how to prescribe recommended drug under various circumstances. (Source: Miller et al. (2005b). Elsevier Reprint License No. 2800411402464)

14

UpToDate, Micromedex, and a variety of electronic textbooks. Some EHRs are proactive and routinely present short informational nuggets adjacent to the order item that the clinician has chosen. Through an **Infobutton** designed to pull context-specific information, EHRs can also pull literature, textbook or other sources of information relevant to a particular clinical situation, and present that information to the clinician on the fly (Del Fiol et al. 2012). The Infobutton standard is now a core CDS functionality within certified

Health IT requirements<sup>24</sup> (see Fig. 14.15). To support this function, HL7 Version 3 standard has produced the Context Aware Knowledge Retrieval Application

24 Certification of Health IT, Testing Process & Test Methods, 2015 Edition Test Method, Clinical Decision Support. 2015 Edition Certification Regulations - 170.315(a)(9): Clinical Decision Support ▶ <https://www.healthit.gov/test-method/clinical-decision-support-cds#ccg> (Accessed 6/4/2020).

The screenshot displays a laboratory results review interface. On the left is a navigation menu with categories like 'Lab summary', 'XA data (old)', and 'Eclipsys Notes'. The main area shows a list of laboratory tests with columns for test name, date, and status. A detailed view of an 'Iron' test is shown, with a result of 41 and a comment: 'Result not available. UIBC 55 ug/dL'. An 'Infobutton Manager' window is open, displaying information for 'Cerner ME DTA: Iron Level' and 'Abnormal Blood Level of Iron', including guidelines and references.

**Fig. 14.15** This figure shows the use of Columbia University Medical Center’s Infobuttons during results review. Clicking on the Infobutton adjacent to the Iron result generates a window (image) with a menu of ques-

tions. When the user clicks on one of the questions, the Infobutton delivers the answers. (Source: Courtesy of Columbia University Medical Center, New York)

“Infobutton” standard).<sup>25</sup> HL7 FHIR also has powerful CDS capabilities; namely, support for CDS Hooks and two scripting languages: FHIRPath<sup>26</sup> and CQL<sup>27</sup> for algebraic and logical calculations (See ► Chap 8).

One idea increasingly of interest is to provide to clinicians at the point of care optimized treatment plans or customized information, derived from patients “just like”

the one in front of the clinician. Conceptually, this “green button” (Longhurst et al. 2014), like other CDS, would be accessible to clinicians at the point of care and provide aggregate patient data (e.g., outcomes to a particular medication for disease treatment according to similar patient characteristics) to help support treatment decisions in the absence of high quality evidence.

### 14.3.5 Care Team and Patient Communication

Communication tools, that support timely and efficient communication between patients and the health care team and amongst team members, can enhance coordination of care and disease management. Patients are provided secure online access to their EHR and integrated communication tools to ask medical questions or conveniently perform other

clinical (e.g., renew a prescription) or administrative tasks (e.g., schedule an appointment) (Tang 2003). Increasingly, the delivery of optimal patient care also requires multiple health care professionals that may cross several organizations; thus, it is important that communication among team members and organizations is delivered effectively, efficiently, and on time. Such communications usually focus on a single patient and may require a care provider to assess or interchange information from several systems and providers in order to coordinate relevant care.

Direct connectivity to patients is and will be increasingly important to patient-provider communication. It will permit direct-to-patient reminders (Sherifali et al. 2011) and deliver home health monitoring data (such as home blood pressure measurements and glucose testing results) to the EHR and other information systems (Earle 2011; Green et al. 2008). The patient's personal health record (PHR) will also become an important destination for clinical messages and test results (see ► Chap. 13). Relevant information can be “pushed” to the patient or their PHR via e-mail, pager services, or other secure texting or closed loop communication (Major et al. 2002; Poon et al. 2002; Gulacti and Lok 2017; Rief et al. 2017; Przvbylo et al. 2014) or “pulled” by users on demand during their routine interactions with the computer.

EHRs can also provide electronic functionality to assist in the transfer (or hand-off) of care responsibility from one clinician to another. When the transfer is between settings (e.g., from hospital to nursing home), the sending clinician usually provides a brief verbal or written turnover note to the receiving clinician(s) summarizing the patient's problems, treatments, and other relevant clinical issues. ■ Figure 14.16 shows an example of a “turn-over report” that includes instructions from the “sending” physician, as well as relevant recent laboratory test results and other data pulled from the patient's EHR and a “to-do” list, that ensures that critical tasks are complete (Stein et al. 2010). Such reports facilitate communication among team members, and can improve both coordination and patient safety. However, keeping the contents

of such reports up to date and accurate can be a challenge (Arsoniadis et al. 2017).

Although most patient encounters are defined by scheduled face-to-face visits (e.g., outpatient visit, home health visit), provider decision-making also occurs during non-face-to-face and nonscheduled events (e.g., patient telephone calls, prescription renewal requests, and the arrival of new test results). Recently, CMS has indicated they will pay for another kind of non-face-to-face event, namely virtual visits.<sup>28</sup> EHRs and other Health IT will support and facilitate these non-face-to-face events, and video-visit capabilities will become part of many EHR vendor system offerings.

EHRs are traditionally bounded by the institution in which they reside. The National Health Information Infrastructure (NHII) (NCVHS 2001) has proposed a future in which providers caring for a patient could reach beyond his or her local institution to automatically obtain patient information from all relevant sources (see ► Chap. 13). Today, examples of such regional “EHRs,” often referred to as **Health Information Exchanges (HIE)**, serve routine and emergency care, public health and other functions. The first HIE was the IHIE (Indiana Health Information Exchange) (McDonald et al. 2005) which started in 1994 with 3 Indianapolis hospitals and now includes hospitals from most of Indiana. Other early HIEs include Ontario, Canada (electronic Child Health Network),<sup>29</sup> Kentucky (Kentucky Health Information Exchange),<sup>30</sup> and Memphis (Frisse et al. 2008). Today, scores of HIEs are in operation ► <https://strategichie.com/membership/member-list/>. A study from the Memphis HIE showed that the extra patient information provided by this HIE saves resource use and costs (Frisse et al. 2011).

According to a December 2018 ONC report, half of all US hospitals now share some data through one or more HIEs.<sup>31</sup>

In 2010, the **Office of the National Coordinator (ONC)** proposed the Nationwide Health Information Network (NwHIN) to connect regional HIEs and promote health data exchange (see ► Chaps. 13 and 31).<sup>32</sup> It

included NHIN Connect and NHIN Direct,<sup>33</sup> the former with a special focus on large enterprises and government organizations, the latter with a focus on simpler or local networks. The Direct protocol<sup>34</sup> is an email (SMTP)-based protocol designed to deliver encrypted messages and attachments securely among pre-arranged groups of individuals or organizations. ONC has nurtured the development of the Direct Protocol and required

31 ► <https://www.ruralcenter.org/resource-library/methods-used-to-enable-interoperability-among-us-non-federal-acute-care-hospitals> (Accessed 6/4/2020).

34 ► [http://wiki.directproject.org/Main\\_Page](http://wiki.directproject.org/Main_Page) (Accessed 6/4/2020).

EHR vendors to support it, and they have, but minimally in some cases.

A least seven organizations, provide general tools and trust policies to create new secure health care networks or connect existing ones. Some of them are direct descendants of NHIN Connect. These seven are described and compared in an excellent 2017 ONC report.<sup>35</sup> Among the seven, Direct Trust and National Association for Trusted Exchange (NATE) use the Direct Protocol exclusively, and Surescripts and eHealth Exchange use it optionally. The other three use a mix of non-Direct Protocols. Some of these organizations are discussing partnerships or mergers. Unfortunately, support for delivering structured data is limited in many of these systems, and EHR vendors have not chosen a common approach.

With the goal of one national network of networks, ONC has proposed an overarching set of policies and protocols, called “The trusted exchange framework and common agreement” (TEFCA).<sup>36</sup> It has been met with both praise and criticism. FHIR offers additional mechanisms for linking independent networks and is highlighted in the TEFCA proposal. To see how this all evolves, stay tuned.

### 14.3.6 Billing and Coding

---

While originally billing and coding systems were most often separate from the main EHR which served as a clinical system of record, over time this has changed. Today, the majority of vendor EHRs have billing and coding functionality, as well as other aspects of revenue cycle (e.g., prior authorization, accounts receivable). Tying the various aspects of revenue cycle functionality into EHRs has proven to have several efficiencies for health care organizations. For instance, the workflow for

---

35 ► [https://www.healthit.gov/sites/default/files/analysis\\_of\\_existing\\_trust\\_arrangements\\_printable.pdf](https://www.healthit.gov/sites/default/files/analysis_of_existing_trust_arrangements_printable.pdf) (Accessed 6/4/2020).

36 ► <https://www.healthit.gov/sites/default/files/page/2019-04/FINALTEFCAQTF41719508version.pdf> (Accessed 6/4/2020).

coders is more streamlined. The same system can be used to review records, code, and provide feedback to clinicians on documentation, as well as allow clinicians to drop charges directly into the EHR. In some cases, EHR coding and billing can also be augmented with 3rd party systems, such as those leveraging computer-assisted coding with clinical NLP technologies (see ► Chap. 9).

## 14.4 EHRs for Secondary and Population-Based Uses

---

This section considers secondary uses of EHRs, which are increasing greatly. Some of this functionality can be done by or in concert with other systems and platforms. We expect that EHRs will continue to evolve and transform as information systems over time with greater analysis and secondary use functions. Medical personnel, quality and patient safety professionals, and administrators use these capabilities to find particular patterns and events that predict patient outcomes. Public health professionals can use reporting functions of computer-stored records for surveillance, including looking for emergence of new diseases or other health threats that warrant medical attention.

### 14.4.1 Population-Based Clinical Care

---

Although the functions of CDS for a single patient on the one hand and across a larger patient population on the other are different, their internal logic is similar. In both, the central procedure is to determine if a single patient at hand or which across the full set or subset of patients satisfy pre-specified criteria and to act appropriately when the patient meets those criteria. Surveillance queries generally address a large subset, or all, of a patient population; the output is often a tabular report of selected raw data on all the patient records retrieved or a statistical summary of the values contained in the records. Decision support systems usually address patients who are under active care and

generate an **alert** or **reminder message** (McDonald 1976) to that patient. Organizations can use these systems at a population level for care coordination, patient empanelment for primary care providers, and other tasks.

For example, a cross-population query can be used to identify patients who are due for periodic screening examinations such as immunizations, mammograms, and cervical Pap tests and then can generate letters to patients or call lists for office staff to encourage the preventive care. This can also be especially useful for conducting ad hoc searches such as those required to identify and notify patients who have been receiving a recalled drug. Such systems can also facilitate quality management and patient safety activities, identify candidate patients for concurrent review and gather many of the data required to complete such audits.

#### 14.4.2 Clinical Research

Researchers can use EHRs particularly associated cross-patient queries and alerting capabilities to identify patients who meet or have a high chance of meeting eligibility requirements for a prospective clinical trial. For example, an investigator could identify all patients seen in a medical clinic who have a particular diagnosis and satisfy the eligibility requirements specified in a given study protocol (Kho et al. 2007). These approaches can sometimes be applied in real time. At one institution, the physician's workstation was programmed to ask permission to invite the patient into a study, when that physician entered a problem that suggested the patient might be a candidate for a local clinical trial. If the physician gave permission, an automated electronic page could then be triggered and sent to the nurse recruiter who would then invite the patient to participate in the study. One early such study was for patients with back pain (Damush et al. 2002).

Randomized **prospective studies** are the gold standard for clinical investigations, but

**retrospective studies** of existing data have contributed much to medical progress (see ► Chap. 29). Retrospective studies can also obtain answers at a small fraction of the time and cost of comparable prospective studies. EHRs can often provide much of the data required for a retrospective study. They can, for example, identify study cases and comparable control cases, and provide data needed for statistical analysis of the comparison cases (Brownstein et al. 2007). Combined with access to discarded specimens, they also offer powerful approaches to retrospective genome association studies that researcher can do much faster and at fraction of the comparable prospective studies (Kohane 2011; Roden et al. 2008).

Computer-stored records do not eliminate all the work required to complete an epidemiologic study; chart reviews and patient interviews may still be necessary. Computer-stored records are likely to be most complete and accurate with respect to visit diagnoses that are carefully coded for administrative purpose, as well as to prescribed drugs, and laboratory tests, because the latter two usually come directly from automated laboratory and pharmacy systems, respectively. Consequently, computer-stored records are likely to contribute to research on a physician's practice patterns, on the efficacy of tests and treatments, and on the toxicity of drugs. The research opportunities will only improve with FHIR API and coding standards required by proposed CMS and ONC rules. NIH and AHRQ have both encouraged research interest in FHIR<sup>37,38</sup> Also, improvements in NLP techniques may make the content of narrative text more accessible to automatic searches (see ► Chap. 9).

38 ► <https://grants.nih.gov/grants/guide/notice-files/NOT-OD-19-122.html> (Accessed 6/4/2020).

### 14.4.3 Quality Reporting

EHRs are also increasingly important in the production or automation of quality reports that are used for both internal quality improvement activities and for external regulatory or public reporting. Although it is difficult for paper-based records to incorporate patient-generated input and it requires careful tagging of data sources, EHRs can increasingly include data contributed by patients (e.g., patient-reported outcomes such as functional status, pain scores, and symptom; review of systems). Patient-reported data is also being incorporated in future quality measures particularly for disease specific or episodic specific conditions, e.g., use of the Seattle Angina Questionnaire Short Form (SAQ-7) and Rose Dyspnea Scale (RDS) following Non-Emergent Percutaneous Coronary Intervention (PCI).<sup>39</sup>

With changing reimbursement payment models focusing more on outcomes measures instead of volume of transactions, generating efficient and timely reports of clinical quality measures will play an increasingly important role in management and payment. FHIR will likely play a role here, as well. FHIR supports the Clinical Quality Language (CQL)<sup>40</sup> and FHIRPath,<sup>41</sup> a subset CQL. CQL was developed for CMS quality reporting but has wider applicability to other initiatives.

### 14.4.4 Administration

In the past, administrators had to rely on data from billing systems to understand practice patterns and resource utilization. However, claims data have their limits, including their delayed and retrospective nature. From direct comparisons between medical record content

and diagnoses coded from that record, we know that the accuracy of coding varies by kind of diagnosis, setting and hospital size, and variability in granularity. Claims data can also provide structured and coded records of ambulatory prescriptions, but generally provide no test results or clinical measurement values. So, considering only claims-based diagnostic codes can lead to inappropriate policymaking and conclusions (Tang et al. 2007).

EHRs complement claim- and administrative-based data and can provide information about the relationships among diagnoses, severity of illness indication, and resource consumption. Thus, these systems are important tools for administrators who wish to make informed decisions in the increasingly value-based world of health care. On the other hand, the use of EHR data for billing and administrative purposes can incentivize clinicians to bias their documentation for maximal payment, and possibly reducing the clinical accuracy of the diagnoses. It may therefore be best to base financial decisions on variables that are not open to interpretation.

Despite Reiser's (1991) clinically oriented goals for EHRs, much of what these systems are currently is driven by complex and prescriptive medical-legal, reimbursement, and regulatory requirements (Cusack et al. 2013). These requirements may lead to redundant data capture, cumbersome documentation processes, and information that is biased towards optimized billing. One potential solution would be policy changes such that the tie between payment and documentation elements are less emphasized, including the proposed CMS rule "Patients Over Paperwork"<sup>42</sup> which features decreased documentation burden for office visits.

## 14.5 Challenges Ahead

Although many commercial products are labeled as EHRs, some do not satisfy all the criteria that we defined at the beginning of this chapter. Even beyond matters of definition, however, it is important to recognize that the concept of an EHR is neither unified nor static. As the capability of technology evolves, the function of the EHR will expand. Certified health IT specifications appear also to have pushed forward certain types of core EHR functionality.

Greater involvement of patients in their own care, for example, means that **personal health records (PHRs)** will increasingly incorporate data captured at home and also support two-way communication between patients and their health care team (see also ► Chap. 13). The potential for patient-entered data includes history, symptoms, and outcomes entered by patients as well as data uploaded automatically by home monitoring devices such as scales, blood pressure monitors, glucose meters, pulmonary function devices, smart phones and Fitbits. By integrating these patient-generated data into the EHR, either by uploading the data into the EHR or by linking the EHR and the PHR, a number of long-term objectives can be achieved: patient-generated data may in some circumstances be more accurate or complete, the time spent entering data during an office visit by both the provider and the patient may be reduced, and the information may allow the production of outcomes measures that are better attuned to patients' goals. Patient-delivered data will be welcome when this information has been requested by the practice (e.g. initial visit history check list), and a mutual understanding exists about the types and volumes of data that can be accepted and delays between receipt and review.<sup>43</sup>

The future of EHRs depends on both technical and nontechnical considerations.

Computing technology will continue to advance, with processing power doubling every 1.5 years according to Moore's law (see ► Chap. 1). Software will improve with more powerful applications, better user interfaces, and more integrated CDS, including CDS using third party solutions and CDS integration specifications (e.g., FHIR®<sup>44</sup>, CDS hooks<sup>44</sup>). New kinds of software that support collaboration will continue to improve; social media are growing rapidly both inside and outside of health care. For example, as both providers and patients engage increasingly in social media, new ways to capture data, share data, collaborate, and share expertise may emerge. Perhaps the greater need for leadership and action will be in the social and organizational foundations that must be laid if EHRs are to serve as the information infrastructure for health care. We touch briefly on some of these challenges in this final section.

### 14.5.1 Usability

An intuitive and efficient user interface is an important desired characteristic of an EHR. Designers must understand the cognitive aspects of the human computer interaction (HCI) and each of the various workflows if they are to build user interfaces that are easy-to-learn and easy-to-use (see ► Chap. 5). Improving these systems using best practices and principles of HCI will require changes not only in how the system behaves but also in how humans interact with the system.

User interface requirements of a nurse entering patient data in the inpatient setting are different from the requirements of a clerk entering patient charges. Usability for clinicians means fast computer response times, and the fewest possible data input fields. *A system that is slow or requires too much input is not usable by clinicians, particularly in the time-constrained setting of clinical care.* The menus and vocabularies that constrain input must

43 We have included examples from various systems in this chapter, both developed by users and commercially available, to illustrate a portion of the functionality of EHRs currently in use.

44 CDS hooks HL7 group. ► [http://wiki.hl7.org/index.php?title=201809\\_CDS\\_Hooks](http://wiki.hl7.org/index.php?title=201809_CDS_Hooks) (Accessed 6/4/2020).

include synonyms for all the ways health professionals name the items, and the system must have keyboard options for all inputs and actions because switching from mouse to keyboard steals user time.

What information the provider needs and what tasks the provider performs should influence what information the EHR presents and how the system presents it. Development of technology that matches the data-processing power of computers with the cognitive capability of human beings to formulate insightful questions and to interpret data is still a rate-limiting step (Tang and Patel 1994). For example, one can imagine an interface in which speech input, typed narrative, and mouse-based structured data entry are accepted and seamlessly stored into a single data structure within the EHR, with a hybrid user display that shows both a narrative version of the information and a structured version of the same information that highlights missing fields or inconsistent values. Along these lines,  Fig. 14.17 shows a historical example of order generation by the Gopher 3 system in operation at Eskanazi Hospital (a.k.a. Wishard hospital) clinics. Physicians would write their problem in narrative text. Using NLP methods in parallel, the computer would generate a list of code orders that it inferred from these notes. Users could then confirm order(s) with simple click(s) and add any further details required to complete each order (Duke et al. 2014). This same functionality is now provided through the Regenstrief Clinical Learning system – a realistic medical record system with rich sample patient data available for teaching medical students about EHR functionality.<sup>45</sup>

### 14.5.2 Standards

We alluded to the importance of standards earlier in this chapter, when we discussed the architectural requirements of integrating data from multiple sources. Standards are the focus

of ► Chap. 8. Here, we stress the importance of national standards to the development, implementation, and use of EHRs (Miller and Gardner 1997). Standards are especially important for integrating clinical data from different organizations. Health information exchanges (HIEs) continue to expand in size and numbers but the healthcare systems that feed them will have adopt meaningful use coding and messages/API structure standards more fully than before. HIEs will be able to efficiently import and integrate structured data about one patient from many organizations. Messaging and API standards are increasingly well developed and in widespread use for laboratory data<sup>46</sup> (HL7s LRI), prescriptions sent to pharmacies<sup>47</sup> (NCPDPs SCRIPT stands), many kinds of diagnostic (DICOM) images.<sup>48</sup> FHIR® is now supported by major federal agencies (ONC, CMS, NIH, CDC, AHRQ and increasingly by the FDA) as well as by the high-tech industry (Apple, Amazon, Google and Microsoft) and health care software developers. It is now mainstream for many in healthcare applications and communications. The incomplete adoption of standard coding systems for observation identifiers, however, remains a major obstacle to the integration of patient data from independent care providers and large care delivery systems alike.

The HIPAA legislation<sup>49</sup> includes mandated standards for administrative messages (×12) privacy, security, and clinical data. Federal agencies have already promulgated regulations based on this legislation for the first three of these categories.<sup>50</sup> A series of legislative measures, notably with the 2009

inferred by NLP analysis to suggest possible matches in the order items box

HITECH Act<sup>51</sup> (see ► Chaps. 8 and 31) and subsequently with the Medicare Access and CHIP Reauthorization Act of 2015 (MACRA),<sup>52</sup> have stimulated significant efforts to increase the adoption and functionality of EHRs, as well as leverage these systems for quality reporting. More recently, the twenty-first Century Cure Act has significant provisions around delivery of Health IT usability (Sect. 4001), Conditions of Certification (Sect. 4002(a)), Trusted Exchange Framework and Common Agreement (Sect. 4003(b)), and guidelines around reasonable and necessary activities that do not constitute information blocking (Sect.

4004)<sup>53</sup> and these positions are present in proposed ONC and CMS rules.

### 14.5.3 Costs and Benefits

The National Academy of Medicine (formerly Institute of Medicine) declared the EHR an essential infrastructure for the delivery of health care, and the protection of patient safety (IOM Committee on Improving the Patient Record 2001). Like any infrastructure project, the benefits specifically attributable to infrastructure are not immediate and sometimes difficult to establish; an infrastructure plays an enabling role in all projects that take advantage of it. Early randomized controlled clinical studies showed that computer-based decision-support systems reduce costs and improve quality compared with usual care supported with a paper medical record

51 ► [https://www.healthit.gov/sites/default/files/hitech\\_act\\_excerpt\\_from\\_arra\\_with\\_index.pdf](https://www.healthit.gov/sites/default/files/hitech_act_excerpt_from_arra_with_index.pdf) (Accessed 6/4/2020).

52 ► CMS.gov: MACRA. ► <https://www.cms.gov/Medicare/Quality-Initiatives-Patient-Assessment-Instruments/Value-Based-Programs/MACRA-MIPS-and-APMs/MACRA-MIPS-and-APMs.html> (Accessed 6/4/2020).

53 H.R.34 – 114th Congress. ► <https://www.congress.gov/bill/114th-congress/house-bill/34> (Accessed 6/4/2020).

(Tierney et al. 1993; Bates et al. 1997, 2003; Classen et al. 1997), and meta-analyses of Health IT have demonstrated quality benefits (Buntin et al. 2011; Lau et al. 2010; Clyne et al. 2012). However, others have not found consistent associations between EHRs and CDS and better quality (Romano and Stafford 2011; Delvaux et al. 2017; Parshuram et al. 2018; Muth et al. 2018).

Because of the significant resources needed and the significant broad-based potential benefits of these systems, the decision to implement an EHR is a strategic one for most healthcare organizations. Hence, the evaluation of the costs and benefits must consider the effects on the organization's strategic goals, as well as the objectives for individual health care (Samantaray et al. 2011). Today, there are a number of **Open Source** options for EHR software with a range of capabilities (Szydykova et al. 2017).

The cost of installing an EHR in a large health system can exceed \$100 million and even \$1 billion for the largest implementations.<sup>54</sup> The cost of the system itself in license fees and related items is usually only a portion of that number. Other costs include configuration, training, and lost revenue as care providers learn to use the system. The benefits of such an investment are often related to the integration of a health system's diverse components into a single, coordinated enterprise.

#### 14.5.4 Leadership

Leaders from all segments of the health care industry must work together to articulate the needs, to continue to define and expand upon the standards, to fund the development, to implement the social change, and to write the laws to accelerate the development and routine use of EHRs in health care. Because of the prominent role of the

federal government in health care—as a payer, provider, policymaker, and regulator—federal leadership to create incentives for developing and adopting standards and for promoting the implementation and use of EHRs remains crucial. Technological change will continue to occur at a rapid pace, driven by consumer demand for entertainment, retail, games, and business tools. Nurturing the use of IT in health care requires leaders including informatician leaders who promote the use of EHRs and work to overcome the obstacles that impede widespread use of computers for the benefit of health care.

#### Suggested Reading

- Barnett, G. O. (1984). The application of computer-based medical-record systems in ambulatory practice. *New England Journal of Medicine*, 310(25), 1643–1650. This seminal article compares the characteristics of manual and automated ambulatory patient record systems, discusses implementation issues, and predicts future developments in technology.
- Bates, D. W., Kuperman, G. J., Wang, S., et al. (2003). Ten commandments for effective clinical decision support: Making the practice of evidence-based medicine a reality. *Journal of the American Medical Informatics Association*, 10(6), 523–530. The authors present ten very practical tips to designers and installers of clinical decision support systems.
- Berner, E. S. (Ed.). (2010). *Clinical decision support systems, theory and practice: Health informatics series* (3rd ed.). New York: Springer. This text focuses on the design, evaluation, and application of Clinical Decision Support systems, and examines the impact of computer-based diagnostic tools both from the practitioner's and the patient's perspectives. It is designed for informatics specialists, teachers or students in health informatics, and clinicians.
- Collen, M. F. (1995). *A history of medical informatics in the United States, 1950–1990*. Indianapolis: American Medical Informatics Association, Hartman Publishing. This rich history of medical informatics from the late 1960s to the late 1980s includes an extremely detailed set of references.

54 EHR Intelligence. Top 5 Most Expensive Implementations of 2017. ► <https://ehrintelligence.com/news/top-5-most-expensive-ehr-implementations-of-2017> (Accessed 6/5/2020).

- Collen, M. F., & Ball, M. J. (Eds.). (2015). *The history of medical informatics in the United States* (2nd ed.). London: Springer-Verlag, Springer Nature. This rich history of medical informatics from the 1990s to mid 2010s (25 years) provides an updated medical informatics perspective. It includes an extremely detailed set of references.
- Hartley, C. P., & Jones, E. D. (2011). *EHR implementation: A step-by-step guide for the medical practice* (2nd ed.). Chicago: American Medical Association. This book provides rich details for implementing an EHR. It is a great resource for anyone trying to learn about EHR deployments, covering topics related to preparation, support, and implementation.
- Institute of Medicine (IOM) Roundtable on Value and Science-Driven Health Care. (2011). *Digital infrastructure for the learning health system: The foundation for continuous improvement in health and health care – workshop series summary*. Washington, DC: National Academy Press. This report summarizes three workshops that presented new approaches to the construction of advanced medical record system that would gather the crucial data needed to improve the health care system.
- Kuperman, G. J., Gardner, R. M., & Pryor, T. A. (1991). *The HELP system*. Berlin/Heidelberg: Springer-Verlag GmbH and Co. K. The HELP (Health Evaluation through Logical Processing) system was a computerized hospital information system developed by the authors at the LDS Hospital at the University of Utah, USA. It provided clinical, hospital administration and financial services through the use of a modular, integrated design. This book thoroughly documents the HELP system. Chapters discuss the use of the HELP system in intensive care units, the use of APACHE and APACHE II on the HELP system, various clinical applications and inactive or experimental HELP system modules. Although the HELP system has now been retired from routine use, it remains an important example of several key issues in EHR implementation and use that continue in the commercial systems of today.
- Osheroff, J., Teich, J., Levick, D., et al. (2012). *Improving outcomes with clinical decision support: An implementers guide* (2nd ed.). Scottsdale: Scottsdale Institute, AMIA, AMDIS and SHM. This text provides guidance on using clinical decision support interventions to improve care delivery and outcomes in a hospital, health system or physician practice. The book also presents considerations for health IT software suppliers to effectively support their CDS implementer clients.
- Sittig, D. F., & Ash, J. S. (2011). *Clinical information systems: Overcoming adverse consequences (Jones and Bartlett series in biomedical informatics)* (1st ed.). Burlington: Jones and Bartlett Learning. This book explores the challenges and obstacles with implementation of clinical information systems including the nine categories of unintended adverse consequences with implementation and optimization of these systems as well as best practices.
- Weed, L. L. (1969). *Medical records, medical evaluation and patient care: The problem-oriented record as a basic tool*. Chicago: Year Book Medical Publishers. In this classic book, Weed presents his plan for collecting and structuring patient data to produce a problem-oriented medical record.

### ? Questions for Discussion

1. What is the definition of an EHR? What, then, is an EHR? What are five advantages of an EHR over a paper-based record? Name three limitations of an EHR.
2. What are the five functional components of an EHR? Think of the information systems used in health care institutions in which you work or that you have seen. Which of the components that you named do those systems have? Which are missing? How do the missing elements limit the value to the clinicians or patients?
3. Discuss three ways in which a computer system can facilitate information transfer between hospitals and ambulatory care facilities, thus enhancing continuity of care for previously hospitalized patients who have been discharged and are now being followed up by their primary physicians.

4. Much of medical care today is practiced in teams, and coordinating the care delivered by teams is a major challenge. Thinking in terms of the EHR functional components, describe four ways that EHRs can facilitate care coordination. Describe two ways in which EHRs are likely to create additional challenges in care coordination.
5. How does the health care financing environment affect the use, costs, and benefits of an EHR? How has the financing environment affected the functionality of information systems? How has it affected the user population?
6. Would a computer scan of a paper-based record be an EHR? What are two advantages and two limitations of this approach?
7. Among the key issues for designing an EHR are what information should be captured and how can it be entered into the system. Physicians may enter data directly or may record data on a paper worksheet (encounter form) for later transcription by a data-entry worker. What are two advantages and two disadvantages of each method? Discuss the relative advantages and disadvantages of entry of free text instead of entry of fully coded information. Describe an intermediate or compromise method.
8. EHR data may be used in clinical research, quality improvement, and monitoring the health of populations. Describe three ways that the design of the EHR may affect how the data may be used for other purposes.
9. Identify four locations where clinicians need access to the information contained in an EHR. What are the major costs or risks of providing access from each of these locations?
10. What are three important reasons to have physicians enter orders directly into an EHR? What are three challenges in implementing such a system?
11. Consider the task of creating a summary report for clinical data collected over time and stored in an EHR. Clinical laboratories traditionally provide summary test results in flowsheet format, thus highlighting clinically important changes over time. A medical record system that contains information for patients who have chronic diseases must present serial clinical observations, history information, and medications, as well as laboratory test results. Suggest a suitable format for presenting the information collected during a series of ambulatory-care patient visits.
12. The public demands that the confidentiality of patient data must be maintained in any patient record system. Describe three protections and auditing methods that can be applied to paper-based systems. Describe three technical and three nontechnical measures you would like to see applied to ensure the confidentiality of patient data in an EHR. How do the risks of privacy breaches differ for the two systems?

## Learning Objectives

After reading this chapter you should know the answers to these questions:

- What is the vision and purpose of Health Information Infrastructure (HII)?
- What kinds of impacts will HII have, and over what time periods?
- How do HII requirements lead to effective architectural specifications?
- What are the political and technical barriers to HII implementation?
- How can HII progress be effectively evaluated?

## 15.1 Introduction

This chapter addresses **health information infrastructure (HII)**, community level informatics systems designed to make comprehensive electronic patient records available when and where needed for the entire population. There are numerous difficult and highly interdependent challenges that HII systems must overcome, including privacy, stakeholder cooperation, assuring all-digital information, and providing financial sustainability. As a result, while HII has been pursued for years with myriad approaches in many countries, progress has been slow and no proven formula for success has yet been identified.

While the discussion here is focused on the development of the HII in the United States, many other countries are involved in similar activities and in fact have progressed further along this road. Canada, Australia, and a number of European nations have devoted considerable time and resources to their own national HIIs. A few countries, such as Finland, Estonia, and Brazil have actually succeeded in developing effective HII systems that have been working nationwide for a number of years. It should be noted, however, that all of these nations have centralized, government-controlled healthcare systems. This organizational difference from the multifaceted, mainly private healthcare system in the U.S. results in a somewhat different set of issues and problems. One can hope that the lessons learned from HII development activi-

ties across the globe can be effectively shared to ease the difficulties of everyone who is working toward these important goals.

HII at first seems like a vague term – what does it really mean? This is not a trivial question – as with all information systems, if we don't understand clearly what we are trying to accomplish, as well as how we will measure whether we've achieved our goals, success will be elusive. The overall goal may be stated as “comprehensive electronic patient information when and where needed.” This includes both immediate access to comprehensive records for individuals (for care) and the ability to search and aggregate information across the population (for public health, medical research, quality improvement, and policy).

We know that patients in hospitals always have a unified chart (be it paper or electronic) that contains all their hospital records from all sources. However, there is no equivalent “outpatient chart” with comprehensive records from all providers in a single place. The lack of this information is a serious problem: a survey of doctor visits in 2015 found that 55% of patients reported that their medical history was missing or incomplete, while 49% indicated that their physician was not aware of which prescription medications they were taking.<sup>1</sup> Naturally, the result of this lack of information is undertreatment, overtreatment, and medical errors.

## 15.2 Vision & Benefits of HII

The vision of HII is comprehensive electronic patient information when and where needed, allowing providers to have complete and current information upon which to base clinical decisions. In addition, clinical decision sup-

1 Surescripts Survey Finds Patients Prefer Digitally Savvy Doctors and Demand a Connected Healthcare Experience. Released 28 Sept 2015. Retrieval 28 Aug 2018: <https://surescripts.com/news-center/press-releases/content/surescripts-survey-finds-patients-prefer-digitally-savvy-doctors-and-demand-a-connected-healthcare-experience>

port (see ► Chap. 22) would be integrated with information delivery. In this way, both clinicians and patients could receive reminders of the most recent **clinical guidelines** and research results. This would avoid the need for clinicians to have superhuman memory capabilities to assure the effective practice of medicine, and enable patients more easily to adhere to complex treatment protocols and to be better informed. Patients could also review and add information to their record and thereby become more active participants in their care. In addition, the availability of comprehensive records for each patient would enable value-added services, such as immediate electronic notifications to patients' family members about emergency care, as well as authorized queries in support of medical research, public health, and public policy decisions.

### 15.2.1 Value Versus Completeness of Information

In considering HII, it is extremely important to appreciate that medical information for a given patient must, in general, be relatively complete before it is truly valuable for clinical use (see ■ Fig. 15.1). For example, if a physician had access to an electronic information system that could retrieve half of each

patient's list of medications, it is unlikely such a system would be actively used. Knowing that the information was incomplete, the physician would still need to rely on other traditional sources of information to fill in the missing data (including questioning the patient). So there would be little added benefit for investing the time to obtain the partial information from the new system. Similarly, applying clinical decision support to incomplete patient data may produce erroneous, misleading, or even potentially dangerous results. Therefore, HII systems must reliably provide reasonably complete information to be valuable to clinicians for patient care, and therefore to make their use worthwhile.

Besides their limited value, incomplete records are potentially dangerous. The conclusions that providers draw from a partial picture of a patient's history may often prove to be incorrect. For example, missing contraindications could result in the prescription of a medication with serious adverse effects. Incomplete records also are a source of unnecessary costs. When test and/or procedure results are not available, but are needed for care, they are likely to be repeated.

Because of the above factors, the cost of obtaining incomplete records is not typically accompanied by substantial benefits. As a result, organizations compiling such records find themselves under great financial stress. Many such "health information exchange"

■ **Fig. 15.1** Estimated value vs. completeness of health information. Medical information of any given type for a patient typically needs to be over 85% complete before it starts being truly valuable to clinicians

(HIE) organizations have failed in the past few years, e.g., Washington (DC), Kansas, Tennessee, CalRHIO, and CareSpark (Kingsport, TN).

Importantly, today no patients in the U.S. can be assured that wherever they seek care, their comprehensive records from all sources will be available to their provider.

The U.S. Congress has recognized the importance of comprehensive records and has mandated that the problem be solved in the 21st Century Cures Act, enacted in late 2016:

- *“The Secretary shall use existing authorities to encourage partnerships ... with the goal of offering patients access to their electronic health information in a single, longitudinal format that is easy to understand, secure, and may be updated automatically.”* [... and ...]
- *“... promote policies that ensure that a patient’s electronic health information is accessible to that patient and the patient’s designees, in a manner that facilitates communication with the patient’s health care providers and other individuals, including researchers, consistent with such patient’s consent.”*<sup>2</sup>

The Final Rule implementing the 21st Century Cures Act,<sup>3</sup> reinforces these goals by requiring application programming interfaces (APIs) that allow all data elements of a patient’s electronic health record to be accessed, exchanged, and used without special effort and a more granular approach to consent management. It also requires that patients be allowed to access all of their electronic health record information at no cost and prohibits “information

blocking” in response to legitimate requests for patient records.

### 15.2.2 Value in Patient Care

The potential benefits of HII are both numerous and substantial. Perhaps most important are error reduction and improved quality of care. Many studies have shown that the complexity of present-day medical care results in very frequent errors of both omission and commission (IOM 1999). The source of this problem was clearly articulated by Masys, who observed that current medical practice depends upon the “clinical decision-making capacity and reliability of autonomous practitioners for classes of problems that routinely exceed the bounds of unaided human cognition” (Masys 2002). Electronic health information systems can contribute significantly to alleviating this problem by reminding practitioners about recommended actions at the point of care. This can include both notifications of actions that may have been missed and warnings about planned treatments or procedures that may be harmful or unnecessary. Literally dozens of research studies have shown that such reminders improve safety and reduce costs (Bates 2000). In one such study, medication errors were reduced by 55% (Bates et al. 1998). Another study by the Rand Corporation showed that only 55% of U.S. adults were receiving recommended care (McGlynn et al. 2003). The same techniques used to reduce medical errors with electronic health information systems also contribute substantially to ensuring that recommended care is provided. This is becoming increasingly important as the population ages and the prevalence of chronic disease increases.

Guidelines and reminders also can improve the effectiveness of dissemination of new research results. Widespread dissemination of new research to the clinical setting is very slow; one study showed an average of 17 years (Balas and Boren 2000). Patient-specific reminders delivered at the point of care, high-

lighting important new research results, could substantially accelerate this adoption rate.

Another important contribution of HII to the research domain is improving the efficiency of clinical trials. At present, most such trials require the creation of a unique information infrastructure to ensure protocol compliance and to collect essential research data. With an effective HII, every practitioner would have access to a fully functional and comprehensive **electronic health record (EHR)** for each patient, so clinical trials could routinely be implemented through the dissemination of guidelines that specify the research protocol. Data collection could occur automatically in the course of administering the protocol, reducing time and costs. In addition, there would be substantial value in analyzing **de-identified aggregate data** from routine patient care to assess the outcomes of various treatments and monitor the health of the population.

Another critical function for HII is early detection of patterns of disease, particularly early detection of outbreaks from newly-virulent microorganisms or possible bioterrorism. Our current system of disease **surveillance**, which primarily depends on alert clinicians diagnosing and reporting unusual conditions, is both slow and potentially unreliable. These problems are illustrated by delayed detection of the anthrax attacks in the Fall of 2001, when seven cases of cutaneous anthrax in the New York City area 2 weeks before the so-called “index” case in Florida went unreported (Lipton and Johnson 2001). Since all the patients were seen by different clinicians, the pattern could not have been evident to any of them even if the correct diagnosis had immediately been made in every case. Wagner et al. described nine categories of requirements for surveillance systems for potential bioterrorism outbreaks—several categories must have immediate electronic reporting to ensure early detection (Wagner et al. 2003).

HII would allow immediate electronic reporting of both relevant clinical events and laboratory results to public health (see

► Chap. 18). Not only would this be an invaluable aid in early detection of bioterrorism, it would also serve to improve the detection of the much more common naturally occurring disease outbreaks. In fact, early results from a number of electronic reporting demonstration projects show that disease outbreaks can routinely be detected sooner than was ever possible using the current system (Overhage et al. 2001). While early detection has been shown to be a key factor in reducing morbidity and mortality from bioterrorism (Kaufmann et al. 1997), it will also be extremely helpful in reducing the negative consequences from other disease outbreaks.

Although the U.S. Congress mandated the creation of a national public health situational awareness network in the Pandemic and All-Hazards Preparedness Acts of both 2006 and 2013, the General Accounting Office has documented that such a system has yet to be deployed in two separate reports<sup>4,5</sup> and has issued letters in both 2019 and 2020<sup>6</sup> highlighting the failure of DHHS to implement the required capabilities. HII can in fact function as an effective public health situational awareness network by reporting and/or providing access to relevant disease events in near real time to public health authorities without the necessity of creating a separate, duplicative, and expensive system solely for public health (Sittig and Singh 2020). For example,

imagine how valuable it would be in tracking the Covid-19 pandemic if timely information on patients reporting relevant symptoms to their physicians were available nationwide on a daily basis.

Finally, HII can substantially reduce healthcare costs. The inefficiencies and duplication in our present paper-based healthcare system are enormous. One study showed that the anticipated nationwide savings from implementing advanced **computerized physician order entry (CPOE)** systems in the outpatient environment would be \$44 billion per year (Johnston et al. 2003), while a related study (Walker et al. 2004) estimated \$78 billion more in savings from **health information exchange (HIE)** (for a total of \$112 billion per year). Substantial additional savings are possible in the inpatient setting—numerous hospitals have reported large net savings from implementation of EHRs. Another analysis concluded that the total efficiency and patient safety savings from HII would be in range of \$142–371 billion each year (Hillestad et al. 2005), and a survey of the recent literature found predominantly positive benefits from HII (Menachemi et al. 2018). It is important to note that much of the savings depends not just on the widespread implementation of EHRs, but the effective interchange of this information to ensure that the *complete* medical record for every patient is immediately available in every care setting.

Inasmuch as the current cost trend of healthcare is unsustainable, particularly in the face of our aging population, this issue is both important and urgent. Without comprehensive electronic patient information, any healthcare reform is largely guesswork in our current “black box” healthcare environment where the results of interventions often take years to understand. We do not currently have mechanisms for timely monitoring of healthcare outcomes to inform needed course corrections in any proposed reform. In essence, healthcare must be “informed” before it can be effectively “reformed.”

### 15.3 History

In the U.S., the first major report to address HII was issued in 1991 by the Institute of Medicine (now known, since 2015, as the National Academy of Medicine, a part of the National Academies of Sciences, Engineering, and Medicine or NASEM). This report, “The Computer-Based Patient Record” (IOM 1991), was the first in a series of national expert panel reports recommending transformation of the healthcare system from reliance on paper to electronic information management (see ► Chap. 14). In response to the IOM report, the Computer-based Patient Record Institute (CPRI), a private not-for-profit corporation, was formed for the purpose of facilitating the transition to computer-based records. A number of **community health information networks (CHINs)** were established around the country in an effort to coalesce the multiple community stakeholders in common efforts towards electronic information exchange. The Institute of Medicine updated its original report in 1997 (IOM 1997), again emphasizing the urgency to apply information technology to the information intensive field of health care.

However, most of the CHINs were not successful. Perhaps the primary reason for this was that the standards and technology were not yet ready for cost-effective community-based electronic HIE. Another problem was the focus on availability of aggregated health information for secondary uses (e.g., policy development), rather than individual information for the direct provision of patient care. Also, there was neither a sense of extreme urgency nor were there substantial funds available to pursue these endeavors. However, at least one community (Indianapolis, Indiana) continued to move forward throughout this period and has now emerged as a national example of the application of information technology to health care both in individual healthcare settings and throughout the community (McDonald et al. 2005).

Widespread attention was focused on this issue with the IOM report “To Err is Human” (IOM 1999). This landmark study documented the accumulated evidence of the high error rate in the medical care system, including an estimated 44,000–98,000 preventable deaths each year in hospitals alone. It has proven to be a milestone in terms of public awareness of the negative consequences of paper-based information management in healthcare. Along with the follow-up report, “Crossing the Quality Chasm” (IOM 2001), the systematic inability of the healthcare system to operate at a high degree of reliability has been thoroughly elucidated. A more recent analysis estimated a much larger number of preventable deaths due to medical errors – over 400,000 (Makary and Daniel 2016). These reports clearly place the blame on the system, not on the dedicated healthcare professionals who work in an environment without effective tools to promote quality and to minimize errors.

Several additional national expert panel reports have emphasized the IOM findings. In 2001, the President’s Information Technology Advisory Committee (PITAC) issued a report entitled “Transforming Health Care Through Information Technology” (PITAC 2001). That same year, the Computer Science and Telecommunications Board of the National Research Council (NRC) released “Networking Health: Prescriptions for the Internet” (NRC 2001), which emphasized the potential for using the Internet to improve electronic exchange of healthcare information. That same year, the National Committee on Vital and Health Statistics (NCVHS) outlined a vision for building a National HII in its report, “Information for Health” (NCVHS 2001). NCVHS, a statutory advisory body to the U.S. Department of Health and Human Services (DHHS), indicated that Federal government leadership was needed to facilitate further development of HII. In response, DHHS began an HII initiative, organizing a large national conference

in 2003 to develop a consensus agenda to guide progress.<sup>7</sup> (Yasnoff et al. 2004)

In April, 2004, a Presidential Executive Order created the Office of the National Coordinator for Health Information Technology (ONC) in DHHS (see also ► Chap. 29). The initial efforts of ONC focused on promoting standards and certification to support adoption of EHRs by physicians and hospitals. It also promoted implementation of an “institution centric” model for HIE by **Regional Health Information Organizations (RHIOs)**, wherein electronic records for a given patient stored at sites of past care episodes are located, assembled, and delivered in real time when needed for patient care. Four demonstration projects implementing this model were funded, but did not lead to sustainable systems.

In 2008, ONC was codified in law by the Health Information Technology for Economic and Clinical Health (HITECH) portion of the ARRA statute (► Chap. 29). In addition, \$20+ billion was appropriated including \$2 billion for ONC and the remainder for payment of EHR incentives through Medicare and Medicaid to providers who achieved “Meaningful Use” of these systems. The ONC used its resources to establish **regional extension centers (RECs)** to subsidize assistance to providers adopting and using EHRs (\$677 million), fund states to establish HIEs (\$564 million) and initiate several research programs.

In December, 2010, the President’s Council of Advisors on Science and Technology (PCAST) issued a report expressing concern about ONC strategy, specifically indicating that its HIE efforts through the states “*will not solve the fundamental need for data to be universally accessed, integrated, and understood while also being protected*” (PCAST 2010).

Findings of a 2011 survey of HIEs “*call into question whether RHIOs in their current form can be self-sustaining and effective*” (Adler-Milstein et al. 2011).

Over the past few years, these concerns have been proven correct; HIE efforts have largely floundered. In the 2013 “reboot” report, a group of U.S. Senators criticized lack of a clear path to interoperability and sustainability, inadequate privacy and security protections, and failure to achieve health care cost reductions.<sup>8</sup> That same year, DHHS itself admitted that “[current policy] alone will not be enough to achieve the widespread interoperability and electronic exchange of information necessary for delivery reform where information will routinely follow the patient regardless of where they receive care” in an RFI requesting ideas for “accelerating HIE progress.”<sup>9</sup> At least one experienced former DHHS official bemoaned the lack of an HII architecture to guide efforts.<sup>10</sup> Even the mainstream media noticed the continuing lack of progress (Creswell 2014).

A systematic review found that HIE use through 2015 in the U.S. was “growing but still limited” (Devine et al. 2017). The official evaluation of ONC’s state HIE program tried to put a positive spin on these activities with the statistically meaningless conclusion that “about half the states [were] performing at or above the national average,” a result that by definition would always be the case. The report also observed that “sustainability was a

persistent concern among grantees.”<sup>11</sup> The latter challenge has since resulted in the shut-down of multiple projects.

Although those few surviving HIEs have nearly all abandoned their original institution-centric architectures in favor of patient-centric repositories (more on HII architecture in ► Sect. 15.5 below), the predicted reductions in health care costs from the widespread use of EHRs have not materialized primarily due to the incomplete nature of patient records available through current HIE systems. A 2017 study observed “To date, only a small number of HIE studies have demonstrated benefits to patients, providers, public health, or payers” (Yeager et al. 2017).

Overall, it is clear that three decades after the 1991 IOM report urging universal adoption of EHRs, the U.S. still lacks a clear and feasible roadmap leading to the ultimate goal of widespread availability of comprehensive electronic patient information when and where needed. Despite much progress, no one in the U.S. as yet receives their medical care with the assured, immediate availability of all their records across multiple providers and provider organizations.

## 15.4 Requirements for HII

As with any informatics system development project, it is critical at the outset to understand the desired end result. In the case of a large, extremely complex system such as HII, this is especially important because there are many stakeholders with conflicting incentives and agendas, as well as challenging policy and operational issues. The ultimate goal is the “universal availability of comprehensive electronic patient records when and where needed.” In transforming this goal into a design specification, it is critical to understand the issues

and constraints that must be addressed. Then any proposed system design must first demonstrate on paper how the objectives will be achieved within those limitations.

### 15.4.1 Privacy and Trust

The most important and overriding requirement of HII is privacy. Clearly, health records are very sensitive – perhaps the most sensitive personal information that exists. In addition to our natural desire to keep our medical information private, improper disclosure can lead to employment and other types of discrimination. Furthermore, failure to assure the privacy of records will naturally result in patients being unwilling to disclose important personal details to their providers – or even to avoid seeking care at all. In addition to the contents of the records, the very existence of certain records (e.g., a visit to psychiatric hospital) is sensitive even if no details are available. Therefore, extraordinary care must be taken to ensure that information is protected from unauthorized disclosure and use.

In general, U.S. Federal law (the HIPAA Privacy Rule as introduced in ► Chap. 12) requires patient consent for disclosure and use of medical records. However, consent is not required for record release for treatment, payment, and healthcare operations. These “TPO” exceptions have, as a practical matter, allowed healthcare organizations to utilize medical records extensively while bypassing patient consent. The organization that holds medical information has sole discretion to make the decision whether a proposed disclosure is or is not a TPO exception. Until recently, TPO disclosures did not even need to be recorded, effectively preventing discovery of improper disclosures. Even under the HITECH legislation that requires records of TPO disclosures, such records are not automatically available to the subjects of the disclosures. The net effect is that individuals not only lack control over the dissemination of their medical records, but are not even informed when they are disclosed beyond where they were created.

It seems appropriate to question whether this disclosure regime is adequate for elec-

tronic health records. The general public understands that making electronic patient records available for good and laudable purposes simultaneously makes them more available for evil and nefarious purposes, thereby necessitating higher levels of protection to avoid abuses. Assigning decision-making for disclosure of personal medical records to anyone other than the patient or the patient’s representative inherently erodes trust. In essence, the patient is being told, “we are going to decide for you where your medical records should go because we know what’s in your interest better than you do.” A patient may wonder why, if a given disclosure is in their interest, their consent would not be sought. Furthermore, failing to seek such consent inevitably leads to suspicion that the disclosure is in fact not in the patient’s interest, but rather in the interest of the organization deciding that the records should be released.

The concern about privacy of medical records is not at all theoretical or insignificant. In at least two consumer surveys, 13–17% of consumers indicated that they already employ “information hiding” behaviors with respect to their medical records<sup>12</sup> (Shortliffe 2011). This includes activities such as obtaining laboratory tests under an assumed name or seeking out-of-state treatment to conceal an illness from their primary care provider. Even assuming that everyone engaged in such behaviors was willing to admit to them in such a survey, this represents a substantial proportion of consumers who would, at a minimum, refuse to participate in an electronic medical information system that did not provide them with control over their own records. Of even greater concern, such a large percentage of consumers would likely organize and use their political power to halt the deployment and operation of such a system. Indeed, it was a much smaller percentage of concerned citizens that, citing the threat to privacy, convinced Congress to repeal the pro-

visions in the original HIPAA legislation calling for a unique medical identifier for all U.S. residents (see ► Chap. 12).

In view of this, there are those who argue that all decisions about release of patient records need to be entrusted to the patient (with rare exceptions, such as mental incompetence). They also suggest that attention to these concerns may be especially important for enabling HII, because patients must trust that their records are not being misused in such a system. Some argue that patients are not sufficiently informed to make such decisions and may make mistakes that are harmful to them, whereas others believe that the negative consequences of delegating this decision-making to others than the patient could be much greater. Advocates of patient control of medical information argue, by analogy, that society has accepted that individuals retain the right to make decisions about how their own money is spent, even though this can lead to adverse consequences when those decisions prove to be unwise. In considering these issues, it should be noted that prior to the 2002 HIPAA Privacy Rule that established the TPO exceptions, both law and practice had always required patient consent for all access to medical records. While acknowledging the need for consumer education about decisions relating to release of medical records, patient-control advocates believe that the same freedom and personal responsibility that applies to an individual's financial decisions should be applied to the medical records domain. These medical information privacy policy issues may be even more urgent in the context of the enhanced trust necessary when seeking to implement an effective and widely accepted HII.

15

### 15.4.2 Stakeholder Cooperation

To ensure the availability of comprehensive patient records, all healthcare stakeholders that generate such records must consistently make them available. While it would be ideal if such cooperation were voluntary and universal, assuring long-term collaboration of competing healthcare stakeholders is problematic.

Indeed, only a handful of communities have succeeded in developing and maintaining an organization that includes the active participation of the majority of healthcare providers. Even in these communities, the system could be disrupted at any time by the arbitrary withdrawal of one or more participants. The unfortunate reality is that healthcare stakeholders are often quite reluctant to share patient records, fearing loss of competitive advantage.
