Therefore, some would argue that mandating healthcare stakeholder participation in a system for sharing electronic patient records is highly desirable, since it would result in consistently more comprehensive individual records. Since imposing a new requirement on healthcare stakeholders would be a daunting political challenge, such an approach would be most easily accomplished as part of an existing mandate. Proponents of this approach have noted that one such mandate that could be utilized is the HIPAA Privacy Rule itself, which requires all providers to respond to patient requests for their own records (U.S. 45 CFR 164.524(a)). Furthermore, if patients request their records in electronic form, and they are available in electronic form, this regulation also requires that they be delivered in electronic form. Although not well known, this latter provision is included in the original HIPAA Privacy Rule (U.S. 45 CFR 164.524(c)(2)), and has been reinforced by HITECH. It is also being promoted by the “blue button” initiative that seeks to allow patients to retrieve their own records electronically<sup>13</sup> and the growing movement by patients advocating guaranteed access to their own data.<sup>14</sup>

Advocates argue that patient control, in addition to being an effective approach to pri-

13 Chopra A, Park T, Levin PL. (2010) ‘Blue Button’ Provides Access to Downloadable Personal Health Data. Retrieval 29 Oct 2018: ► <http://www.whitehouse.gov/blog/2010/10/07/blue-button-provides-access-downloadable-personal-health-data>

14 Miliard M. (2014) Patients want online access to records. Healthcare IT News (5 May 2014). Retrieval 29 Oct 2018: ► <https://www.healthcareitnews.com/news/patients-want-online-access-records>

vacy, could also serve to ensure ongoing, consistent healthcare stakeholder participation. Of course, in order for this approach to be practical, the rights of patients to electronic copies of their records under HIPAA would need to be universally enforced. Such enforcement has to date been inconsistent, and, until recently, exclusively dependent on the Office of Civil Rights at DHHS (since patients do not have a private right of action). Under HITECH, state attorneys general may also bring legal action, which provides another legal avenue for improving compliance.

Another option to ensure that providers make their electronic records available to patients for use in compiling comprehensive records would be to create a linkage to reimbursement for care. In this scenario, each provider would be required to offer to deposit the new information generated from an encounter in a place of the patient's choice. In cases where the patients designated a destination for their information, payment for the care received would be contingent on the deposit of the required data. While this may seem somewhat coercive and even radical, it is consistent with practices in other service industries. Whether it be car repair, plumbing, or legal services, payment is nearly always contingent on the client receiving detailed justifications and descriptions of the services provided. While a growing number of health care providers are increasingly providing such "visit summaries," at least in paper form, this remains the exception in the medical domain.

### 15.4.3 Ensuring Information in Standard Electronic Form

---

It is self-evident that the electronic exchange of health information cannot occur if the information itself is not in electronic form. Over the past decade, nearly all U.S. hospitals and most U.S. physicians have adopted EHRs as a result of the Federal government's "Meaningful Use" financial incentives.

However, the major obstacle for physician adoption of EHRs has not been merely cost, as is often cited, but the very unfavorable

ongoing cost/benefit ratio. Most of the benefits of EHRs in physician offices accrue not to the physician, but to other stakeholders. In one study, 89% of the economic benefit was attributed to other stakeholders (Hersh 2004). It is unreasonable to expect physicians to shoulder 100% of the cost of systems while accruing only 11% of the benefits. Even as physician EHR adoption levels have increased, there have been increasing complaints about the burden that EHRs impose on physicians (Sinsky et al. 2016).

It is important to note that EHRs alone, even if adopted by all healthcare providers, are a necessary but not sufficient condition for achieving HII. Indeed, each EHR simply converts an existing paper "silo" of information to electronic form. These provider-based systems manage the *provider* information on the patient in question, but do not have *all* the information for each patient. To achieve the goal of availability of comprehensive patient information, there must also be an efficient and cost-effective mechanism to aggregate the scattered records of each patient from all their various providers. Such aggregation also requires effective standards for encoding and communicating EHR information. Major gains in quality and efficiency of care will be attainable only through HII that ensures the availability of every patient's comprehensive record when and where needed.

### 15.4.4 Financial Sustainability

---

There are three fundamental approaches that can be used individually or in combination to provide long-term financial sustainability for HII: (1) public subsidy; (2) leveraging anticipated future healthcare cost savings; and/or (3) leveraging new value created. The first approach has been advocated by those who assert, with some justification, that HII represents a public good that benefits everyone. They compare HII to other publicly available infrastructure, such as roads, and suggest that taxation is an appropriate funding mechanism. Of course, new taxes are consistently unpopular and politically undesirable, and

other key infrastructures such as public utilities and the Internet, although regulated, are funded through user fees rather than taxation. Note, however, that at least two U.S. states (Maryland and Vermont) are using this mechanism to help fund their HII.

The most common approach suggested for long-term HII sustainability is leveraging anticipated healthcare cost savings. This is based on the substantial and growing body of evidence that the availability of more comprehensive electronic patient records to providers results in higher quality and lower cost care (AHRQ 2006; Menachemi et al. 2018). Some of the best examples include large, mostly closed healthcare systems such as Kaiser, Group Health and the Veterans Administration, where the availability of more complete patient records in electronic form over time has been consistently associated with both cost savings and better care. While the case for HII reducing healthcare costs is compelling, the distribution and timing of those savings is difficult to predict. In addition, cost savings to the healthcare system means revenue losses to one or more stakeholders – clearly an undesirable result from their perspective. Finally, the allocation of savings for a given population of patients is unknown, with the result that organizations are reluctant to make specific financial commitments that could be larger than their own expected benefits.

The final but least frequently mentioned path to financial sustainability of HII is utilizing the new value created by the availability of comprehensive electronic information. While it is widely recognized that this information will be extremely valuable for a wide variety of purposes, this option has remained largely unexplored. One example of such new value is the potential reduction in cost for delivering laboratory results to ordering physicians. The expenses borne by individual laboratories for their own infrastructure providing this essential service can be greatly reduced by a single uniform community infrastructure providing electronic delivery to physicians through one mechanism. Another example is availability of

medical information for research – both to find eligible subjects for clinical trials and to utilize the data itself for research queries. While this latter application has the potential to defray a substantial portion of the costs of HII, it requires efficient mechanisms for both searching data and recording and maintaining patient consent that have not generally been incorporated into HII systems.

Perhaps the most lucrative HII revenue source lies in the development of innovative applications that rely on the underlying information to deliver compelling value to consumers and other healthcare stakeholders. For example, HII allows the delivery of timely and accurate reminders and alerts to patients for recommended preventive services, needed medication refills, and other medically related events of immediate interest to patients and their families. It also would allow deployment of applications that assist consumers automatically with management of their chronic diseases. Utilizing new value to finance HII avoids the prediction and allocation problems inherent in attempts to leverage expected healthcare cost savings, with the added incentive that any such savings would fully accrue to whoever achieves them.

#### 15.4.5 Community Focus

Most observers believe that successful HII must be focused on the community. An essential element in HII is trust, which is inherently local. Furthermore, health care itself is predominantly local, since the vast majority of medical care for residents of a given community is provided in that community. Indeed, people traveling away from home who are injured or become ill inevitably will return home at their earliest opportunity if their condition permits (and does not resolve quickly). Since medical care is predominantly local, creating a system that delivers comprehensive electronic patient information in a community solves the overwhelming majority of information needs in that community. While move-

ment of health information over long distances has some value and ultimately must be addressed to assure completeness of records, its contribution to a total solution is marginal.

The lack of any examples of working HII in communities larger than about 10 million people provides additional evidence of the need for local focus. Keeping the scope of such projects relatively small also increases their likelihood of success by reducing complexity, thereby avoiding the huge increases in failure rates of extremely large-scale IT projects. This rule of thumb is reinforced by the relatively small populations of countries that have successfully implemented effective HII such as Finland (5.5 million) and Estonia (1.3 million).

In thinking about HII, analogies are often made to the international financial system that efficiently transfers and makes funds available to individuals anywhere in the world. However, it is often forgotten that these financial institutions, that also are heavily dependent on trust, began as “building and loan funds” in very small communities designed to share financial resources among close neighbors. It took many decades of building trust before large-scale national and international financial institutions emerged.

#### **15.4.6 Governance and Organizational Issues**

---

Trust is arguably the most important element in considering the appropriate governance for HII. Even in a system where patients exert full control over their own records, the organization that operates the HII must earn the full faith and confidence of consumers for the security, integrity, and protection of the records, as well as ensuring that records are appropriately available only for purposes that consumers specify. Furthermore, the organi-

zation ideally must be devoid of any biases or hidden agendas that would favor one category of healthcare stakeholders over another, or favor specific stakeholders within a given category.

None of the existing healthcare stakeholders seem well suited to meet the trust requirement. Many argue that government cannot operate an HII because it is inherently not trusted with sensitive personal records, and furthermore needs to assume the role of providing regulatory oversight for whatever organization does take the HII responsibility. Similarly, it seems problematic for employers to be responsible for the HII since one of the primary concerns of consumers is to avoid disclosing sensitive medical information to their employers. Health plans and insurers are typically not trusted by consumers because their incentives are not aligned – they have a financial incentive to deny care, which is a natural concern to consumers. Hospitals are in competition with each other and therefore are not in a good position to cooperate in a long-term HII effort. Physicians are the most trusted healthcare stakeholders, from a consumer perspective, but are not organized in a way to facilitate the creation of HII. Furthermore, they are also in competition with each other and, most importantly, do not generally have the informatics capabilities necessary for such a complex endeavor.

Therefore, many believe that an independent (perhaps entirely new) organization is needed to operate HII in communities. This organization would have no direct connections to existing healthcare stakeholders and therefore would be unbiased. Its sole function would be to protect and make available comprehensive electronic patient records on behalf of consumers. Such an independent organization would also ideally facilitate cooperation among all existing stakeholders, who would know that the HII activity was completely neutral and designed primarily to serve consumers.

## 15.5 Architecture for HII

### 15.5.1 Institution-Centric Architecture

Initially, most developing HII systems chose an institution-centric approach to data storage, leaving patient records wherever they are created (■ Fig. 15.2). Although records are not stored centrally in this model, there is a need to maintain at least a central index of where information can be found for a particular patient; without such an index, finding information about each patient would require queries to every possible source of medical information worldwide -- clearly an impractical approach. When a given patient's record is requested, the index is used to generate queries to the locations where information is stored. The responses to those queries are then aggregated (in real time) to produce the patient's complete record. After the patient encounter, the new data is entered into the clinician's EHR system and another pointer (to that system) is added to the index so it will be queried (in addition to all the other prior locations) next time that patient's record is requested.

While this architecture appeals to health-care stakeholders because they continue to "control" the records they generate, one can argue that it fails to meet several key require-

ments, does not scale effectively, and is complex and expensive to operate. The most critical requirement that is not addressed by this architecture is searching the data, e.g., to find all patients with a cholesterol level above 300. To do such a search, the records of every patient must be assembled from their various locations and examined one at a time. Known as a sequential search, it has a very long completion time that increases linearly with the size of the population. For example, in a modest-sized HIE with 500,000 patients, assuming retrieval and processing of each patient's records requires just 2 seconds (a very low estimate), each such search would take at least 12 days (1 million seconds). Furthermore, every such search would require that each provider record system connected to the HIE retrieve and transmit all its information -- a very substantial computing and communications burden (that also increases the risk of interception of information). In standard database systems, impractical sequential search times are reduced by pre-indexing the contents of the records. However, such pre-indexing would in essence create a central repository of indices that could be used to reconstruct most of the original data, and therefore is inconsistent with this architectural approach.

It may be argued that the searches could themselves be distributed to the provider systems, and then the results aggregated into a

■ **Fig. 15.2** Institution-centric HII architecture. (1) The clinician EHR requests prior patient records from the HIE; this clinician's EHR is added to the index for future queries for this patient (if not already present). (2) Queries are sent to EHRs at all sites of prior care recorded in the HIE Index. (3) EHRs at each prior site of care return records for that patient to the HIE; the

HIE must wait for all responses. (4) The returned records are assembled and sent to the clinician EHR; any inconsistencies or incompatibilities between records must be resolved in real time. (5) After the care episode, the new information is stored in the clinician EHR only. (Used with permission of Health Record Banking Alliance (HRBA))

coherent result. However, this approach also fails because individual patient records are incomplete in each system. Therefore, searches that require multiple items of patient data (e.g., patients with chest pain who have taken a certain medication in the past year), will produce anomalous results unless all the instances of the relevant data for a given patient are in a single provider system (i.e., if one system finds a patient with chest pain, but without any indication of the medication of interest [which is in another provider's system], that patient will not be reported as satisfying the conditions) (Weber 2013). It is possible to launch multiple searches each limited to a single criterion and then combine the results from each to generate a correct result. However, this would require multiples of the completion time for a single criterion (e.g.,  $12 \text{ days} \times 2 = 24 \text{ days}$  for the two criteria example), making the retrieval times and processing burdens even more untenable.

In addition to the scaling issues for this architecture related to searching, there is also a problem with response time for assembling a patient record. When a given patient record is requested, the locations where the patient has available records are found using the central index. Then, a **query-response cycle** is required for each location where patient records are available. Following completion of the query-response cycles, all the information obtained must be integrated into a comprehensive

record and made available to the requestor. While the query-response cycles can all be done in parallel, the final integration of results must wait for the slowest response. As the number of connected systems increases, so does the probability of a slow (or absent) response from one of them when queried for patient records. In addition, more systems mean more processing time to integrate multiple sources of information into one coherent record. Thus, the response time will become slower as the number of connected systems increases (Lapsia et al. 2012).

The institution-centric architecture also introduces high levels of operational complexity. Since the completeness of retrieval of a given patient's records is dependent on the availability of all the systems that contain information about that patient, ongoing real-time monitoring of all connected information sources is essential. This translates into a requirement for a  $24 \times 7$  **network operations center (NOC)**, that constantly monitors the operational status of every medical information system and is staffed with senior IT personnel who can immediately troubleshoot and correct any problems detected (■ Fig. 15.3). Even with modest system failure rates (e.g., one per thousand), a community with thousands of EHRs will typically have a handful of systems that are unresponsive to queries for patient records and require immediate expert attention to restore to full operation.

■ **Fig. 15.3** Example of a Network Operations Center (NOC). (Image used by permission of NTT Ltd (available at ► <https://www.gin.ntt.net/support-center/noc/>))

The cost of this around-the-clock monitoring is very substantial, since a staff of at least five full-time network engineers is required to assure that at least one person is always available for every shift 7 days a week.

Adding to the cost of the NOC, every EHR system in an institution-centric model must incur additional expenses to always be able to respond to queries in real-time. This will be extremely problematic for physician offices, since their EHR systems will need to operate  $24 \times 7$  and include additional hardware, software, and telecommunications capabilities to simultaneously support such queries while also serving its local users. Clearly, the transaction volumes generated will be substantial, since each patient's records will be queried whenever they receive care at any location. Contrast this to a central repository model where the information from a care episode is transmitted once to the repository and no further queries to the source systems are ever needed. This analysis has been confirmed by a simulation study of the institution-centric architecture demonstrating that both the transaction volume and probability of incomplete records (from missing data due to a malfunctioning network node) increase exponentially with the average number of sites where each patient's data is located (Lapsia et al. 2012).

## 15.5.2 Patient-Centric Architecture (Health Record Banking)

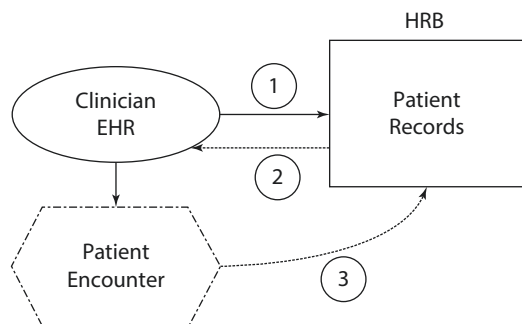

Health record banking is a patient-centric approach to developing community HII that both addresses the key requirements and can overcome the challenges that have stymied current efforts<sup>15</sup> (Yasnoff et al. 2013). A **health record bank (HRB)** is defined as “an indepen-

dent organization that provides a secure electronic repository for storing and maintaining an individual's lifetime health and medical records from multiple sources and assuring that the individual always has complete control over who accesses their information” (Detmer et al. 2008).

Using a community HRB to provide patient information for medical care is straightforward (■ Fig. 15.4). Prior to seeking care (or at the time of care in an emergency), the patient gives permission for the caregiver to access his/her HRB account records (either all or part) through a secure Internet portal. The provider then accesses (and optionally, downloads) the records through a similar secure web site. When the care episode is completed, the caregiver then transmits any new information generated to the HRB to be added to the account-holder's lifetime health record. The updated record is then immediately available for subsequent care.

### ■ History of HRBs

The health record banking concept has been evolving for over two decades since it was initially proposed (Szolovits et al. 1994). The

■ Fig. 15.4 Patient-centric HII architecture. (1) The clinician EHR requests prior patient records from the HRB. (2) The prior patient records are immediately sent to the clinician EHR. (3) After the care episode, the new information is stored in the clinician EHR and sent to the HRB; any inconsistencies or incompatibilities with prior records in the HRB need to be resolved before that patient's records are requested again (but not in real time). 15 Yasnoff WA. (2006) *Health Record Banking: A Practical Approach to the National Health Information Infrastructure*. Retrieval 29 Oct 2018: <http://nhiiadvisors.com/slides/Health%20Rec%20Banking.html>

term “health information bank” was introduced in 1997 in the U.K. (Dodd 1997), and was subsequently described as the “bank of health” (Ramsaroop and Ball 2000). A legal analysis of the implications of a “health record trust” was published in 2002 (Kostyack 2002), an Italian system known as the “health current account” was described in 2004 (Saccavini and Greco 2004), and the “health record bank” concept was described by Dyson in 2005 (Dyson 2005). In 2006, a Heritage Foundation policy paper endorsed health record banking,<sup>16</sup> additional papers described HRBs in more detail (Ball and Gold 2006; Shabo 2006), the non-profit Health Record Banking Alliance was formed,<sup>17</sup> the State of Washington endorsed the concept after a 16-month study,<sup>18</sup> and the non-profit Dossia consortium was formed by several large employers to implement and operate an HRB for their employees. In 2007, the Information Technology and Innovation Foundation recommended that the health record banking approach be used to build the U.S. HII,<sup>19</sup> while Gold and Ball described the “health record banking imperative” (Gold and Ball 2007). That same year, both Microsoft and Google introduced patient-controlled medical record repositories. In 2009, three pilot HRBs were funded by the State of Washington and

the role of HRBs in protecting privacy was described (Kendall 2009). The HRB concept, although not always named as such, started appearing with greater frequency in articles discussing the need for comprehensive EHRs (Steinbrook 2008; Mandl and Kohane 2008; Kidd 2008; Miller et al. 2009; Krist and Woolf 2011).

More recently, discussion and activities related to HRBs have accelerated and expanded even more. Multiple articles have been published advocating for patient control of their own records and considering the issues involved<sup>20</sup> (Kish and Topol 2015; Haun and Topol 2017). An entire supplement to the *Journal of General Internal Medicine* was devoted exclusively to this topic (JGIM 2015). Even a White House Senior Advisor and the Administrator of CMS have joined the chorus touting the advantages of patient control of their own records.<sup>21</sup> In addition, at least two publications have discussed using the value of the information to facilitate sustainability<sup>22</sup> (Porter 2018).

There are also a continuing stream of articles describing HRBs and advocating for their establishment and use. These include the rationale for HRBs (Yasnoff et al. 2013), potential HRB use in public health (Yasnoff et al. 2014), and a description of lessons

learned from an early HRB startup (Yasnoff and Shortliffe 2014). Endorsement of the HRB concept (albeit referenced under various different terms) has come from a variety of sources including a prominent observer of the digital transformation of health care (Mikk et al. 2017), a policy think tank,<sup>23</sup> a former ONC Director,<sup>24</sup> and a leading market research firm.<sup>25</sup> Even the current CMS Administrator has been openly advocating for lifetime, longitudinal patient records accessible to and controlled by patients.<sup>26</sup>

Several countries have established successful HRBs, including Finland,<sup>27</sup> Estonia,<sup>28</sup> and Brazil.<sup>29</sup> In addition, a number of startup

companies such as Project Hugo,<sup>30</sup> CareDox,<sup>31</sup> Patients Know Best,<sup>32</sup> Betterpath,<sup>33</sup> and Ciitizen<sup>34</sup> (as well as a number of others) are pursuing the challenge of developing HRBs. Even the tech giant Apple appears to be moving towards HRB implementation with its Apple Health Kit serving as the infrastructure for a patient record repository controlled by individuals on their own smartphones.<sup>35</sup>

#### ■ How Requirements Lead to HRB Architecture

■ Figure 15.5 shows how the HII requirements for complete records, low cost, and high benefits lead directly to the HRB architecture. In order to ensure complete records, information from each patient encounter must be available. The only currently available mandate for this is for the patient to request records (in digital form) from their provider, invoking their rights under the HIPAA privacy rule. In order for patients to feel comfortable doing that, they must trust the system. The first element of trust is the architectural end point of security; the patients must know that the records being sent from their provider will be protected from improper use. This also leads to the architectural end point of patient control of all access to the records; how can it be justified to patients for some other entity to

**Fig. 15.5** How requirements lead to HRB architecture. This diagram shows how the key requirements of complete records, low cost, and high benefits lead directly to the architectural specifications of patient access control, a repository for data storage, and trustworthy security that are characteristic of health record banks

decide which records to release to whom and when? In order to assure feasible patient access control, the records must be stored in a repository (the third and final architectural end point) so that patients have a single point for indicating and revising their record access permissions.

The requirement for low cost means that the architecture must be simple. The most straightforward architecture for compiling and accessing complete records for each person is a repository – it is easy (and therefore inexpensive) to implement and operate.

Finally, the requirement for high value leads to the intermediate requirement to be able to search records across the population. It is those searching operations that provide critical information of great value for public health, medical research, quality improvement, and policy. Such searchability is much more easily achieved when the records are in a repository.

Therefore, the architecture needed for a low cost, high benefit HII with complete records is a secure repository with record access controlled by patients. These are the exact characteristics of health record banks, which were conceived and designed to specifically address these key HII requirements.

#### ■ Patient Control Ensures Privacy and Stakeholder Cooperation

In an HRB, everything is done with *consumer consent*, with account-holders controlling their copy of all their records and deciding who gets to see any or all of it. This protects privacy (since each consumer sets their own customized privacy policy), promotes trust, and ensures stakeholder cooperation since all holders of medical information must provide it when requested by the patient (Kendall 2009). Of course, the operations of an HRB must be open and transparent with independent auditing of privacy practices. World-class state-of-the-art computer security is needed to protect the HRB, which will be a natural target for hackers. At least one new security approach is now available that absolutely prevents large-scale data loss from a repository of medical records (Yasnoff 2016), the key security requirement for an HRB (see subsection on HRB Security below).

Natural concerns arise from the ability of the patient to suppress any or all of their HRB account information, which could lead to misdiagnosis and dangerous treatment. This capability could be abused by patients who, for example, may seek multiple prescriptions for controlled substances for the pur-

pose of diversion for illegal sale. With respect to the possibility of medical errors resulting from incomplete information, the patient would be clearly and unmistakably warned about this when choosing not to disclose any specific information (e.g., “Failure to disclose any of your medical information may lead to serious medical problems, including your death”). The expectation is that few people will choose to do this, particularly after such a warning. However, as noted earlier, 13–17% of patients already engage in this practice, leading many observers to conclude that the general public may not be comfortable with a system that provides easy access to their records unless they are in control of such access. This issue ultimately becomes one of public policy and may also be a subject of discussion between the doctor and the patient (i.e., the doctor will want to be assured by the patient that all information is being provided). Clearly, physicians should not be liable for the consequences of the patient’s choice to withhold information.

With respect to patients who use their power to hide information as a way to facilitate improper or illegal activity, there is clearly an overriding public policy concern. For example, in the case of controlled substances, it may be necessary to report to the physician (or, if legislatively mandated, to regulatory authorities) whenever a patient suppresses any information about controlled substance prescriptions. The information itself would still be under the patient’s control, but the physician would be alerted with a notice such as “some controlled substance prescription information has been withheld at the patient’s request.” There may be other situations where such warnings are needed.

- **Assuring that Standardized, Encoded Electronic Patient Information Is Consistently Deposited**

HRBs can provide ongoing incentives for deposits of EHR records by clinicians, which

would help to offset the unfavorable cost/benefit of EHRs for office-based providers. These incentives could be paid on a per-encounter or per-month basis. In addition, those few physicians who do not currently have EHRs could receive no-cost Internet-accessible EHR systems (at HRB expense) with the understanding that information from patient encounters would be automatically transferred to the HRB. Another option is to link reimbursement for medical services to HRB deposits – i.e., providers would not be paid unless the medical record information generated from those services is transmitted to an HRB. This makes sense economically, as the value of medical services is greatly limited if the information about patients is not readily available for their ongoing care.

Incentives for HRB deposits also serve to ensure compliance with data standards, both initially and on an ongoing basis. Clearly, any EHR provided through the HRB would, by definition, transmit information back to the HRB in a standard format (since the HRB would only provide systems that can do so). For physicians who already have EHRs, HRB reimbursements for deposits from those systems would naturally require complete and fully encoded encounter data using established standards to be sent to the HRB. Over time, higher levels of encoding of medical information can be promoted through the gradual introduction of more stringent standards requirements (with plenty of lead time to allow for system upgrades). Compliance with such changes in standards could also be further assured through a direct relationship to reimbursement.

- **HRB Business Model**

Health record banking has advantages on both the cost and revenue sides of the business model; the cost is lower and the revenue opportunities greater. Because of the lower operating costs and additional functionality

for searching records, one can envision a variety of business models for HRBs that do not depend on public subsidies or attempt to capture any healthcare savings, but are solely funded through new value created for consumers and other stakeholders.<sup>36</sup>

Due to the simplicity of HRB operations, the cost is substantially less than an equivalent institution-centric architecture. For an HRB, providing access at the point of care only involves a single retrieval from the bank's repository of records. In an institution-centric model, the records for a given patient are located at an arbitrary number of dispersed sites, and must be assembled in real-time and integrated into a comprehensive record before they can be used for patient care. Not only is this process of assembly complex, time-consuming, and prone to error, it necessitates, as noted above, the creation of a fully staffed  $24 \times 7$  NOC to monitor the availability of all information sources as well as troubleshoot and correct those that are malfunctioning.

The estimated cost for the NOC in an institution-centric model is substantial. For example, given a population of 1,000,000, at least 1,000 systems would need monitoring (one for every 1,000 patients). Assuming a reasonable failure rate for fully functional query connectivity to each system of once/year (representing a **mean time between failures [MTBF]** of over 8,700 hours), there would be an average of 2.73 failures/day or 0.91 failures per 8-hour shift that would need troubleshooting attention. A minimum staff for the NOC would be one person  $24 \times 7$ ; given 21 shifts/week plus leeway for vacations and sick leave, this would require at least 5 full-time equivalent staff costing about \$200,000 each including equipment, overhead

and fringe benefits. Assuming an additional \$500,000/year for hardware and software to operate the institution-centric system (over and above the data repository needed for an HRB) yields an annual cost of \$1.5 million or \$1.50/person/year. This would add nearly 20% for the institution-centric model to the estimated \$8/person/year needed to operate an HRB (Kaelber et al. 2008).

Beyond this, the additional costs imposed in the institution-centric model for each connected EHR for additional hardware, software, telecommunications capability, and additional operational expenses to maintain  $24 \times 7$  system availability must also be included. Even if such costs were only a very modest \$1,000/year/system (less than \$100/month), this would result in an additional \$1,000,000 or \$1/person/year. Adding this to the \$1.50/person/year for the NOC gives a total estimated cost of \$2.50/person/year, resulting in over 30% higher costs for the institution-centric model than a basic HRB. Added to this would be the costs and complexity of establishing and maintaining data sharing agreements among all the entities, which would be substantial.

An HRB with comprehensive electronic medical records for individuals in a community can generate substantial value (Yasnoff and Shortliffe 2014). In addition to empowering physicians to provide safer, more effective, and more efficient care, the availability of such records readily enables many types of heretofore infeasible yet very desirable services for patients, providers, and other stakeholders.

Perhaps the most compelling example of a service for patients is the "peace of mind" alert that immediately notifies the patient's loved ones about a critical event, such as an emergency room visit. As soon as the emergency provider accesses the patient's HRB record, the alert, which is delivered electronically in a manner chosen by the recipient, is delivered. Such a service is particularly valuable for children of seniors who may not be

36 Health Record Banking Alliance. (2012) Health Record Banking: A Foundation for Myriad Health Information Sharing Business Models. White Paper (12 Dec 2012). Retrieval 29 Oct 2018: ► [http://www.healthbanking.org/uploads/9/6/9/4/9694117/hrba\\_white\\_paper\\_business\\_model\\_dec\\_2012.pdf](http://www.healthbanking.org/uploads/9/6/9/4/9694117/hrba_white_paper_business_model_dec_2012.pdf)

immediately notified that their parent is undergoing emergency care.

Another example of a patient service is the “preventive care reminder” that indicates to the patient recommended preventive interventions, e.g. a flu shot, customized based on demographics and history. Since the reminder is based on comprehensive records, it is highly likely to be correct, and therefore relevant, to the patient. Once the service is obtained, further reminders would cease. In this way, patients would not be distracted by irrelevant or redundant reminders.

A third example of a patient service is medication refill reminders. These could be sent via text message, allowing the patient to respond briefly to indicate approval of the refill. While a number of pharmacies currently provide such services, the HRB reminders would be independent of pharmacy, and the record of the patient’s permission for such communications would only need to be maintained in one place.

An example of a service for providers is the “normal or unchanged lab result” message to patients. Every day, providers review results for previously ordered tests and communicate those results with their recommendations to their patients. With an HRB, deposits of new lab results that are either normal, or within a specified range of a previous result for that patient, could be automatically sent to the patient over the provider’s signature indicating that all is well. It would no longer be necessary for the provider to take the time to review and comment manually on such results, which would be a significant productivity enhancement.

There are many other potentially valuable benefits of comprehensive HRB patient records, such as the ability to comprehensively monitor clinical care for public health, query clinical records for research and policy purposes (with patient permission), and eliminate the need for separate registries of clinical information (e.g. diabetes, asthma, cancer, immunization) since all the data normally stored in such registries would already be available in the HRB.

## ■ HRB Security

It has long been known that centralized data storage is the best way to ensure security (Turn et al. 1976). The reason for this is clear: distributed data is inherently less secure since it must be transmitted multiple times for each use. However, the single source of all data provided by a central database is also an inherent weakness; if all the data is accessible all-at-once for good purposes, it must necessarily also be available for misappropriation and misuse. Multiple recent large-scale healthcare security breaches (Associated Press 2015; Abelson and Goldstein 2015; Reuters 2015) validate the risk of centralizing substantial amounts of sensitive medical information. How can data for each person in a community be readily available while ensuring its security?

The **personal grid architecture** (Yasnoff 2016) addresses this difficult problem by storing each patient’s information in a separate file, separately encrypted with its own strong password. The clear advantage of this approach is that there is no longer a single access point for multiple patient records. Indeed, if an adversary somehow obtained a complete copy of all the data, it would be of very limited value since access to each individual record would require breaking a strong encryption key, a very costly and time-consuming process. Thus, not only is the data protected, but the incentive for hackers to obtain the data is largely eliminated.

However, this approach also has a serious drawback with respect to searching records across a population. To do this, each record must be retrieved, decrypted, and searched in sequence, which is prohibitively slow. Indeed, the reason relational and other databases are used for storage is that these systems “pre-index” the data to allow rapid retrieval across records. Such “pre-indexing” is not compatible with the personal grid architecture as it would create the single access point to all the data that the architecture has deliberately eliminated to ensure security, thereby defeating the core purpose of the approach.

Fortunately, the development of cloud computing has provided a convenient, acceptable solution to searching across population

data in the personal grid. Although sequential searching, which is inherently slow, is still required, the searching can be distributed over hundreds or even thousands of servers from a cloud computing provider. While the amount of computing needed remains the same, this parallel approach reduces the search time by orders of magnitude. It is estimated, for example, that the search time for a population of 5 million using 500 parallel search servers would be just 7 minutes. In the medical environment, there are no use cases where response times for population searches need to be less than an hour (in fact, overnight is usually adequate), so this searching methodology can effectively overcome the requirement for sequential search that the personal grid imposes to ensure security.

Some observers have suggested that blockchain, the increasingly popular secure distributed ledger methodology<sup>37,38</sup> could be a useful alternative for securing medical records. However, blockchain has a number of serious drawbacks for this application: (1) Medical records are massively larger than financial ledger entries, so the storage requirements for the required copies of the entire dataset at each of the multiple blockchain nodes would be prohibitive; (2) Every blockchain node would receive and have a copy of everyone's medical records for that dataset, which unnecessarily increases the risk of a security breach even if the records are encrypted both in transit and at rest; (3) Adding records to the blockchain requires extensive computing resources for which there is no clear source of compensation; and (4) Security for medical records must be trusted by the general public, which requires that they understand why the records are

secure. The complexity of blockchain and its dependence on advanced encryption and game theory methods makes it extremely difficult and time consuming to fully explain to non-technical audiences, precluding an informed basis for widespread trust. In view of these issues, the effective, inexpensive, and easy-to-understand personal grid architecture is a better choice to meet the security requirements for medical record storage.

#### ■ Summary Comparison of Institution-Centric and Patient-Centric Architectures

■ Table 15.1 summarizes the characteristics of the institution-centric approach to HII compared to the patient-centric (HRB) model. The patient-centric model is simpler and more straightforward, and deals directly with the issue of privacy by putting patients in control of their own information. Interoperability is much more easily accomplished in the patient-centric model since standards compliance can be reinforced with financial incentives, and reconciliation of inconsistencies between records need not be real-time. The patient-centric approach is financially sustainable with a variety of business models, and can provide powerful incentives to clinicians to deposit EHR data for their patients. Finally, the patient-centric model avoids the substantial processing burden on clinician EHRs from queries each time any patient whose record is stored is seen anywhere. In each of the categories of requirements, organizational issues, cost, operations, and incentives, the patient-centric approach has substantial advantages.

## 15.6 Progress Towards HRBs

### 15.6.1 HRB Opposition

If, as has been clearly elucidated in this chapter, HRBs are the most effective and efficient solution for HII architecture, why hasn't this approach been widely adopted? The short answer is that key healthcare stakeholders, such as insurers, health plans, and hospitals often oppose it (although typically not

37 Brakeville S and Perepa B. (2018) Blockchain basics: Introduction to distributed ledgers. IBM Developer Tutorial (31 Oct 2018). Retrieval at:

**Table 15.1** Comparison of the institution-centric and patient-centric approaches to HII

Issue	Institution-centric	Patient-centric
<i>Requirements</i>		
Privacy	Patient consent difficult to implement; many complex data sharing agreements needed	Simple; patients in control of all access to their own records; consent easy to implement
Security	Inherently weak because records transmitted multiple times for each use	Very strong using new security techniques that eliminate large-scale data loss from repositories
Searchability	Impractical to search population data	Search feasible using parallel processing in the cloud
Completeness	Requires queries to all data sources each time a patient's records are requested; all must respond for completeness	Comprehensive data available at all times for each patient
<i>Organizational issues</i>		
Cooperation needed	Extensive; community-wide	Unifying; HIPAA mandates records on patient request
Organizational complexity	High; ongoing collaboration of multiple competing stakeholders necessary	Low; HRB is neutral and independent of all stakeholders
<i>Cost</i>		
Startup cost	Substantial (due to high complexity)	Moderate
Operational cost	Inefficient/expensive	Efficient/inexpensive
Business model	Complex; no clear approach has emerged; typically requires ongoing subsidies from health care stakeholders	Sustainable using new value of complete information; many options possible funded by patients/payers/purchasers
<i>Operations</i>		
IT design	Complex, based on “fetch and show”; requires queries to multiple entities, real-time reconciliation of inconsistencies, and NOC	Simple, based on “deposit once to account”; no secondary queries or real-time reconciliation needed; NOC unnecessary
Reliability	Prone to error (record sources unavailable)	Reliable; one operation to retrieve individual patient data
Interoperability	Compliance voluntary	Compliance can be assured with financial incentives
<i>Incentives</i>		
Clinician incentives	Not included	Easy to include
Clinician burden	Extensive; incoming query each time current patients seen anywhere increases EHR costs	Minimal; information deposited once in HRB; no incoming queries

openly). However, this is an oversimplification of the complex incentives involved.

For insurers, their claims data provides the most comprehensive picture of individual health care service usage. While this information is not sufficiently detailed to facilitate clinical management of patients, it gives the insurers the “informational advantage” in negotiations with their customers, employers that purchase insurance for their employees, and their payees, physicians, hospitals, and health plans. HRBs would make much more detailed information about each patient potentially available to all healthcare stakeholders, eliminating this informational advantage. In addition, HRBs have the potential to reduce health care costs. While this would seem to be positive for insurers (making their offerings less expensive to employers), it also would reduce their profitability, which is typically a percentage of those health care costs. For these reasons (and perhaps others), insurers have worked actively against HRB development, for example, by legislatively derailing promising efforts to jump start HRB development in Washington State. Of course, since comprehensive patient-controlled electronic records are so appealing to the public, the opposition of insurers has been behind the scenes. The latter is a theme that is common to all the stakeholder opposition, as it is difficult to openly justify opposing the safer, more effective, more efficient care likely to result from HRBs.

Health plans and hospitals have somewhat different reasons for opposing HRBs. Mostly, this involves concerns about empowering their competitors. Typically, the largest hospitals and health plans in each region have more complete information than their smaller competitors, and therefore see HRBs as weakening or eliminating that perceived market advantage. Sadly, this is true despite the fact that HRBs would allow all providers to deliver better care. Another issue, particularly for hospitals, is that they are concerned about the idea of sharing their electronic patient information after spending hundreds of millions of dollars (or more) to install and operate

EHR systems. The financial interests of health plans and hospitals also appear to conflict with the deployment of HRBs, since their adoption would likely reduce their fee-for-service incomes by eliminating unnecessary and duplicative care. Again, this opposition is behind the scenes to avoid having to openly advocate for higher institutional income over patient safety and effective, efficient care.

In a situation such as this, where progress that would benefit everyone (i.e., HRBs) is opposed by specific groups, one would hope that the government, representing the interests of all the people, would help ensure that the good of everyone prevails. However, in the U.S., the ability of the government to impose major changes is quite limited (due to the system of “checks and balances”), and is especially so when the proposed changes are opposed by many key stakeholders. It has therefore been relatively easy for major healthcare stakeholders to delay and/or redirect HRB efforts by, for example, advocating for other solutions, raising seemingly valid objections to reasonable efforts to move forward, or creating organizations that appear to be working towards a solution while in reality being dedicated to maintaining the status quo.

### 15.6.2 Factors Accelerating HRB Progress

---

Perhaps the most important factor accelerating HRB progress is the recent and ongoing change in the reimbursement system for care. The move from “fee for service” to “pay for value” is changing the incentives for all health care stakeholders. Under “fee for service,” the more efficient care enabled by HRBs would directly translate to lower reimbursement, a clearly undesirable outcome for providers. But a “pay for value” system financially rewards efficiency, thereby creating a strong incentive for the more complete and timely patient information that HRBs can make available. While the transition from “fee for service” to “pay for value” is still in its relatively early stages, it is reasonable to expect that ongoing

progress in this direction will be accompanied by growing support for the HRB architecture.

In addition, the growing recognition of an “individual right” to personal data ownership and control is also an enabling force for HRB adoption. The adoption of the EU General Data Protection Rule<sup>39</sup> as well as the widespread backlash against use of individual data for profit without permission of the data subjects<sup>40,41,42</sup> is creating a higher level of awareness and support for personal data control. This is likely to accelerate the demand for organizations such as HRBs that can provide individuals with the ability to capture and control their sensitive medical record information.

There are at least four additional factors that are currently facilitating and even accelerating the development of health record banks (HRBs):

- Patient records are now largely electronic.
  - This is a necessary prerequisite for any HII approach. Thanks largely to the subsidies to providers and hospitals to acquire EHR systems, most patient records are now digital.
- Effective standards are available.
  - Standards for transmission of EHR data have evolved. While not perfect, the HL7 CCDA standard is an effective methodology for transmitting and receiving patient data. Other potentially even more effective standards, such as

FHIR (Fast Healthcare Interoperability Resources), are rapidly evolving.

- Smart phones are nearly ubiquitous
  - Smart phones provide a convenient and readily accessible mechanism for individuals to access and control their digital health records.
- New computer security methods can prevent large-scale breaches
  - Community-based repositories of digital health records must be able to reliably prevent large-scale breaches. The new “personal health grid” architecture does this in an easy-to-understand way.

Finally, as mentioned earlier, there are now several successful examples of HRB implementations outside the U.S. As the benefits of these systems are documented and become more widely known, this should also increase the demand for HRBs throughout the world.

## 15.7 Evaluation

The last element in the strategy for promoting a complex and lengthy project such as the HII is evaluation to both gauge progress and define a complete system. Evaluation measures should have several key features. First, they should be sufficiently sensitive so that their values change at a reasonable rate (a measure that only changes value after 5 years will not be particularly helpful). Second, the measures must be comprehensive enough to reflect activities that affect most of the stakeholders and activities needing change. This ensures that efforts in every area will be reflected in improved measures. Third, the measures must be meaningful to policymakers. Fourth, periodic determinations of the current values of the measures should be easy so that the measurement process does not detract from the actual work. Finally, the totality of the measures must reflect the desired end state so that when the goals for all the measures are attained, the project is complete.

A number of different types or dimensions of measures for HII progress are possi-

ble. Aggregate measures assess HII progress over the entire nation. Examples include the percentage of the population covered by an HII and the percentage of healthcare personnel who utilize EHRs. Another type of measure is based on the setting of care. Progress in implementation of EHR systems in the inpatient, outpatient, long-term care, home, and community environments could clearly be part of an HII measurement program. Yet another dimension is healthcare functions performed using information systems support, including, for example, registration systems, decision support, and CPOE. Finally, it is also important to assess progress with respect to the semantic encoding of EHRs. Clearly, there is a progression from the electronic exchange of images of documents, where the content is only readable by the end user viewing the image, to fully standardized and encoded EHRs where all the information is indexed and accessible in machine-readable form.

Sadly, the evidence is now overwhelming that U.S. HIEs in their current form are, with rare exceptions, not succeeding. Labkoff and Yasnoff described four criteria for the quantitative evaluation of HII progress in communities: (1) completeness of information, (2) degree of usage, (3) types of usage, and (4) financial sustainability (Labkoff and Yasnoff 2007). Using these criteria, four of the most advanced community HII projects in the U.S. achieved scores of 60–78% (on a 0–100 scale), indicating substantial additional work was required before the HII could be viewed as complete.

The 2010 PCAST report stated, “*HIEs have drawbacks that make them ill-suited as the basis for a national health information architecture*” (PCAST 2010). Among those drawbacks, PCAST cited administrative burdens (data sharing agreements to ensure stakeholder cooperation), financial sustainability, interoperability, and an architecture that cannot be scaled effectively. A recent survey of HIEs (Adler-Milstein et al. 2011) found only 13 HIEs in the U.S. (covering 3% of hospitals

and 0.9% of physician practices) capable of meeting Stage 1 Meaningful Use criteria, and even those metrics by no means ensure the availability of comprehensive electronic patient information when and where needed. Of those, only 6 were reported to be financially viable. More importantly, *none* of the HIEs surveyed had the capabilities of a comprehensive system as specified by an expert panel.

Overall, the current approaches to building HII consistently fail to meet one or more of the requirements described above: privacy, stakeholder cooperation, ensuring fully electronic information, financial sustainability, and independent governance. While these problems are highly interdependent, it is useful to consider them in the context of the decisions that communities have made about HII architecture, privacy, and business model that, while appearing attractive to stakeholders in the short term, have so far been largely unsuccessful. Exploration and large-scale testing of alternative approaches that directly address the requirements, such as health record banking, seem both necessary and increasingly urgent.

## 15.8 Conclusions

---

While progress has been made and efforts are continuing, successful development and operation of comprehensive HII systems remains a largely unsolved problem in the U.S. Happily, we are now seeing successful HII implementations in other countries that can provide important examples of feasible and effective systems. The extensive focus on building HII systems has greatly improved our understanding of the requirements, barriers, and challenges, as well as potential solutions. Despite the daunting obstacles, the benefits of HII are sufficiently urgent and compelling to ensure major ongoing work in this domain. Through these activities, the HII path to comprehensive electronic patient records when and where needed is becoming clearer, and substantial

additional progress is highly likely over the next few years.

### Questions for Discussion

1. Make the case for and against investing \$billions in the HII. How successful have the HITECH Meaningful Use

incentives been in promoting HII development? What could have been done differently to make them more effective?

2. What organizational options would you consider if you were beginning the development of HII? What are the pros and cons of each? How would you proceed with making a decision about which one to use?
3. Estimate the required bandwidth and transaction rate for patient-centric (HRB) vs. institution-centric HII architecture.
4. Consider the policy implications of universal availability of comprehensive electronic patient records. What are the risks and how could they be mitigated?
5. Given the architectural and other advantages of HRBs, why have most communities adopted institution-centric architectures up to now? What are some steps that might be helpful in encouraging communities to evaluate alternative architectures such as HRBs?
6. Show specifically the potential locations where patient consent functionality could be added to the institution-centric and patient-centric HII architectures in  Figs. 15.2 and 15.4 and describe the granularity of consent that would be possible at each proposed location. After eliminating any redundant functionality, compare and contrast the consent implementation issues for the two alternative architectures, describing the advantages and disadvantages of each. Which architecture more efficiently addresses the issue of patient consent? Why?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

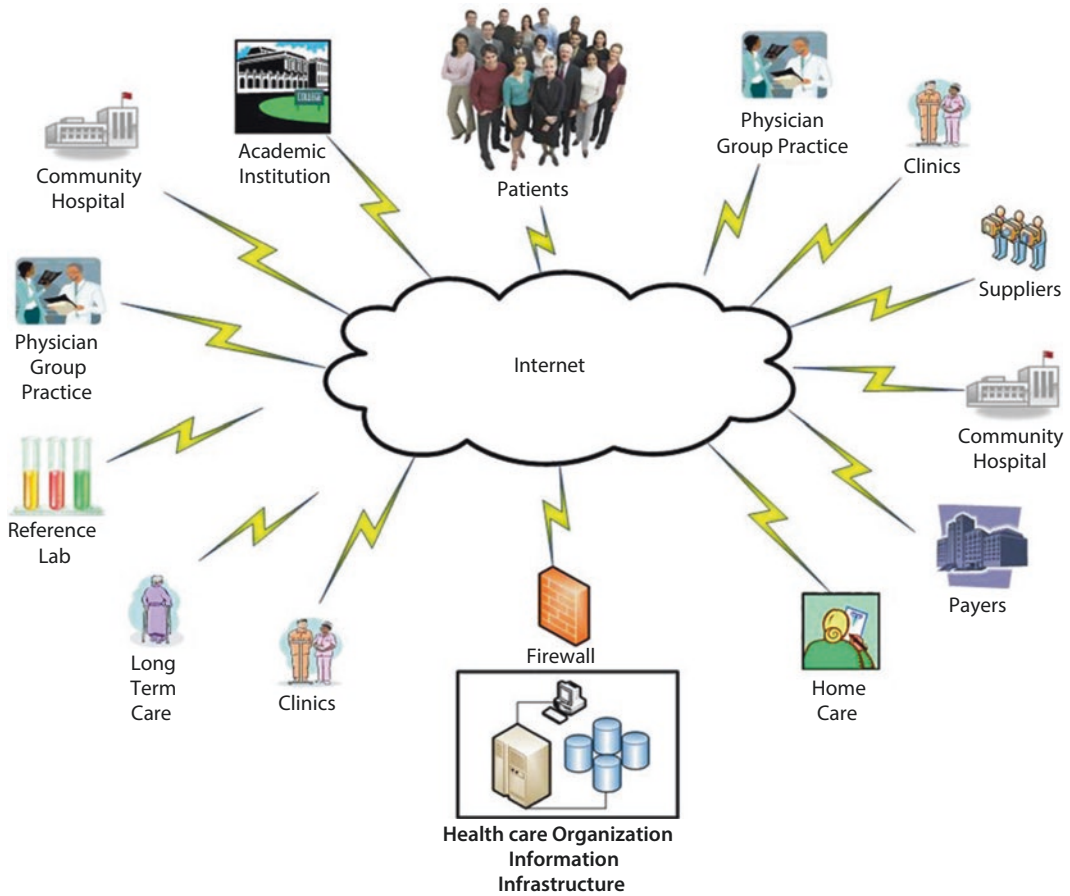

- What are the primary information requirements of health care organizations (HCOs)?
- What are the clinical, financial, and administrative functions provided by health care information systems (HCISs), and what are the potential benefits of implementing such systems?
- How have changes in health care delivery models changed the scope and requirements of HCISs over time?
- How do differences among business strategies and organizational structures influence information systems choices?
- What are the major challenges to implementing and managing HCISs?
- How are ongoing health care reforms, technological advances, and changing social norms likely to affect HCIS requirements in the future?

## 16.1 Overview

**Health care organizations (HCOs)**, and **Integrated Delivery Networks (IDNs)** like many other business entities, are information-intensive enterprises. Health care personnel require sufficient data and information management tools to make appropriate decisions. At the same time, they need to care for patients and manage and run the enterprise; they also need to document and communicate plans and activities, and to meet the requirements of numerous regulatory and accrediting organizations. *Clinicians* assess patient status, plan patient care, administer appropriate treatments, and educate patients and families regarding clinical management of various conditions. They are also concerned about evaluating the clinical outcomes, quality, and increasingly, the cost of health services provided. *Administrators* determine appropriate staffing levels, manage inventories of drugs and supplies, and negotiate payment contracts for services. *Governing boards* make decisions about whether to invest in new busi-

ness lines, how to partner with other organizations, and how to eliminate underutilized services. Collectively, health care professionals comprise a heterogeneous group with diverse objectives and information requirements, and in the end, all are expected to be focused on the *patients* who are, after all, the reason for all of this.

The purpose of **health care information systems (HCISs)** is to support the access, processing, and management of the information that health care professionals need to perform their jobs effectively and efficiently. HCISs facilitate communication, integrate information, and coordinate action among multiple health care professionals—and increasingly, patients. In addition, HCISs organize and store substantial amounts of data and they support record-keeping and reporting functions. Many of the clinical information functions of an HCIS were detailed in our discussion of the computer-based patient record (CPR) in ► Chap. 14; systems to support nurses and other care providers are discussed in ► Chap. 17. Furthermore, HCISs are key elements that interface with the health information infrastructure (HII), as discussed in ► Chap. 15. An HCIS also supports the financial and administrative functions of a health organization and associated operating units, including the operations of ancillary and other clinical-support departments. The evolving complexities of HCOs place great demands on an HCIS. Many HCOs are broadening their scope of activities to cover the care continuum, partially in response to **Accountable Care Organization (ACO)**, **Value-based Purchasing** and **Bundled Payment** initiatives from the federal government. HCISs must organize, manage, and integrate large amounts of clinical and financial data collected by diverse users in a variety of organizational settings (from patient homes to physicians' offices to hospitals to health care systems) and must provide health care workers (and, increasingly, patients) with timely access to complete, accurate, and up-to-date information presented in a useful format. The diversity and extent of the modern IDN is illustrated in ■ Fig. 16.1.

**Fig. 16.1** Major organizational components of an integrated delivery network (IDN). A typical IDN might include several components of the same type (e.g., clinics, community hospitals, physician group

practices, etc.). Components within the same geographic area may have direct data connections, but increasingly the Internet is the preferred way to connect organizational components

## 16.2 Historical Evolution of the Technology of Health Care Information Systems (HCISs)

Technological advances as well as changes in the information and organizational requirements of HCOs, have driven many of the changes in system architecture, hardware, software, and functionality of HCISs over time. The tradeoff between functionality and ease of integration is an important factor that influences the choices that vendors have made in systems design.

### 16.2.1 Central and Mainframe-Based Systems

The earliest HCISs (typically found in hospitals) were designed according to the philosophy that a single comprehensive or **central computer system** could best meet an HCO’s information processing requirements. Advocates of the centralized approach emphasized the importance of first identifying all the hospital’s information needs and then designing a single, unified framework to meet these needs. Patient management and billing functions were the initial focus of such efforts. One

result of this design goal was the development of systems in which a single large computer performed all information processing and managed all the data files using application-independent file-management programs—initially focusing almost exclusively on financial and billing data. Users accessed these systems via general-purpose **video-display terminals (VDTs)** affectionately known as “green screens” because the displayed numbers and text were often green on a dark background.

Central systems integrated and communicated information well because they provided users with a centralized data store and a single, standardized method to access information simply and rapidly. On the other hand, the biggest limitation of central systems was their inability to accommodate the diverse needs of individual departments. There is a tradeoff between the uniformity (and relative simplicity) of a generalizable system and the nonuniformity and greater responsiveness of custom-designed systems that solve specific problems for specialized departments. Generality—a characteristic that enhances communication and data integration in a homogeneous environment—can be a drawback in an HCO because of the complexity and heterogeneity of the information-management tasks. As a result, central systems have proved too unwieldy and inflexible to support evolving HCO requirements, except in smaller facilities.

## 16.2.2 Departmental Systems

By the late 1970s, departmental systems had begun to emerge. Advances in technology resulted in decreases in the price of hardware and improvements in software, making it feasible for individual departments within a hospital to acquire and operate their own computers. In a **departmental system**, one or a few computers can be dedicated to processing specific functional tasks within the department. Distinct software application modules carry out specific tasks, and a common framework, which is specified initially, defines the interfaces that will allow data to be shared among the modules. Radiology

(► Chap. 22) and Laboratory systems are examples of these types of systems. As HCOs increasingly selected the best functionality for their departmental systems, their IT strategy became known as **best of breed**.

The departmental approach responded to many of the challenges of central systems. Although individual departmental systems are constrained to function with predefined interfaces, they do not have to conform to the general standards of an overall system, so they can be designed to accommodate the special needs of specific areas. For example, the processing capabilities and file structures suitable for managing the data acquired from a patient-monitoring system in the intensive-care unit (analog and digital signals acquired in real time) differ from the features that are appropriate for a system that reports radiology results (image and text storage and processing). Furthermore, modification of departmental systems, although laborious with any approach, is simpler because of the smaller scope of the system. The price for this greater flexibility is increased difficulty in integrating data and communicating among modules of the HCISs. In reality, installing a system is never as easy as simply plugging in the connections.

The challenge of sharing data among many different information systems that emerged in the 1980s and 1990s was daunting. As noted earlier, the various components of the HCISs were in most cases developed by different vendors, using different hardware (e.g., DEC, IBM), operating systems (e.g., PICK, Altos, DOS, VMS, MUMPS on minicomputers, and IBM's 360 OS on mainframes) and programming languages (e.g., BASIC, PL/I, COBOL, MUMPS, and even Assembler). Sharing data among two different systems typically required a two-way interface—one to send data from System A to System B, the other to send data or acknowledge receipt from B back to A. Adding a third system didn't require simply one additional interface because the new system would in many cases have to be interfaced to both of the original systems, resulting in the possibility of six interfaces. Introducing a fourth system into the HCIS environment

■ **Fig. 16.2** The challenge of moving data from one system to another becomes complicated with the addition of each new system. Considering that even small size hospitals may have several hundred applications, interfacing is a major challenge. While not all systems need to have two-way interfaces to every other system, this figure illustrates the challenges that even small numbers of systems bring

increased the complexity further, since it often meant the need for two-way interfaces to each of the original three systems, for a total of 12 (■ Fig. 16.2). With the prospect of interfaces increasing exponentially as new systems were added (represented by the formula,  $I = n(n-1)$  where  $I$  represents the number of interfaces needed and  $n$  represents the number of systems), it was clear that a new solution was needed to address the complexity and cost of interfacing.

In response, an industry niche was born which focused on creating a hardware and software application combination designed to manage the interfacing challenges among disparate systems in the HCIS environment. Instead of each system having to interface to every other system independently, an interface engine served as the central connecting point for all interfaces (■ Fig. 16.3). Each system had only to connect to the interface engine; the engine would then manage the sending of data to and from any other system that needed it. The interface engine concept, which originated in health care, has given rise to a whole

■ **Fig. 16.3** The introduction of the Interface Engine (IE) made system interfaces much more manageable, particularly so with the implementation of HL7 data messaging standards. With an IE, each additional system only added two additional interfaces to the mix, one to send data and one to acknowledge receipt of the data

series of strategies for managing multiple systems. Many of the vendors who got their start in health care interfacing subsequently found new markets in financial services as well as other industries.

Continued advancements in departmental systems were made possible as computing power increased and corresponding costs decreased through the advent of microcomputers. Even smaller ancillary departments such as Respiratory Therapy, which previously could not justify a major computer acquisition, could now purchase dedicated file servers and workstations and participate in the HCIS environment. Health care providers in nursing units or at the bedside, physicians in their offices or homes, and managers in the administrative offices could eventually access and analyze data locally using what were initially termed microcomputers (later known as desktop personal computers or PCs).

### 16.2.3 Integration Challenges

In the early 1980s, researchers at the University of California, San Francisco (UCSF) Hospital successfully implemented one of the first **Local Area Networks (LANs)**

to support communication among several of the hospital's standalone systems. Using technology developed at the Johns Hopkins University, they connected minicomputers that supported patient registration, medical records, radiology, the clinical laboratory, and the outpatient pharmacy. Interestingly, each of the five computer systems was different from the others: the computers were made by different manufacturers and ran different operating systems but were able to communicate with each other through standardized communications protocols.

By the late 1980s, HCISs based on evolving network-communications standards were being developed and implemented in HCOs. As **distributed computer systems**, connected through electronic networks, these HCISs consisted of a federation of independent systems that had been tailored for specific application areas. The computers operated autonomously and shared data (and sometimes programs and other resources, such as printers) by exchanging information over a local area network (LAN) using standard protocols such as **TCP/IP** and **Health Level 7 (HL7)** for communication and in many cases utilizing the interface engine strategy we discussed earlier in ► Sect. 16.2.2. One advantage of LAN-connected distributed systems was that individual departments could have greater flexibility in choosing hardware and software that optimally suited their specific needs. On the downside, the distribution of information processing capabilities and responsibility for data among diverse systems made the tasks of data integration, communication, and security more difficult—a fact that continues to the present day. Development of industry-wide standard network and interface protocols such as TCP/IP and HL7 has eased the technical problems of electronic communication considerably.

Still, there are problems to overcome in managing and controlling access to a patient database that is fragmented over multiple computers, each with its own file structure and method of file management. Furthermore, when no global architecture or vocabulary standards are imposed on the HCISs, individual departments and entities may encode

data values in ways that are incompatible with the definitions chosen by other areas of the organization. The promise of sharing among independent departments, entities, and even independent institutions has increased the importance of defining clinical data standards (see ► Chap. 7) As noted earlier, some HCOs pursued a best of breed strategy in which they chose the best system, regardless of vendor and technology, then worked to integrate that system into their overall HCIS environment. Some HCOs modified this strategy by choosing suites of related applications, e.g., selecting all ancillary systems from a single vendor (also known as **best of cluster**), thereby reducing the overall number of vendors they work with and, in theory, reducing the costs and difficulty of integration.

Commercial software vendors have supported this strategy by broadening their offerings of application suites and managing the integration at the suite level rather than at the level of individual applications. For example, Epic, one of the major enterprise-wide HCIS vendors, started in the late 1960s with a focus on physician billing systems, and over the subsequent 40 years evolved into a fully integrated product suite encompassing ambulatory, inpatient, ancillary and billing functionality. Cerner, another major enterprise-wide HCIS vendor, started with a suite of products for ancillary systems such as clinical laboratories, pharmacy and radiology, and over a similar time period evolved into a full-service product suite including inpatient, outpatient and billing functionality.

With the increasing availability of single vendor systems, the need to develop and implement applications that support the specific functionality has diminished significantly. PC-based universal workstations are now the norm and some HCOs and IDNs support thousands of PCs in enterprise-wide networked environments. The requirement for direct access to independent ancillary systems has been largely eliminated not only by enterprise data networks, but by vendors offering integrated product suites which include support for general clinical as well as ancillary service functionality. Where specialized systems remain, interfaces join such systems to

a core clinical system or to a centralized clinical data repository. These permit the ability to access patient databases (by clinicians), human resources documents (by administrators and employees), financial information (by administrators) and basic information about facilities, departments, and staff (by the public) through a single enterprise-wide data network (See ■ Fig. 16.1).

Historically, as more information systems were added to the HCIS environment, the challenge of moving data from one system to another became overwhelming. In response, beginning in the 1980s, two unique developments occurred: (1) the interface engine; and (2) Health Level Seven (HL7), a standard for the structure of the data messages that were being sent from one information system to another (see ► Chap. 7).

The creation of HL7 was yet another response to the challenge of moving data among disparate health care systems. HL7 is a health care-based initiative focused on the development of data messaging standards for the sharing of data among the many individual systems that comprise an HCIS. The basic idea was to use messaging standards so that data could be sent back and forth using standard formats within the HCIS environment. Most of the departmental systems that were introduced at this time were the products of companies focused on specific niche markets, including laboratories, pharmacies and radiology departments. Consequently, there was strong support for both the interface engine and the HL7 efforts as mechanisms to permit smaller vendors to compete successfully in the marketplace. In recent years, many of these pioneering vendors have been purchased and their products included as components of larger single vendor product families.

In hospitals, clinical and administrative personnel have traditionally had distinct areas of responsibility and performed many of their functions separately. Thus, it is not surprising that administrative and clinical data have often been managed separately—administrative data in business offices and clinical data in medical-records departments. When computers were first introduced, the hospital's information processing was often performed on

separate computers with separate databases, thus minimizing conflicts about priorities in services and investment. In addition, information systems to support hospital functions and ambulatory care historically have, due to organizational boundaries, developed independently. Many hospitals, for example, have rich databases for inpatient data but maintain less information for outpatients. As **fee-for-service** reimbursement models continue to be challenged for their focus on activity-driven care, alternatives such as **ACOs**, **bundled payments** for services, and **pay for performance** proposals will stimulate efforts toward greater data integration.

By the late 1980s, **clinical information system (CIS)** components of HISs offered clinically oriented capabilities, such as order writing and results communications. During the same period, **ambulatory medical record systems (AMRSs)** and **practice management systems (PMSs)** were being developed to support large outpatient clinics and physician offices, respectively. These systems performed functions analogous to those of hospital systems, but were generally less complex, reflecting the complexity of patient care delivered in outpatient settings. However, there has historically been little or no systems integration between hospital and ambulatory settings.

The historical lack of integration of data from diverse sources creates a host of problems. If clinical and administrative data are stored on separate systems, then data needed by both must either be entered separately into each system, be copied from one system to another, or data from both sources transferred to yet another location to be analyzed. In addition to the expense of redundant data entry and data maintenance incurred by these approaches (see also the related discussion for the health information infrastructure in ► Chap. 15), the consistency of information tends to be poor because data may be updated in one place and not in the other, or information may be copied incorrectly from one place to another. In the extreme example, the same data may be represented differently in different settings. As we noted earlier within the hospital setting, many of these issues have been addressed through the development of

automated interfaces to transfer demographic data, orders, results, and charges between clinical systems and billing systems. Even with an interface engine managing data among disparate systems, however, an organization still must solve the thorny issues of synchronization of data and comparability of similar data types.

With the development of IDNs and other complex HCOs, the sharing of data elements among operating units becomes both more critical and more problematic. Data integration issues are further compounded in IDNs by the acquisition of previously independent organizations that have clinical and administrative information systems incompatible with those of the rest of the IDN. It is still not unusual to encounter minimal automated information exchange among organizations even within an IDN. Patients register and reregister at the physician's office, diagnostic imaging center, ambulatory surgery facility, and acute-care hospital—and sometimes face multiple registrations even within a single facility. Each facility may continue to keep its own clinical records, and shadow files may be established at multiple locations with copies of critical information such as operative reports and hospital discharge summaries. Inconsistencies in these multiple electronic and manual databases can result in inappropriate patient management and inappropriate resource allocation. For example, medications that are first given to a patient while she is a hospital inpatient may inadvertently be discontinued when she is transported to a rehabilitation hospital or nursing home. Also, information about a patient's known allergies and medication history may be unavailable to physicians treating an unconscious patient in an emergency department.

The objectives of coordinated, high-quality, and cost-effective health care cannot be completely satisfied if an organization's multiple computer systems operate in isolation. Unfortunately, free-standing systems within HCOs are still common, although HCOs and IDNs are increasingly investing in the implementation of new more consistent systems across all their facilities or in integrat-

ing existing systems to allow data sharing. The capital investment required to pursue a strategy of system-wide data integration can be significant, and with ongoing challenges to reimbursement rates for both hospitals and physicians, the funding to pursue this strategy is often limited either due to competing investment requirements (e.g., acquiring or maintaining buildings and equipment) or the continued downward trend in reimbursement for services.

#### 16.2.4 Evolution to Enterprise-Wide Health Care System Information Systems

---

If an HCO or IDN is to manage patient care effectively, project a focused market identity, and control its operating costs, it must perform in a unified and consistent manner. For these reasons, information technologies to support data and process integration are recognized as critical to an IDN's or HCO's operations. From an organizational perspective, information should be available when and where it is needed; users must have an integrated view, regardless of system or geographic boundaries; data must have a consistent interpretation; and adequate security must be in place to ensure access only by authorized personnel and only for appropriate uses. Unfortunately, these criteria are much easier to describe than to meet.

Over time, changes in the health care economic and regulatory environments have radically transformed the structure, strategic goals, and operational processes of health care organizations through a gradual shifting of financial risk from third party payers (e.g., traditional insurance companies such as Blue Cross and Blue Shield, Medicare and Medicaid programs that emerged in the 1960s and 1970s) to the providers themselves and in many cases directly to the patient through higher deductibles, co-pays, benefit caps, etc. This shifting of risk initially brought about a consolidation of health care providers into **integrated delivery networks (IDNs)** in the 1990s.

Mergers and acquisitions (M&A) have been an important part of corporate life for close to 200 years; in health care, the M&A experience has been largely felt over the past 20 years. One major difference is that HCOs often form “affiliations” rather than participate in outright merger and acquisition activity—except in situations in which HCOs actually acquire physician practices. So while “M&A” is an appropriate reference for corporate activity outside of health care, “MA&A” (Mergers, Affiliations and Acquisitions) may be a more appropriate term for the health care industry. Cost savings are often touted as the rationale for M&A activity, but that goal is seldom able to be documented and more typical the result is to drive excess capacity from the system (e.g., an oversupply of hospital beds) and to secure market share.

IDNs are still a prominent feature in many health care markets, often driven by new regulatory requirements aimed at improved efficiency while emphasizing greater patient privacy and safety. While the most successful of IDNs have achieved a measure of structural and operational integration, gains from the integration of clinical activities and from the consolidation of HCISs have been much more difficult. Many IDNs scaled back their original goals for integrating clinical activities and began to shed home care services, health plans and managed care entities. Most recently, the pendulum has swung back as IDNs acquire both physician practices and hospitals while shifting their focus to becoming identified as an ACO, as reimbursement constraints and federal ACO initiatives strive to improve both the efficiency and effectiveness of HCOs. All these changes have tremendous implications for HCISs.

The expertise gained from managing an inpatient-driven organization producing a relatively large amount of revenue from a relatively small set of events (e.g., a hospital) does not readily translate to the successful management of other organizational activities that in many cases required many more events to produce a similar level of revenue (e.g., from outpatient clinics). In some cases, it was even a challenge to translate management processes from inpatient operations to outpatient clinics, or one hospital to another.

Attempts to apply hospital management principles to ambulatory clinics have been challenged because inpatient-based hospitals generate a relatively small number of patient bills with high dollar amounts whereas ambulatory clinics do just the opposite—generate a relatively large number of patient bills, each with a relatively small dollar amount. To date, it is fair to say that few IDNs have gained the degree of cost savings and efficiencies they had originally projected. The immense upfront costs of implementing (or integrating) the required HCISs have contributed to this limited success. Regardless of organizational structure, all health care organizations are striving toward greater information access and integration, including improved information linkages with physicians and patients. The “typical” IDN is a melding of diverse organizations, and the associated information systems infrastructure is still far from integrated; rather, it remains in many cases an amalgam of heterogeneous systems, processes, and data stores (Blackstone & Fuhr Jr. 2003; Kastor 2001; Shortell et al. 2000).

### 16.2.5 Information Requirements

The most important function of any HCIS is to present data to decision makers so that they can improve the quality and timeliness of the decisions they need to make. From a clinical perspective, the most important function of an HCIS is to present patient-specific data to care givers so that they can easily interpret the data for diagnostic and treatment planning purposes and support the necessary communication among the many health care workers who cooperate in providing health services to patients. From an administrative perspective, the most pressing information needs are those related to the daily operation and management of the organization—bills must be generated accurately and rapidly, employees and vendors must be paid, supplies must be ordered, and so on. In addition, administrators need information to make short-term and long-term planning decisions.

Since clinical system information requirements are discussed in ► Chaps. 14, 17, 21,

and 24, we focus here on operational information requirements, and specifically on four broad categories: daily operations, planning, communication, and documentation and reporting.

- *Operational requirements.* Health care workers—both care givers and administrators—require detailed and up-to-date information to perform the daily tasks that keep a hospital, clinic, or physician practice running—the bread-and-butter tasks of the institution. These include not only clinical activities, but financial management, acquisition and management of supplies, posting charges, sending bills and receiving payments. Queries for operational purposes can include: In what room is patient John Smith? What drugs is he receiving? What tests are scheduled for Mr. Smith during his stay and after his discharge? What insurance coverage does he have? Is the staffing skill mix sufficient to handle the current volume and special needs of patients in Care Center 3 West? What are the names and telephone numbers of patients who have appointments for tomorrow and need to be called for a reminder? What authorization is needed to perform an ultrasound procedure on Jane Blue under the terms of her health insurance coverage? Are the daily, monthly and annual financial reports accurate? Are the charges for services and supplies accurately collected and transferred to the billing system? Are bills sent out in a timely manner and remittances received and posted to the correct accounts? HCISs can support these operational requirements for information by organizing data for prompt and easy access. Because the HCO may have developed product-line specialization within a particular facility (e.g., a diagnostic imaging center or women’s health center), however, answering even a simple request may require accessing information stored in different systems at several different facilities.
- *Planning requirements.* Health professionals also require information to make short-term and long-term decisions about patient care and organizational management. The importance of appropriate clinical

decision-making is obvious—we devote all of ▶ Chaps. 3 and 24 to explaining methods to help clinicians select diagnostic tests, interpret test results, and choose treatments for their patients. The decisions made by administrators and managers are no less important to their choices concerning the acquisition and use of health care resources. In fact, clinicians and administrators alike must choose wisely in their use of resources to provide high-quality care and excellent service at a competitive price. In addition, HCOs live in a highly regulated world and must report to local, state, federal and private entities on how they manage the care they provide and on the safety of that care. HCISs should help health care personnel (including auditors) to answer queries such as these: What are the organization’s clinical guidelines for managing the care of patients with this condition? Have similar patients experienced better clinical outcomes with medical treatment or with surgical intervention? What are the financial and medical implications of closing the maternity service? If we added six care managers to the outpatient-clinic staff, can we improve patient outcomes and reduce emergency admissions? Will the proposed contract to provide health services to Medicaid patients be profitable given the current cost structure and current utilization patterns? How many incidents occurred during the last month, including patient falls, medications that were given to the wrong patient or administered with the wrong dose? How often were supplies such as fire extinguishers or oxygen sources inspected? Often, the data necessary for planning and meeting regulation requirements are generated from many sources. HCISs can assist by aggregating, analyzing, and summarizing the information relevant to decision-making and compliance.

- *Communication requirements.* Communication and coordination of patient care and operations across multiple personnel, multiple business units, and far-flung geography are not possible without investment in an underlying technology infrastruc-

ture. For example, the routing of paper medical records, a cumbersome process even within a single hospital, is an impossibility for a regional network of providers trying to act in coordination. Similarly, it is neither timely nor cost effective to copy and distribute hard copy documents to all participants in a regionally distributed organization. An HCO's technology infrastructure can enable information exchange via web-based access to shared databases and documents, collaborative platforms, electronic mail, document-management systems, and on-line calendaring systems, as well as providing and controlling access for authorized users at the place and time that information is required.

- *Documentation and reporting requirements.* The need to maintain records for future reference or analysis and reporting makes up the fourth category of informational requirements. Some requirements are internally imposed. For example, a complete record of each patient's health status and treatment history is necessary to ensure continuity of care across multiple providers and over time. External requirements create a large demand for data collection and record keeping in HCOs (as with mandated reporting of vaccination records to public health agencies). As discussed in ► Chap. 14, the medical record is a legal document. If necessary, the courts can refer to the record to determine whether a patient received proper care. Insurance companies require itemized billing statements, and medical records substantiate the clinical justification of services provided and the charges submitted to them. The **Joint Commission (JC)**, which certifies the qualifications and performance of many health care organizations, has specific requirements concerning the content and quality of medical records, as well as requirements for organization-wide information-management processes. Furthermore, to qualify for participation in the Medicare and Medicaid programs, the JC requires that hospitals follow standardized procedures for auditing the medical staff and monitoring the quality

of patient care, and they must be able to show that HCOs meet the safety requirements for infectious disease management, buildings, and equipment. Employer and consumer groups are also joining the list of external monitors.

### 16.2.6 Process Integration

To be truly effective, information systems must mesh smoothly with the people who use them and with the specific operational workflows of the organization. But **process integration** poses a significant challenge for HCOs and for the HCIS's as well. Today's health care-delivery models represent a radical departure from historical models of care delivery. Changes in reimbursement and documentation requirements often lead, for example, to changes in the responsibilities and work patterns of physicians, nurses, and other care providers; the development of entirely new job categories (such as care managers who coordinate a patient's care across facilities or between encounters); and the more active participation of patients in their own personal health management (■ Table 16.1). Process integration is further complicated in that component entities typically have evolved different operational policies and procedures, which can reflect different historical and leadership experiences from one office to another, or in the extreme example, from one floor to another within a single hospital.

The most progressive HCOs are developing new enterprise-wide processes for providing easy and uniform access to health services, for deploying consistent clinical guidelines, and for coordinating and managing patient care across multiple care settings throughout the organization. Integrated information technologies are essential to supporting such enterprise-wide processes. Mechanisms for information management aimed at integrating operations across entities must address not only the migration from legacy systems but also the migration from legacy work processes to new, more consistent and more standardized policies and processes within and across entities.

**Table 16.1** The changing health care environment and its implications for an IDN's core competencies. Columns 1 and 2 are used with permission with CSC. Column 3 is the authors' addition

Characteristics	Old care model	Twentieth Century care model	Twenty-first Century care model
Goal of care	Manage sickness	Manage wellness	Prevent illness
Center of delivery system	Hospital	Primary-care providers/ ambulatory settings	Physician offices, retail clinics
Focus of care	Episodic acute and chronic care	Population health, primary care	Preventive care
Driver of care decisions	Specialists	Primary-care providers/ patients	Patients with support of physicians, physician assistants, nurse practitioners
Metric of system success	Number of admissions	Number of enrollees	Patient outcomes
Performance optimization	Optimize individual provider performance	Optimize system-wide performance	Optimize patient outcomes
Utilization controls	Externally controlled	Internally controlled	Value based care
Quality measures	Defined as inputs to system	Defined as patient satisfaction	Value of care provided through measurement of patient outcomes
Physician role	Autonomous and independent	Member of care team; user of system-wide guidelines of care	Guiding physician assistants, providing oversight to nurse practitioners
Patient role	Passive receiver of care	Active partner in care	Primary driver of care

The introduction of new HCISs changes the workplace. Research has shown that in most cases the real value from an investment in information systems comes only when underlying work processes are changed to take advantage of the new information technology (see [Figs. 16.4](#) and [16.5](#)). At times, these changes can be substantial. The implementation of a new system offers an opportunity to rethink and redefine existing work processes to take advantage of the new information-management capabilities, thereby reducing costs, increasing productivity, or improving service levels. For example, providing electronic access to information that was previously accessible only on paper can shorten the overall time required to complete a multi-step activity by enabling conversion of serial processes (completed by multiple workers using the same record sequentially) to concurrent processes (completed by the workers accessing an

electronic record simultaneously). More fundamental business transformation is also possible with new technologies; for example, direct entry of medication orders by physicians, linked with a decision-support system, allows immediate checking for proper dosing and potential drug interactions, and the ability to recommend less expensive drug substitutes (Vogel 2003).

Few health care organizations today have the time or resources to develop entirely new information systems or redesign processes on their own; therefore, most opt to purchase commercial software products and to use consultants to assist them in the implementation of industry “best practices”. Although these commercial systems allow some degree of custom tailoring, they also reflect an underlying model of work processes that may have evolved through development in other health care organizations with different underlying

## Order Entry Management Tasks Before Automation

Physician Tasks	Nursing Tasks	Clerk Tasks
Locate patient chart		Locate patient chart
Review clinical results (lab, radiology, etc.)		Transcribe orders-to clerk kardex, to nurse kardex
Jot notes from clinical results	Locate patient chart	If clarification is needed, contact nurse
Examine patient (s)	Verify orders transcribed correctly	Complete requisitions-lab, radiology, etc.
Locate patient chart	“Note” new med orders correct on medication records	Send requisitions to depts or put in a pick up area
Review record again	Sign off on each set of orders	Send via fax or call depts for new orders- diet, respiratory, etc
Open “orders” tab	Close chart	Locate medication records
Write orders	“Unflag” chart indicating orders complete	Enter new medication orders
If writing discharge order-write discharge prescriptions	Put chart back in chart rack	Note status/completion of each item on order
Sign orders	Carry out orders or assign to staff to complete	Close chart
“Flag” chart that new orders are present	Educate patient on new orders as needed	“Flag” chart that orders have been transcribed
Replace chart in rack		Put chart back in rack
If wrote STAT orders, notify clerk and nurse		
<b>13 steps</b>	<b>9 steps</b>	<b>12 steps</b>

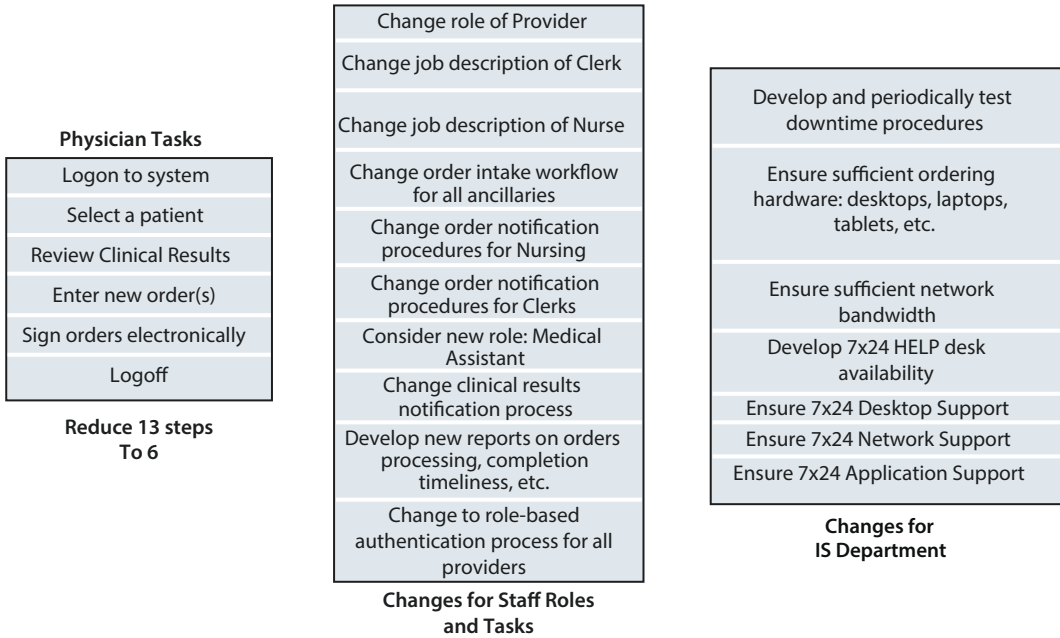

**Fig. 16.4** The process of managing the manual creation of orders requesting services on behalf of patients in a hospital involves numerous tasks performed not only by the ordering physician, but by nursing and clerical staff

operational policies and procedures. To be successful, HCOs typically must adapt their own work processes to those embodied in the systems they are installing (For example, some commercial systems require care providers to discontinue and then reenter all orders when a patient is admitted to the hospital after being monitored in the emergency department). Furthermore, once the systems are installed and workflows have been adapted to them, they become part of the organization's culture—and any subsequent change to the new system may be arduous because of these workflow considerations. Decision-makers should take great care when selecting and configuring a new system to support and enhance desired work processes. Such organizational workflow adaptation represents a significant challenge to the HCO and its systems planners. Too often organizations are unable to realize the full potential return on their HCIS investments when they attempt to change

the system to accommodate historical work flows, even before the new system is installed. Such management practices can significantly reduce much of the potential gains from the HCO's IT investment.

The **Health Information Technology for Economic and Clinical Health Act of 2009, (HITECH)** signed into law as Title XIII of **American Recovery and Reinvestment Act of 2009 (ARRA)** economic stimulus bill, provided almost \$30 Billion as an incentive for hospitals and physician practices to acquire and implement Electronic Medical Records (EMRs). As a result, during subsequent years, over 90% of hospitals and physician practices implemented EMRs. Consolidation among the vendor community, particularly for inpatient products, occurred during the same period with companies like Epic, Cerner, Meditech and Allscripts dominating the market and at the same time enhancing their product suites to incorporate most of the

**Benefits from reduced tasks for Provider  
require additional "complementary"  
management changes**

**Fig. 16.5** The implementation of an electronic physician order entry system reduces the number of tasks that a physician needs to perform to enter an order, but

such a system will only be successful if other “complementary” changes are made to both the workflow of staff and the responsibilities of the IS Department

HCIS functionality needed by hospitals. This has led to the demise of the “best of breed” strategy we mentioned earlier, as hospitals focused more on single vendor solutions. The market for ambulatory systems, on the other hand, has remained highly fragmented, with as many as 700 vendors competing for market share.

To meet the continually evolving financial and quality documentation requirements of today’s health care environment, HCOs must continually evolve as well—and the analogy between changing an HCO and turning an aircraft carrier seems apt. Although an HCO’s business plans and information-systems strategies may be reasonable and necessary, changing ingrained organizational behavior can be much more complex than changing the underlying information systems. Technology capabilities often exceed an HCO’s ability to use them effectively and efficiently. Successful process integration requires not only successful deployment of the technology but also sus-

tained commitment of resources to use that technology well; dedicated leadership with the willingness to make difficult, sometimes unpopular decisions; education; and possibly new performance incentives to overcome cultural inertia and politics. Government incentives to stimulate HCOs toward the **Meaningful Use** of information technology, which emerged from the 2010 Health care Reform legislation are a recent example of attempts to bring process integration and data integration together.

**16.2.7 Security and Confidentiality Requirements**

HCISs are one of the most frequent targets of hackers. They seek to gain access to health care data, which contains more personalized data (and hence is considered more valuable) than what is typically collected in other industries. Breaches of health care data stored

in both provider organizations and insurance companies have increased significantly over the past several years—often exceeding breaches of financial organization data found in organizations such as banks. In addition, the task of breaking into and stealing health care data has been superseded by ransomware--hackers blocking access to the data and demanding payment (often in bitcoin, which tends to be less traceable than cash payments). Using ransomware is much easier for hackers since data does not need to be moved and then offered for sale; payments come directly from the organization that was hacked in order to obtain the code needed to unblock access.

The protection of health information from unwanted or inappropriate use is governed not only by the trust of patients in their health providers but also by law. In accordance with the **Health Insurance Portability and Accountability Act (HIPAA) of 1996** (► Chap. 12), the Secretary of Health and Human Services recommended that “Congress enact national standards that provide fundamental privacy rights for patients and define responsibilities for those who serve them.” This law and subsequent federal regulations now mandate standardized data transactions for sending data to payer organizations, the development and adherence to formal policies for securing and maintaining access to patient data, and under privacy provisions, prohibit disclosure of patient-identifiable information by most providers and health plans, except as authorized by the patient or explicitly permitted by legislation. Subsequent updates to the HIPAA regulations have strengthened considerably the requirements for security and privacy protections and have also given patients the right to pursue actions against both organizations and individuals when they feel that their personal information has been compromised. HIPAA also provides consumers with significant rights to be informed about how and by whom their health information will be used, and to inspect and sometimes amend their health information. Stiff criminal penalties including fines and possible imprisonment are associated with noncompliance or the knowing misuse of patient-identifiable information.

Computer systems can be designed to provide security, but only people can promote the trust necessary to protect the confidentiality of patients’ clinical information. In fact, most breaches and inappropriate disclosures stem from human actions rather than from computer system failures. To achieve the goal of delivering coordinated and cost-effective care, clinicians need to access information on specific patients from many different locations. However, it is difficult to predict in advance which clinicians will need access to which patient data and from which locations. And unfortunately, there is an inverse relationship between ease of access and security robustness. Therefore, an HCIS must strike a balance between restricting information access, enabling health care workers to do their jobs, and ensuring the accountability of the users of patient information.

With federal requirements to provide patients with access to their data through portals, the risk of inappropriate access only increases. In addition, more and more devices (e.g., ventilators, monitoring machines, IV pumps) are connected to HCO’s internal communications networks, making the **Internet of Things (IoT)**-- a reality in health care. To build trust with its patients and meet HIPAA requirements, an HCO should adopt a three-pronged approach to securing information. First, the HCO needs to designate a security officer (and typically a privacy officer as well) and develop uniform security and confidentiality policies, including specification of sanctions, and to enforce these policies rigorously. Second, the HCO needs to train employees so they understand the appropriate uses of patient-identifiable information and the consequences of violations. Third, the HCO must use electronic tools such as intrusion detection, access controls and audit trails not only to discourage misuse of information, but also to inform employees and patients that people who access confidential information without proper authorization or a “need to know”, can be tracked and will be held accountable.

### 16.2.8 The Impact of Health Care Information Systems

On average, health care workers in administrative departments spend about three-fourths of their time handling information; workers in nursing units spent about one-fourth of their time on these tasks. The fact is that information management in health care organizations, even with significant computerization, is a costly activity in terms of both time and money. The collection, storage, retrieval, analysis, and dissemination of the clinical and administrative information necessary to support the organization's daily operations, to meet external and internal requirements for documentation and reporting, and to support short-term and strategic planning remain important and time-consuming aspects of the jobs of health-care workers.

Today, the justifications for implementing HCISs include cost reduction, productivity enhancements, and quality and service improvement, as well as strategic considerations related to competitive advantage, patient expectations, and regulatory compliance:

- *Cost reduction.* Much of the historical impetus for implementing HCISs was their potential to reduce the costs of information management in hospitals and other facilities largely by reducing the number of employees. HCOs continue to make tactical investments in information systems to streamline administrative processes and departmental workflows. Primary benefits that may offset some information-systems costs include reductions in labor requirements, reduced waste (e.g., dated surgical supplies that are ordered but unused or food trays that are delivered to the wrong destination and therefore are wasted), and more efficient management of supplies and other inventories. Large savings can be gained through efficient scheduling of expensive resources such as surgical suites and imaging equipment. In addition, HCISs can help to eliminate inadvertent ordering of duplicate tests and procedures. Once significant patient data are available online, information systems can reduce the costs of storing, retrieving, and transporting charts in the medical-records department.
- *Productivity enhancements.* A second area of benefit from an HCIS comes in the form of improved productivity of clinicians and other staff. With continuing (and at times increasing) constraints on reimbursements, HCOs are continually faced with the challenge of doing more with less. Providing information systems support to staff can in many cases enable them to manage a larger variety of tasks and data than would otherwise be possible using strictly manual processes. Interestingly, in some cases hospital investments in an HCIS support the productivity improvement of staff that are not employed by the hospital, namely the physicians, and can even extend to payers by lowering their costs. One of the major challenges with introducing a new HCIS is that the productivity of users may actually decrease in the initial months of the implementation. With complex clinical applications, learning new ways of working can lead to high levels of user dissatisfaction in addition to lowered productivity.
- *Quality and service improvement.* As HCISs have broadened in scope to encompass support for clinical processes, the ability to improve the quality of care has become an additional benefit. Qualitative benefits of HCISs include improved accuracy and completeness of documentation, reductions in the time clinicians spend documenting (and associated increases in time spent with patients), fewer drug errors and quicker response to adverse events, and improved provider-to-provider communication. Through telemedicine and remote linkages (see ► Chap. 20), HCOs can expand their geographical reach and improve delivery of specialist care to rural and outlying areas. Once patient data are converted from a purely transaction format to a format better suited for analytic work, the use of **clinical decision-support systems** in conjunction with a clinically focused HCIS can produce impressive benefits, namely improving the quality of care

while reducing costs (► Chap. 24) (Bates and Gawande 2003; James and Savitz 2011; Goldzweig, et al. 2009; Himmelstein and Woolhandler 2010; McCullough et al. 2010; Castaneda et al. 2015).

- *Competitive advantage.* Information technologies must be deployed appropriately and effectively; however, with respect to HCISs, the question is no longer whether to invest, but rather how much and what to buy. Although some organizations still attempt to cost justify all information-systems investments, many HCOs have recognized that HCISs are “**enabling technologies**” which means that the value comes not from the system itself but from what it “enables” the organization to do differently and better (Vogel 2003). If workflow and processes are not changed to take advantage of the technology, the value of the investment will largely go unrealized. And it is not just the ratio of financial benefits to costs that is important; access to clinical information is necessary not only to carry out patient management, but also to attract and retain the loyalty of physicians who care for (and thus control much of the HCO’s access to) the patients. The long-term benefits of clinical systems include the ability to influence clinical practices by reducing large unnecessary variations in medical practices, to improve patient outcomes, and to reduce costs—although these costs might be more broadly economic and societal than related to specific reductions for the hospital itself (Leatherman et al. 2003; James and Savitz 2011; Gottlieb et al. 2015). Physicians ultimately control the great majority of the resource-utilization decisions in health care through their choices in prescribing drugs, ordering diagnostic tests, and referring patients for specialty care. Thus, providing physicians with access to information on “best practices” based on the latest available clinical evidence, as well as giving them other clinical and financial data to make appropriate decisions, is an essential HCIS capability.
- *Regulatory compliance.* Health care is among the most heavily regulated industries in our

economy. State and federal regulatory agencies perform a variety of oversight activities, and these require increasingly sophisticated and responsive HCISs to provide the necessary reports. For example, the Food and Drug Administration now mandates the use of barcodes on all drugs. Similarly, HIPAA rules specify how personal health information must be managed as well as the required content and format for certain electronic data transactions for those HCOs that exchange data electronically. OSHA, the Department of Labor, the Environmental Protection Agency, the Nuclear Regulatory Commission, and a host of other agencies all have an interest in seeing that the health care provided by HCOs is consistent with standards of safety and fairness.

- *Consumerism and patient expectations.* As medical breakthroughs promise better outcomes for patients, the patients as consumers are becoming more involved. Federal mandates have driven the creation of **Patient Portals**, essentially dedicated web sites for patients to access and in some cases contribute to their own medical records. While there are limitations to patient involvement (e.g., to date the number of patients accessing and contributing through portals has not met expectations, and older, sicker patients often have limited abilities to access and/or understand their own data)—it is likely that trends toward more patient involvement will continue.

### 16.2.9 Managing Information Systems in a Changing Health Care Environment

Despite the importance of integrated information systems, implementation of HCISs has proved to be a daunting task, often requiring a multiyear capital investment of hundreds of millions of dollars and forcing fundamental changes in the types and ways that health care professionals perform their jobs. To achieve the potential benefits, HCOs must plan carefully and invest wisely. The grand challenge

for an HCO is to implement an HCIS that is sufficiently flexible and adaptable to meet the changing needs of the organization. Given the rapidly changing environment and the multiyear effort involved, people must be careful to avoid implementing a system that is obsolete functionally or technologically before it becomes operational. Success in implementing an HCIS entails consistent and courageous handling of numerous technical, organizational, and political challenges.

### 16.2.10 Changing Technologies

---

As we discussed in ► Chap. 6, dramatic changes in computing and networking technologies are continuing to occur. These advances are important in that they allow quicker and easier information access, less expensive computational power and data storage, greater flexibility, and other performance advantages. A major challenge for many HCOs is how to decide whether to support a best of breed strategy, with its requirement either to upgrade individual systems and interfaces to newer products or to migrate from their patchwork of legacy systems to a more integrated systems environment. Such migration requires integration and selective replacement of diverse systems that are often implemented with closed or nonstandard technologies and medical vocabularies. Unfortunately, the trade-off between migrating from best of breed to more integrated systems is that vendors offering more integrated approaches seldom match the functionality of historical best of breed environments, although with each new software version the gap lessens. As a result, best of breed strategies are becoming less of an option since commercial vendors are broadening and deepening the scope of their application suites to minimize the challenges of building and managing interfaces and to protect their market share. In a sense, it is the information content of the systems and the ability to implement them that is much more important than the underlying technology—as long as the data are accessible, the choice of specific technology is less critical.

### 16.2.11 Changing Culture

---

In the current health care environment, physicians are confronted with significant obstacles to the practice of medicine as they have historically performed it. Physicians' long history of entrepreneurial practice is changing as more and more physicians work directly as employees of HCOs and fewer and fewer own their own practices. As a result, physicians face significant adjustments as they are confronted by pressures to practice in accordance with institutional standards aimed at reducing variation in care, and to focus on the costs of care regardless of whether those costs are borne by HCOs or by third party payers. They are expected to assume responsibility not simply for healing the sick, but for the wellness of people who come to them not as patients but as members of health plans and health maintenance organizations. In addition, they must often work as members of collaborative patient-care teams. The average patient length of stay in a hospital is decreasing; at the same time, the complexity of the care provided both during and after discharge is increasing. The time allotted for an individual patient visit in an ambulatory setting is decreasing as individual clinicians face economic incentives to increase the number of patients for whom they care each day. Some HCOs, aided by federal funding incentives, are now instituting **pay-for performance** incentives to reward desired work practices. At the same time, it is well known that the amount of knowledge about disease diagnosis and treatment increases significantly each year, with whole new areas of medicine being added from major breakthroughs in areas such as genomic and imaging research. To cope with the increasing workload, greater complexity of care, extraordinary amounts of new medical knowledge, new skills requirements, and the wider availability of medical knowledge to consumers through the Internet, both clinicians and health executives must become more effective information managers, and the supporting HCISs must meet their ever more complex workflow and information requirements. As the health care culture and the roles

of clinicians and health executives continue to change, HCOs must constantly reevaluate the capabilities of information technology to ensure that the implemented systems continue to match user requirements and expectations.

### 16.2.12 Changing Processes

Developing a new vision of how health care will be delivered and managed, designing processes and implementing supporting information systems are all critical to the success of evolving HCOs. Changes in workflow processes affect the jobs that people do, the skills required to do those jobs, and the fundamental ways in which they relate to one another. For example, models of care management that cross organizational or specialty boundaries encourage interdisciplinary care teams to work in harmony to promote health as well as treat illness. Although information systems are not the foremost consideration for people who are redesigning processes, a poor information-systems implementation can institutionalize bad processes.

HCOs periodically undertake various process redesign initiatives (following models such as **Six Sigma**, **Kaizen** or **LEAN**), and these initiatives can lead to fundamental transformations of the enterprise. Indeed, work process redesign is essential if information systems are to become truly valuable “enablers” in HCOs. Too often, however, the lack of a clear understanding of existing organizational dynamics leads to a misalignment of incentives—a significant barrier to change—or to the assumption that simply installing a new computer system will be sufficient to generate value. Moreover, HCOs, like many organizations, are collections of individuals who often have natural fears about and resistance to change. Even under the best of circumstances, there are limits to the amount of change that any organization can absorb. The magnitude of work required to plan and manage organizational change is often underestimated or ignored. The handling of people and process issues has emerged as one of the most critical success factors for HCOs as they implement new work methods and new and upgraded information systems.

### 16.2.13 Changing Sources of Data

Historically the sources of data for electronic systems in health care were relatively limited. Transactions resulting from activities like lab tests, radiological studies, medications prescribed and given, and specific clinical activities such as inpatient encounters with physicians or outpatient visits were recorded and charges for these transactions were then posted to a patient’s account. Once the inpatient stay or the ambulatory visit was completed, the charges were collected into a bill which was then sent to the patient’s third-party payer (e.g., Medicare, Medicaid or a private insurance company) or to the patient directly. The amount of actual data processed from these transactions is relatively small. Even a complex series of clinical encounters between a patient and a physician can be captured in as little as 4–500 kb of data, or the equivalent of about 200 pages of text.

In recent years, however, there has been an explosion of data, both in terms of *volume* and of *complexity*. Data sources that create images (e.g., radiological studies, pathology slides) can generate data that easily grows. While an individual projection image can range from 8 to 32 MB in size, and a digital mammography image can range from 8 to 50 MB, CT and MRI scans generate relatively small individual images but complete studies can include literally thousands of images and grow to GBs in size. As imaging technology continues to develop with both more detailed individual images and greater number of images per study, the amount of data being collected and stored can be expected to grow exponentially.

In addition to the growth in data from these more traditional modalities, new data sources are being added to data already being collected and stored. As a result, HCISs must continue to evolve to incorporate access to this data. Since the completion of the initial Human Genome Sequencing project in 2003, for example, data from genomic studies has become an increasingly important source for clinicians. Sequencing machines today can produce a million times more data than what was collected in 2004, and more sequences

can be run in an hour than were produced in the previous decade. Not only is this a huge amount of data, it is in a format quite different from historical clinical data—hence the increase in *complexity* as well as *volume*.

We are also seeing an explosion of data from another source: wearables. These are devices that individuals wear on their arm or wrist, collecting data on various aspects of a person's physical health. It has been predicted that over the next few years, there could be as many as 6–700 million wearable devices worldwide.

One example of a device measuring health data is the continuous glucose monitor (CGM). CGMs can capture close to 300 data points each day or approximately 110,000 data points annually. With close to 30 million people diagnosed with diabetes in the US, even if only half of those use a CGM, there could be close to 3.3E12 data points collected annually.

New sources of data are being created almost constantly. As electronic sensors and connectivity are increasingly embedded in devices, many of them designed to monitor and manage the health of individuals, the amount of data collected will continue to grow. With the Internet as the backbone, there is almost no limit to what can be measured and connected electronically resulting in a true **Internet of Things (IoT)**.

The challenge of an HCIS is to enable clinicians to access these new sources of data, to understand their importance and relevance, and to then use them to enhance their diagnostic and therapeutic capabilities, leading hopefully to better outcomes for their patients.

### 16.2.14 Management and Governance

■ Figure 16.6 illustrates the information-technology environment of an HCO composed of two hospitals, an owned physician practice, affiliated nursing homes and hospice, and several for-profit service organizations. Even this relatively simple environment presents significant challenges for the management and governance of information systems. For

example, to what extent will the information management function be controlled centrally versus decentralized to the individual operating units and departments? How should limited resources be allocated between new investment in strategic projects (such as office-based data access for physicians) and the often critical operational needs of individual entities (e.g., replacement of an obsolete laboratory information system)? Academic medical centers with distinct research and educational needs raise additional issues for managing information across operationally independent and politically powerful constituencies.

Trade-offs between functional and integration requirements, and associated contention between users and information-systems departments, will tend to diminish over time with the development and widespread adoption of technology standards and common clinical-data models and vocabulary. On the other hand, an organization's information-systems "wants" and "needs" will always outstrip its ability to deliver these services. Political battles will persist, as HCOs and their component operating units wrestle with the age-old issues of how to distribute scarce resources among competing, similarly worthy projects.

A formal HCIS governance structure with representation from all major constituents provides a critical forum for direction setting, prioritization, and resource allocation across an HCO. Leadership by respected clinical peers has proved a critical success factor for clinical systems planning, implementation, and acceptance. In addition, the creation of an Information Systems Advisory or Steering Committee composed of the leaders of the various constituencies within the HCO, can be a valuable exercise if the process engages the organization's clinical, financial, and administrative leadership and users and results in their gaining not only a clear understanding of the highest-priority information technology investment requirements but also provides a sense of accountability and ownership over the HCISs and their various functions (Vogel 2006). This supports one of the principles of information technology governance: *how* an institution makes IT investment deci-

Fig. 16.6 An example of an information systems environment for a small integrated delivery network (IDN). Even this relatively simply IDN has a complex

mix of information systems that pose integration and information management challenges for the organization

sions is often more important than *what* specific decisions are made (Weill and Ross 2004; Haddad et al. 2018). Because of the dynamic nature of both health care business strategies and the supporting technologies, many HCOs have seen the timeframes of their strategic information-management thinking shrink from 5 years to three, and then be changed yet again through annual updates.

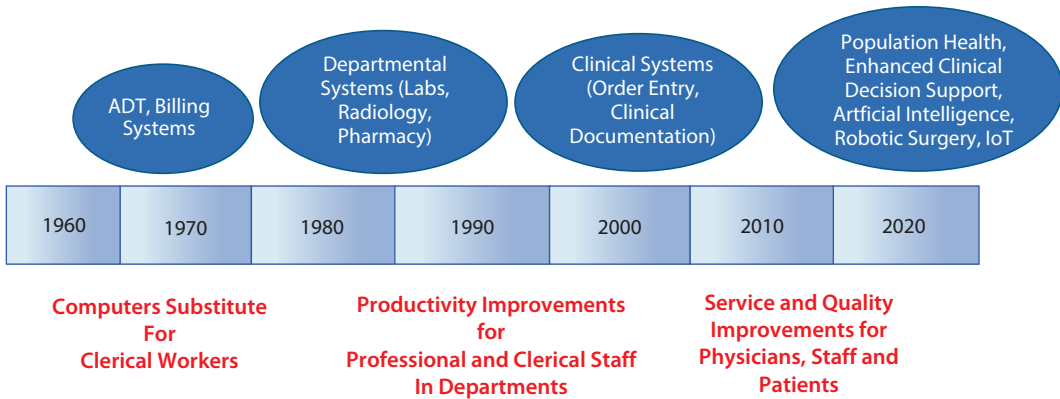

As described in Sect. 16.1, the HCISs support a variety of functions, ranging from the delivery and management of patient care to the administration of the HCO. From a functional perspective, HCISs typically consist of components that support five distinct purposes: (1) patient management and billing, (2) ancillary services, (3) care delivery and clinical documentation, (4) clinical decision support, (5) institutional financial and resource management (Fig. 16.7).

### 16.3 Functions and Components of a Health Care Information System

Carefully designed computer-based information systems can increase the effectiveness and productivity of health professionals, improve the quality and reduce the costs of health services, and improve levels of service and of

#### 16.3.1 Patient Management and Billing

Systems that support patient management functions perform the basic HCO operations related to patients, such as registration, scheduling, admission, discharge, transfer among

**Fig. 16.7** The evolution of computing systems in hospitals has followed a path that parallels the evolution of computing systems in general. From mainframes to minicomputers to desktops, and more recently mobile devices, the purpose and function of systems in hospi-

tals has followed a path from financial systems to departmental systems to systems designed specifically to enhance the productivity and raise the quality of health care services

locations, and billing. Historically within HCOs, maintenance of the hospital census and a patient billing system were the first tasks to be automated—largely because a patient’s location determined not only the daily room/bed charges (since an ICU bed was more expensive than a regular medical/surgical bed) but where medications were to be delivered, and where clinical results were to be posted. Today, virtually all hospitals and ambulatory centers and many physician offices use a computer-based **master patient index (MPI)** to store patient-identification information that is acquired during the patient-registration process, and link to simple encounter-level information such as dates and locations where services were provided. The MPI can also be integrated within the registration module of an ambulatory care or physician-practice system or even elevated to an **enterprise master patient index (EMPI)** across several facilities. Within the hospital setting, the census is maintained by the **admission–discharge–transfer (ADT)** module, which is updated whenever a patient is admitted to the hospital, discharged from the hospital, or transferred from one bed to another.

Registration and patient census data serve as a reference base for the financial programs that perform billing functions. When an HCIS is extended to other patient-care settings—e.g., to the laboratory, pharmacy, and other ancillary departments—patient-management

systems provide a common reference base for the basic patient demographic data needed by these systems. Without access to the centralized database of patient financial, demographic, registration and location data, these subsystems would have to maintain duplicate patient records. In addition, the transmission of registration data can trigger other activities, such as notification of hospital house-keeping when a bed becomes available after a patient is discharged. The billing function in these systems serves as a collection point for all the chargeable patient activity that occurs in a facility, including room/bed charges, ancillary service charges, and supplies used during a patient’s stay.

Scheduling in a health care organization is complicated because patient load and resource utilization can vary by day, week, or season or even through the course of a single day simply due to chance, emergencies that arise, or to patterns of patient and physician behavior. Effective resource management requires that the appropriate resources be on hand to meet such fluctuations in demand. At the same time, resources should not remain unnecessarily idle since that would result in their inefficient use. The most sophisticated scheduling systems have been developed for the operating rooms and radiology departments, where scheduling challenges include matching the patient not only with the providers but also with special equipment and support staff

such as technicians. **Patient-tracking applications** monitor patient movement in multistep processes; for example, they can monitor, estimate, and manage patient wait times in the emergency department.

Within a multi-facility HCO, the basic tasks of patient management are compounded by the need to manage patient care across multiple settings, some of which may be supported by independent information systems. Is the Patricia C. Brown who was admitted last month to Mountainside Hospital the same Patsy Brown who is registering for her appointment at the Seaview Clinic? Integrated delivery networks ensure unique patient identification either through conversion to common registration systems or, more frequently, through implementation of an EMPI that links patient identifiers and data from multiple registration systems.

### 16.3.2 Ancillary Services

Ancillary departmental systems support the information needs of individual clinical departments within an HCO. From a systems perspective, those areas most commonly automated are the laboratory, pharmacy, radiology, blood-bank, operating rooms, and medical-records departments, but can also include specialized systems to support cardiology (for EKGs), respiratory therapy and social work. Such systems serve a dual purpose within an HCO. First, ancillary systems perform many dedicated tasks required for specific departmental operations. Such tasks include generating specimen-collection lists and capturing results from automated laboratory instruments in the clinical laboratory, printing medication labels and managing inventory in the pharmacy, and scheduling examinations and supporting the transcription of image interpretations in the radiology department. In addition, information technology coupled with robotics can have a dramatic impact on the operation of an HCO's ancillary departments, particularly in pharmacies (to sort and fill medication carts) and in clinical laboratories (where in some cases the only remaining manual task is the collection of the specimen and its transport to the laboratory's robotic

system). Second, the ancillary systems contribute major data components to online patient records, including laboratory-test results and pathology reports, medication profiles, digital images (see ► Chap. 22), records of blood orders and usage, and various transcribed reports including history and physical examinations, operating room and radiology reports. HCOs that consolidate ancillary functions outside hospitals to gain economies of scale—for example, creating outpatient diagnostic imaging centers and reference laboratories—increase the complexity of integrated patient management, financial, and billing processes.

### 16.3.3 Care Delivery and Clinical Documentation

Electronic medical record (EMR) systems that support care delivery and clinical documentation are discussed at length in ► Chap. 14. Although comprehensive EMRs are the ultimate goal of most HCOs, many organizations today are still building more basic clinical-management capabilities. Automated **order entry** and **results reporting** are two important functions provided by the clinical components of an HCIS. Health professionals can use the HCIS to communicate with ancillary departments electronically, eliminating the easily misplaced paper slips or the transcription errors often associated with translating handwritten notes into typed requisitions, thus minimizing delays in conveying orders. The information then is available online, where it is easily accessible by any authorized health professional that needs to review a patient's medication profile or previous laboratory-test results. Ancillary departmental data represent an important subset of a patient's clinical record. A comprehensive clinical record, however, also includes various data that clinicians have collected by questioning and observing the patient, including the history and physical report, progress notes and problem lists. In the hospital, an HCIS can help health personnel perform an initial assessment when a patient is admitted to a unit, maintain patient-specific care plans, chart vital signs, maintain medication-administration records, record

diagnostic and therapeutic information, document patient and family teaching, and plan for discharge (also see ► Chap. 17). Many organizations have developed diagnosis-specific **clinical pathways** that identify clinical goals, interventions, and expected outcomes by time period. Using clinical pathways, case managers or care providers can document actual versus expected outcomes and are alerted to intervene when a significant unexpected event occurs. More hospitals are now implementing systems to support what are called **closed loop medication management systems** in which every task from the initial order for medication to its administration to the patient is recorded in an HCIS—one outcome of increased attention to patient safety issues.

With the shift toward delivering more care in outpatient settings, clinical systems have become more common in ambulatory clinics and physician practices. Numerous vendors have introduced software compatible with **smart phones, tablets**, and other mobile devices designed specifically for physicians in ambulatory settings, so that they can access appropriate information even as they move from one exam room to another. Such systems allow clinicians to record problems and diagnoses, symptoms and physical examinations, medical and social history, review of systems, functional status, active and past prescriptions, provide access to therapeutic and medication guidelines, etc. The most successful systems are integrated with a practice management system, providing additional support for physician workflow and typical clinic functions, for example, by documenting telephone follow-up calls or printing prescriptions. In addition, specialized clinical information systems have been developed to meet the specific requirements of intensive-care units (see ► Chap. 21), long-term care facilities, home-health organizations, and specialized departments such as cardiology and oncology.

### 16.3.4 Clinical Decision Support

---

Clinical decision-support systems (► Chap. 24) directly assist clinical personnel in data interpretation and decision-making. Once the basic clinical components of an HCIS are well

developed, clinical decision-support systems can use the information stored there to monitor patients and issue alerts, to make diagnostic suggestions, to provide limited therapeutic guidance, and to provide information on medication costs. These capabilities are particularly useful when they are integrated with other information-management functions. For example, a useful adjunct to **computer-based physician order-entry (CPOE)** is a decision-support program that alerts physicians to patient food or drug allergies; helps physicians to calculate patient-specific drug-dosing regimens; performs advanced order logic, such as recommending an order for prophylactic antibiotics before certain surgical procedures; automatically discontinues drugs when appropriate or prompts the physician to reorder them; suggests more cost-effective drugs with the same therapeutic effect; or activates and displays applicable clinical-practice guidelines (see ► Chap. 24). **Clinical-event monitors** integrated with results-reporting applications can alert clinicians to abnormal results and drug interactions by electronic mail, text message or page. In the outpatient setting, these event monitors may produce reminders to provide preventive services such as screening mammograms and routine immunizations. The same event monitors might trigger access to the HCO's approved formulary, displaying information that includes costs, indications, contraindications, approved clinical guidelines, and relevant online medical literature (Kaushal et al. 2003). Unfortunately, an overabundance of alerts has also caused care givers to experience alarm fatigue resulting in them ignoring potentially critical warnings.

### 16.3.5 Financial and Resource Management

---

Financial and administrative systems assist with the traditional business functions of an HCO, including management of the payroll, human resources, general ledger, accounts payable, and materials purchasing and inventory. Most of these data-processing tasks are well structured and have been historically labor intensive and repetitious—ideal opportunities

for substitution with computers. Furthermore, with the exception of patient-billing functions, the basic financial tasks of an HCO do not differ substantially from those of organizations in other industries. Not surprisingly, financial and administrative applications have typically been among the first systems to be standardized and centralized in IDNs.

Conceptually, the tasks of creating a patient bill and tracking payments are straightforward, and financial transactions such as claims submission and electronic funds transfer have been standardized to allow **electronic data interchange (EDI)** among providers and payers. In operation, however, patient accounting requirements are complicated by the myriad and oft-changing reimbursement requirements of government and third-party payers. These requirements vary substantially by payer, by insurance plan, by type of facility where service was provided, and often by state. As the burden of financial risk for care has shifted from third party payers to providers (through **per diem** or **diagnosis-based reimbursements**), these systems have become even more critical to the operation of a successful HCO. As another example, managed care contracts add even more complexity, necessitating processes and information systems to check a patient's health-plan enrollment and eligibility for services, to manage referrals and preauthorization for care, to price claims based on negotiated contracts, and to create documentation required to substantiate the services provided.

As HCOs increasingly go "at risk" for delivery of health services by negotiating **per diem, diagnosis-based, bundled and capitated payments**, their incentives need to focus not only on reducing the cost per unit service but also on maintaining the health of members while using health resources effectively and efficiently. Similarly, the HCO's scope of accountability broadens from a relatively small population of sick patients to a much larger population of plan members (such as might be found in ACOs), most of whom are still well.

**Provider-profiling systems** support utilization management by tracking each provider's resource utilization (costs of drugs prescribed, diagnostic tests and procedures ordered, and so on) compared with severity-

adjusted outcomes of that provider's patients such as their rate of hospital readmission and mortality by diagnosis. Such systems are also being used by government bodies and consumer advocate organizations as they publicize their findings, often through the Internet. **Contract-management systems** have capabilities for estimating the costs and payments associated with potential managed care contracts and comparing actual with expected payments based on the terms of the contracts. More advanced managed-care information systems handle **patient triage** and medical management functions, helping the HCOs to direct patients to appropriate health services and to proactively manage the care of chronically ill and high-risk patients. Health plans, and IDNs that incorporate a health plan, also must support payer and insurance functions such as claims administration, premium billing, marketing, and member services.

As HCOs continue to seek ways to reduce their expenses, they are introducing both more automation and more integration into "back office" systems. Enterprise Resource Planning (ERP) systems integrate human resources functions with payroll, accounts receivable and payment systems and overall supply management. ERP systems can be effectively integrated with other components of the HCIS, e.g., nurse staffing systems and surgical scheduling systems, in an attempt to use information to optimize operations and resource utilization. Implementing these systems can bring challenges similar to clinical systems, albeit with different types of employees. Long term employees often develop their own styles of managing information based on historical patterns and preferences, much of which must change when an ERP system is implemented.

## 16.4 Forces That Will Shape the Future of Health Care Information Systems Management

---

As we have discussed throughout this chapter, the changing landscape of the health-care industry and the strategic and operational

requirements of HCOs and IDNs have accelerated the acquisition and implementation of HCISs. The acquisition and implementation of **Electronic Medical Records (EMRs)** have been a particular focus, especially with the availability of federal stimulus funding through the provisions of the **Health Information Technology for Economic and Clinical Health (HITECH) Act** under the **American Recovery and Reinvestment Act of 2009 (ARRA)**. Although there are many obstacles to implementation and acceptance of smoothly functioning, fully integrated HCISs, few people today would debate the critical role that information technology plays in an HCO's success or in an IDN's efforts at clinical and operational management.

We have emphasized the dynamic nature of today's health care environment and the associated implications for HCISs. A host of new requirements loom that will challenge today's available solutions. We anticipate additional expectations and requirements associated with the changing organizational landscape, technological advances, and broader societal changes.

#### 16.4.1 Changing Organizational Landscape

Although the concepts underlying HCOs and IDNs are no longer new, the underlying organizational forms and business strategies of these complex organizations continue to evolve. The success of individual HCOs varies widely. Some, serving target patient populations such as those with heart disease or cancer or age-defined groups such as children, have been relatively more successful financially than those attempting to serve patients across a wide range of illnesses or those attempting to combine diverse missions of clinical care, teaching and research. IDNs, on the other hand, have by and large failed to achieve the operational improvements and cost reductions they were designed to deliver. It is possible that entirely new forms of HCOs and IDNs will emerge in the coming years. Key to understanding the magnitude of the information systems challenge for IDNs in particular is recognizing the extraordinary pace

of change—IDNs reorganize, merge, uncouple, acquire, sell off, and strategically align services and organizational units in a matter of weeks. While information technology is itself changing with accelerating frequency, today's state-of-the-art systems (computer systems and people processes) typically require months or years to build and refine.

The continuing pressures of the market place, including the downward trend in reimbursements and the evolving efforts by the Federal government to change the payment structure from **Procedure-based Payments** to **Value-Based Payments** has led to merger and acquisition activity across the health care industry. Although the outright merger or acquisition of one HCO by another HCO is still relatively infrequent, HCO's and IDNs have increasingly targeted physician practices for acquisition in order both to control the flow of patients to inpatient beds and to increase the standardization of care protocols across physician groups. In addition, in situations in which an outright merger or acquisition seems likely to be unsuccessful, affiliations between HCOs are an increasingly common strategy to ensure better coordination across historically competing boundaries.

All too frequently, business deals are cut with insufficient regard to the cost and time required to create the supporting information infrastructure. For IDNs even in the best of circumstances, the cultural and organizational challenges of linking diverse users and care-delivery settings will tax their ability to change their information systems environments quickly enough. These issues will increase in acuity as operational budgets continue to shrink—today's HCOs and IDNs are spending significant portions of their capital budgets on information-systems investments. In turn, these new investments translate into increased annual operating costs (costs of regular system upgrades, maintenance, user support, and staffing). Still most health care organizations devote at most 3–4% of their total revenues to their information systems operating budgets; in other information-intensive industries (e.g., financial services, air transportation), the percentage of operating budgets devoted to information technology investment can be three to four times higher (Weil 2001).

### 16.4.2 Changes Within the HCIS Organization

Information technology in the health care industry became a major focus for investment starting in the late 1980s and early 1990s, as developments in both hardware and software technology led both to increased affordability and enhanced functionality. We noted earlier the evolution from mainframes to minicomputers to networked PCs, as well as the transformation of application suites from enterprise-wide financial and billing systems to more departmentally-focused information technology investment decisions in provider organizations. This evolution led to an ever-more complex computing environment encompassing a diversity of hardware and software and networking capabilities to enable everything to work together. Organizational capabilities to manage these changes evolved as well, from a small group of technicians managing a mainframe environment to a growing number not only of technicians, but groups of dedicated application support staff, networking engineers and specialists in desktop support. Information Services Departments began to replace “Data Processing Departments” and their reach and importance to the organization. Leaders were no longer department directors but “Chief Information Officers” (CIOs), charged with responsibilities as diverse as keeping the systems running on a daily basis, overseeing the seemingly endless upgrades to both hardware and software, aligning information technology investments with business strategy, and keeping the personal data of patients secure from unauthorized access. As “CIOs” they were expected to lead the procurement of new hardware and software in conjunction with other “C-Suite” executives or physician leaders of the various departments seeking to introduce computers into their work environments. Most often these were systems supporting administrative and financial processes or ancillary departments like the laboratory or the radiology or pharmacy departments.

However, with the 1991 publication of The Institute of Medicine’s *The Computer-Based Patient Record: An Essential Technology for*

*Health Care* (Institute of Medicine 1991) an entire new era of information technology began to emerge with the goal of capturing all clinical activity electronically, giving rise to Electronic Medical Records. Followed a little more than a decade later by an executive order from then President George Bush with the goal of creating an electronic medical record within a decade, and then the financial incentives in the 2009 HITECH legislation to induce hospitals and physician offices to implement EMRs, the complexity of the health care computing environment increased dramatically. In addition, with the new emphasis on clinical computing, physicians as the primary users of clinical systems became much more invested not only in what functionality was being purchased, but who was leading the purchasing process.

During the 1990s and into the 2000s, an entire generation—including clinicians—became more sophisticated users of computer technology. As clinical systems came to be many organizations’ largest information technology investment, clinicians sought to exercise more leadership in system selection and implementation. The position of Chief Medical Information (or Informatics) Officer (CMIO) was created, at times reporting to the Chief Information Officer (CIO), but at other times reporting outside of the historical information technology chain of command. Additional recognition for computer-savvy clinicians came with the creation in 2011 of a formal board certification in Clinical Informatics. In addition, with the increasing importance of clinical computing capabilities, provider organizations began looking to recognize formally the physician informatics leaders by appointing them to the CIO position. More traditional CIOs with backgrounds in business or computing became in some organizations relegated to operational roles—keeping the data center and the network running on the 24-hour basis that was essential in a health care environment. Some organizations created separate roles for Chief Technology Officers (CTOs) or Chief Innovation Officers that had little or no operational responsibilities. Additionally, as HCO’s began to recognize the impact of social media

on their marketing efforts, the role of Chief Digital Officer also started to emerge.

These organizational changes can be expected to continue as responses to not only more complex clinical and computing environments, but also to the overwhelming importance of clinical activities overall to the success of any provider organization. The roles and responsibilities of these various information CxO positions can be expected to continue to evolve as both the overall organizational landscape and the capabilities of computer systems evolve as well.

### 16.4.3 Technological Changes Affecting Health Care Organizations

Future changes in technology are hard to predict. For example, although we have heard for over two decades that seamless voice-to-text systems are 5 years away from practical use, with the introduction of controlled vocabularies in areas such as radiology and pathology, we are beginning to see commercial products that can “understand” dictated speech and represent it as text that can then be structured for further analysis. Both the emergence of increasingly powerful processor and memory chips, and the decreasing cost of storage media will continue to be a factor in future health-systems design—although the tsunami of data coming from imaging modalities and from genomic medicine sequencing and analysis will continue to be a significant challenge (see ► Chaps. 2, 22, and 26). The ever expanding availability of Internet access, the increasing integration of voice, video, and data, and platforms which permit the integration of these various technologies as well as the availability of ever smaller platforms like tablets and smart phones, will challenge HCOs and IDNs—and HCISs—to have communications capacity not only within their traditional domain but also to an extended enterprise that may include patients’ homes, schools, and workplaces. The design of modern software based on the replicability of code, coding standards such as **XML**, **C++**, **C#**, **Python**, and **Java** and frameworks such

as **Microsoft’s .NET** should eventually yield more flexible information technology systems.

One of the most significant technological challenges facing HCOs and IDNs today occurs because, while much of the health care delivered today continues to be within the four walls of a physician’s office or a hospital, new venues such as retail clinics are growing in number and geographical distribution. Further, as the population ages, patients may seek care from a multitude of sources, including primary and specialty practices, multiple hospital visits (and even visits to multiple hospitals) and may increasingly be monitored in their homes. Health care information technologies (and clinical systems in particular) have focused historically on what happens within a physician’s office or within a hospital, and not across physicians’ office nor between the physicians’ office and the hospital nor in the home of the patient. As technology developments increasingly permit care to be provided outside physician offices and hospitals, HCISs will be challenged to incorporate if not the data, then at least the access to these new sources of data.

In general, EMR products on the market today started with a single purpose: to automate the workflow of clinicians within a particular organizational setting. Among other features, EMRs focus on making data from previous encounters or activities easier to access and assuring that orders for tests and x-rays have the correct information, or that the next shift knows what went on previously. Despite visible successes and failures for all manner of products, EMRs in general can facilitate the automation of a complex workflow—of automating intra-organizational clinical processes as well as those that cross organizational boundaries.

Architectures that focus on what happens *within* organizational boundaries do not easily facilitate access to data *across* organizational boundaries. This is the challenge of **interoperability**. Recognizing that patients often receive care in a variety of organizational settings—hospitals, physicians offices, rehabilitation facilities, pharmacies, retail clinics, their homes, etc.—the challenge is to extend the internal workflow beyond the boundaries of individual organizations so

that data is available across a continuum of care. Interoperability then is not so much about what happens *within* an organization (although there can be challenges here as well), but what happens *across* organizational boundaries.

An *intra*-organizational architecture focuses on facilitating real time communications among providers, on optimizing the process of collecting data at the point of care, and on ensuring that clinical tasks are carried out in an appropriate sequence. An *inter*-organizational architecture needs to minimize the duplicate collection of data in different care settings, to facilitate quick searches of relevant data from a variety of (often external) sources, and to rank data in terms of relevance to a particular clinical question. Transitioning from *intra*- to *inter-organizational* data sharing is a significant technological challenge. While Health Information Exchanges (**HIEs**) and Health Record Banks (**HRBs**) are at the forefront of this transition (see ► Chap. 15), over time we can expect that the architectures of clinical systems that currently focus on what happens *within* an organization will need to transition to facilitate what happens *across* organizations.

Security and confidentiality concerns will likely increase as the emergence of a networked society profoundly changes our thinking about the nature of health care delivery. It is no longer only physicians or their orders that generate clinical data; increasingly patients are generating their own data either through wearables or through devices that measure their health in their own homes. Health services are still primarily delivered locally—we seldom leave our local communities to receive health care except under the most dire circumstances. In the future, providers and even patients will have access to health care experts that are dispersed over state, national, and even international boundaries. Distributed health care capabilities will need to support the implementation of collaborative models that could include virtual house calls and routine **remote monitoring** via telemedicine linkages (see ► Chap. 20).

#### 16.4.4 Societal Change

At the beginning of the twenty-first century, clinicians find themselves spending less time with each patient and more time with administrative and regulatory—and often data entry--tasks. This decrease in clinician-patient contact has contributed to declining patient and provider satisfaction with electronic care-delivery systems. At the same time, empowered health consumers interested in self-help and unconventional approaches have access to more health information than ever before. These factors are changing the interplay among physicians, care teams, patients, and external (regulatory and financial) forces. The changing model of care, coupled with changing economic incentives to deliver measurable high-quality care at lower cost, places a greater focus on wellness and preventative and lifelong care. Although we might agree that aligning economic incentives with wellness is a good thing, this alignment also implies a shift in responsibility from care givers to patients.

Like the health care environment, the technological context of our lives is also changing. The Internet has already dramatically changed our approaches to information access and system design. Concurrent with the development of new standards of information display and exchange is a push led by the entertainment industry (and others) to deliver broadband multimedia into our homes. Such connectivity has the potential to change care models more than any other factor we can imagine by bringing fast, interactive, and multimedia capabilities to the household level. Finally, vast amounts of information can now be stored efficiently remotely, e.g., in the **cloud**, and on movable media such as **memory sticks**, which brings more flexibility as well as more risk, as such devices are both more convenient and more susceptible to being lost or misplaced. With the increase in the availability of consumer-oriented health information, including, for example, video segments that show the appearance and sounds of normal and abnormal conditions or demonstrate common procedures for home care

and health maintenance, we can expect even more changes in the traditional doctor/patient relationship.

With societal factors such as the focus on the outcomes of care pushing our HCOs and IDNs to change, cost constraints continuing to loom large, and the likely availability of extensive computing and communications capacity in the home, in the work place, and in the schools, HCOs and health providers are increasingly challenged to rethink the basic operating assumptions about how to deliver care. The traditional approach has been facility and physician centric—patients usually come to the hospital or to the physician’s office at a time convenient for the hospital or the physician. The HCO and IDN of the twenty-first century may have to be truly “patient centric”, operating within a health care delivery system without walls, where routine health management is conducted in nontraditional settings, such as homes and workplaces with increasing volumes and complexity of the data required to provide care.

### Suggested Readings

Christensen, C., Grossman, J., & Hwang, J. (2009). *The innovator’s prescription*. New York: McGraw-Hill This book builds on the author’s previous work on disruptive innovation with specific applications to the health care industry. Christensen uses terms such as “precision medicine” to describe the advent of more personalized approaches to medical diagnosis and treatment and builds on his analysis of disruptive business models in other industries to analyze both the underlying problems and challenges of our health care delivery system.

Institute of Medicine, *The Computer-Based Patient Record: An Essential Technology for Health Care*, (1991) Washington, DC: The National Academies Press. <https://doi.org/10.17226/5306>. This book was one of first major attempts to argue for the use of computer technology to improve patient outcomes.

Lee, T., & Mongan, J. (2009). *Chaos and organization in health care*. Cambridge, MA: The MIT Press The authors describe the current health care situation as one simply of “chaos”. Among the solutions they propose are increas-

ing the use of electronic medical records and information technology in general for sharing knowledge.

Ong, K. (2011). *Medical informatics: An executive primer* (2nd ed.). Chicago: Health care and Management Information Systems Society An excellent overview of the challenges facing information technology applications in hospitals, physicians’ offices, and in the homes of patients. Also includes a discussion of recent federal legislation intended to stimulate the use of electronic medical records and the challenges of measuring how to determine whether such investments are in fact “meaningfully used”.

Porter, M., & Teisberg, E. (2006). *Redefining health care: Creating value-based competition on results*. Cambridge, MA: Harvard Business School Press The authors begin with a very straightforward assumption, which is that “the way to transform health care is to realign competition with value for patients” (p. 4), and proceed with an exhaustive discussion of the historical failures at reforming the health care system, the challenges inherent in physician-provider organization relationships, and how the only likely solution set to the current high cost of health care is to focus our efforts on what brings value to the patients.

Vogel, L. (2018). *Who knew? Inside the complexity of American health care*. New York: Taylor-Francis Identifies the major factors that combine to make health care the most complex industry in the American economy.

### Questions for Discussion

1. Briefly explain the differences among an HCO’s operational, planning, communications, and documentary requirements for information. Give two examples in each category. Choose one of these categories and discuss similarities and differences in the environments of an integrated delivery network, a community-based ambulatory-care clinic, and a specialty-care physician’s office. Describe the implied differences in these units’ information requirements.
2. Describe three situations in which the separation of clinical and administrative

information could lead to inadequate patient care, loss of revenue, or inappropriate administrative decisions. Identify and discuss the challenges and limitations of two methods for improving data integration.

3. Describe three situations in which lack of integration of information systems with clinicians' workflow can lead to inadequate patient care, reduced physician productivity, or poor patient satisfaction with an HCO's services. Identify and discuss the challenges and limitations of two methods for improving process integration.
4. Describe the trade-off between functionality and integration. Discuss three strategies currently used by HCOs to minimize this tradeoff.
5. Assume that you are the chief information officer of multi-facility HCO. You have just been charged with planning a new clinical HCIS to support a large tertiary care medical center, two smaller community hospitals, a nursing home, and a 40-physician group practice. Each organization currently operates its own set of integrated and standalone technologies and applications. What technical and organizational factors must you consider? What are the three largest challenges you will face over the next 24 months?
6. How do you think the implementation of clinical HCISs will affect the quality of relationships between patients and providers? Discuss at least three potential positive and three potential negative effects. What steps would you take to maximize the positive value of these systems?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What is patient-centered care? How does it differ from traditional, clinician-centric care?
- What are the information management challenges in patient-centered care?
- What are the roles of electronic health records and other informatics applications in supporting patient-centered care?
- What forces and developments have led to the emergence of patient-centered care systems?
- What collaborative processes are required to design patient-centered care systems and the electronic health records to support such care?
- How is current informatics research advancing progress toward collaborative, interdisciplinary, patient-centered care?

## 17.1 Information Management in Patient-Centered Care

Patient care is the focus of many clinical disciplines—medicine, nursing, pharmacy, nutrition, therapies such as respiratory, physical, and occupational, and others. Although the work of the various disciplines sometimes overlaps, each has its own primary focus, emphasis, and methods of care delivery. Each discipline's work is complex in itself, and collaboration among disciplines, an essential component of patient-centered care, adds another level of complexity. In all disciplines, the quality of clinical decisions depends in part on the quality of information available to the decision-maker. The systems that manage information for patient-centered care are therefore critical tools. Their fitness for the job varies, and the systems enhance or detract from patient-centered care accordingly. This chapter describes information management issues in patient-centered care, the emergence of patient-centered care systems in relation to these issues, the interdisciplinary collabo-

ration required to develop patient-centered care systems, and current research. In so doing, it will demonstrate the necessity of a patient-centered perspective in the design of electronic health records (EHRs) and other patient-care systems.

As described later in this chapter, reports of the National Academies, Federal Government mandates, and a variety of social forces have called for transformation in the organization, delivery, financing, and quality of health care. The demand is for evidence-based, cost-effective, **patient-centered care**. Informatics is seen as essential to the provision, monitoring, and improvement of such care.

### 17.1.1 From Patient Care to Patient-Centered Care

Patient-centered care is a collaborative, interdisciplinary process focused on the care recipient in the context of the family, significant others, and community. A distinguishing feature of patient-centered care is the patient's active collaboration in shared decision-making, as contrasted to traditional clinician-centered care where the clinician holds the preponderance of power and authority. Patient-centered care empowers patients to actively participate in care by presenting treatment options that are consistent with patient values and preferences and in a format or context that is understandable and actionable (Krist and Woolf 2011; Payton et al. 2011). Typically, patient care includes the services of physicians, nurses, and members of other health disciplines according to patient needs: physical, occupational, and respiratory therapists; nutritionists; psychologists; social workers; and many others. Each of these disciplines brings specialized perspectives and expertise. Specific cognitive processes and therapeutic techniques vary by discipline, but all disciplines share certain commonalities in the provision of care.

In its simplest terms, the process of patient-centered care begins with collecting data and assessing the patient's current status and expressed concerns in comparison to cri-

teria or expectations of normality. Through cognitive processes specific to the discipline, diagnostic labels are applied, therapeutic goals are identified with timelines for evaluation, and therapeutic interventions are selected and implemented. The patient participates, as he or she is able, in determining therapeutic goals and selecting personally acceptable interventions from the options and their potential consequences as described by the clinician. At specified intervals, the patient is reassessed, the effectiveness of care is evaluated, and therapeutic goals and interventions are continued or adjusted as needed. If the reassessment shows that the patient no longer needs care, services are terminated. This process was illustrated for nursing in 1975 (Goodwin & Edwards 1975) and was updated and made more general in 1984 (Ozbolt et al. 1984). The flowchart reproduced in  Fig. 17.1 could apply equally well to other patient-care disciplines.

Although this linear flowchart helps to explain some aspects of the process of care, it is, like the solar-system model of the atom, a gross simplification. Frequently, for example, in the process of collecting data for an initial patient assessment, the nurse may recognize (diagnose) that the patient is anxious about her health condition. Simultaneously with continuing the data collection, the nurse sets a therapeutic goal that the patient's anxiety will be reduced to a level that increases the patient's comfort and ability to participate in care. The nurse selects and implements therapeutic actions of modulating the tone of voice, limiting environmental stimuli, maintaining eye contact, using gentle touch, asking about the patient's concerns, and providing information. All the while, the nurse observes the effects on the patient's anxiety and adjusts his behavior accordingly. Thus, the complete care process can occur in a microcosm while one step of the care process—data collection—is underway. This simultaneous, nonlinear quality of patient care poses challenges to informatics in the support of patient care and the capture of clinical data.

Each caregiver's simultaneous attention to multiple aspects of the patient is not the only complicating factor. Just as atoms

become molecules by sharing electrons, the care provided by each discipline becomes part of a complex molecule of interdisciplinary, patient-centered care. Caregivers and developers of informatics applications to support care must recognize that true patient-centered care is as different from the separate contributions of the various disciplines as an organic molecule is from the elements that go into it. The contributions of the various disciplines are not merely additive; as a therapeutic force acting upon and with the patient, the work of each discipline is transformed by its interaction with the patient and the other disciplines in the larger unity of patient-centered care.

### 17.1.2 Patient-Centered Care in Action

---

A 75-year-old woman with osteoarthritis, high blood pressure, and urinary incontinence is receiving care from a physician, a home-care nurse, a nutritionist, a physical therapist, and an occupational therapist. From a clinician-centered, additive perspective, each discipline could be said to perform the following functions:

1. Physician: diagnose diseases, prescribe appropriate medications, authorize other care services
2. Nurse: assess patient's understanding of her condition and treatment and her self-care abilities and practices; assess patient's concerns, values, and preferences regarding the management of her health; teach and counsel as needed; help patient to perform exercises at home; identify and help patient overcome barriers to self-care and participation in her recovery plan; report findings to physician and other members of care team
3. Nutritionist: assess patient's nutritional status and eating patterns; prescribe and teach appropriate diet to control blood pressure and build physical strength
4. Physical therapist: prescribe and teach appropriate exercises to improve strength and flexibility and to enhance cardiovascular health, within limitations of arthritis

**Fig. 17.1** The provision of nursing care is an iterative process that consists of steps to collect and analyze data, to plan and implement interventions, and to evaluate the results of interventions (Source: Adapted with permission from Ozbolt et al. (1985). © Springer Nature)

5. Occupational therapist: assess abilities and limitations for performing activities of daily living; prescribe exercises to improve strength and flexibility of hands and arms; teach adaptive techniques and provide assistive devices as needed

to go out. The nurse reports this to the physician and the other clinicians so that they can understand why the patient is not carrying out the prescribed regime. The physician then changes the strategy for treating hypertension while initiating treatment for urinary incontinence. The nurse helps the patient to understand the interaction of the various treatment regimes, provides practical advice and assistance in dealing with incontinence, and helps the patient to find personally acceptable ways to follow the prescribed treatments. The nutritionist works with the patient on the timing

In a collaborative, interdisciplinary, patient-centered practice, the nurse discovers that the patient is not taking walks each day as prescribed because her urinary incontinence is exacerbated by the diuretic prescribed to treat hypertension, and the patient is embarrassed

of meals and fluid intake so that the patient can exercise and sleep with less risk of urinary incontinence. The physical and occupational therapists adjust their recommendations to accommodate the patient's personal needs and preferences while moving toward the therapeutic goals. Finally, the patient, rather than being assailed with the sometimes conflicting demands of multiple clinicians, is supported by an ensemble of services that meets shared therapeutic goals in ways consistent with her preferences and values.

This kind of patient-centered collaboration requires exquisite communication and feedback. The potential for information systems to support or sabotage patient-centered care is obvious.

### 17.1.3 Coordination of Patient-Centered Care

---

When patients receive services from multiple clinicians, patient-centeredness requires coordinating those services. Coordination includes seeing that patients receive all the services they need in logical sequence without scheduling conflicts and ensuring that each clinician communicates as needed with the others. Sometimes, a **case manager** or **care coordinator** is designated to do this coordination. In other situations, a physician or a nurse assumes the role by default. Sometimes, coordination is left to chance, and both the processes and the outcomes of care are put at risk. In recognition of this, the Institute of Medicine designated coordination of care as 1 of 14 priorities for national action to transform health care quality (Adams & Corrigan 2003). The **Health Information Technology for Economic and Clinical Health Act (HITECH Programs 2009<sup>1</sup>)** calls for patients to have a **medical home**, a primary care practice that will maintain a comprehensive problem list to make fully informed decisions in coordinating their care. In addition, Accountable

Care Organizations seek to integrate providers and services to generate value for defined populations. Substantial federal investment in health information technology (HIT) through the HITECH and 21st Century Cures Acts dramatically increased the adoption and use of EHRs (Adler-Milstein & Jha 2017). While HIT spending increased markedly, care coordination technologies have not been a focus. HIT tools dedicated to coordination processes could improve care of complex patients through increased access to data, facilitated communication, timely shared decisions, and greater engagement of patients and their families as partners in their care plans. Well-designed information systems with patient facing-technologies (e.g., **personal health records** and **patient portals**) enable care coordination as they ensure that patients and providers have immediate access to accurate health information at home and across care settings (Ahern et al. 2011; Collins, Bavuso et al. 2017; Collins, Klinkenberg-Ramirez et al. 2017; Collins, Rozemblum et al. 2017).

### 17.1.4 Patient-Centered Care Across Multiple Patients

---

Delivering and managing interdisciplinary patient-centered care for an individual is challenging enough, but patient care has yet another level of complexity. Each clinician is responsible for the care of multiple patients. In planning and executing the work of patient-centered care, each professional must consider the competing demands of all the patients for whom she is responsible, as well as the exigencies of all the other professionals involved in each patient's care. Thus, the nurse on a post-operative unit must plan for scheduled treatments for each of her patients to occur near the optimal time for that patient. She must take into account that several patients may require treatments at nearly the same time and that some of them may be receiving other services, such as imaging or physician's visits, at the time when it might be most convenient for the nurse to administer the treatment. When unexpected needs arise, as they often do—an

emergency, an unscheduled patient, observations that could signal an incipient complication—the nurse must set priorities, organize, and delegate to be sure that at least the critical needs are met. Similarly, the physician must balance the needs of various patients who may be widely dispersed throughout an institution. Decision-support systems have the potential to provide important assistance for both the care of individual patients and the organization of the clinician’s workload.

### 17.1.5 Integrating Indirect-Care Activities

Finally, clinicians not only deliver services to patients, with all the planning, documenting, collaborating, referring, and consulting attendant on direct care; they are also responsible for **indirect-care** activities, such as teaching and supervising students, attending staff meetings, participating in continuing education, and serving on committees. Each clinician’s plan of work must allow for both the direct-care and the indirect-care activities. Because the clinicians work in concert, these plans must be coordinated.

In summary, patient care is an extremely complex undertaking with multiple levels. To achieve patient-centered care, each clinician’s contributions to the care of every patient must take into account not only that patient’s values, preferences, and concerns, but also the ensemble of contributions of all clinicians involved in the patient’s care and the interactions among them, and this entire suite of care must be coordinated to optimize effectiveness and efficiency. These very complex considerations are multiplied by the number of patients for whom each clinician is responsible. Patient care is further complicated by the indirect-care activities that caregivers must intersperse among the direct-care responsibilities and coordinate with other caregivers. The resulting cognitive workload frequently overwhelms human capacity. Systems that effectively assist clinicians to manage, process, and communicate the data, information, and

knowledge essential to patient-centered care are critical to the quality and safety of that care.

### 17.1.6 Information to Support Patient-Centered Care

As complex as patient care is, the essential information for direct, patient-centered care is defined in the answers to the following questions:

- What are the patient’s needs, concerns, preferences, and values?
- Who is involved in the care of the patient?
- What information does each clinician require to make decisions in his or her professional domain?
- From where, when, and in what form does the information come?
- What information does each clinician generate? Where, when, and in what form is it needed?

The framework described by Zielstorff, Hudgings, and Grobe (1993) provides a useful heuristic for understanding the varied types of information required to answer each of these questions. As listed in [Table 17.1](#), this framework delineates three information categories: (1) patient-specific data about a particular patient acquired from a variety of data sources; (2) agency-specific data relevant to the specific organization under whose auspices the health care is provided; and (3) domain information and knowledge specific to the health care disciplines.

The framework further identifies four types of information processes that information systems may apply to each of the three information categories. *Data acquisition* entails the methods by which data become available to the information system. It may include data entry by the care provider, patient, or family, or acquisition from a medical device or from another computer-based system. *Data storage* includes the methods, programs, and structures used to organize data for subsequent use. Standardized coding and classification

**Table 17.1** Framework for design characteristics of a patient-care information system with examples of patient-specific data, agency-specific data, and domain information and knowledge for patient care

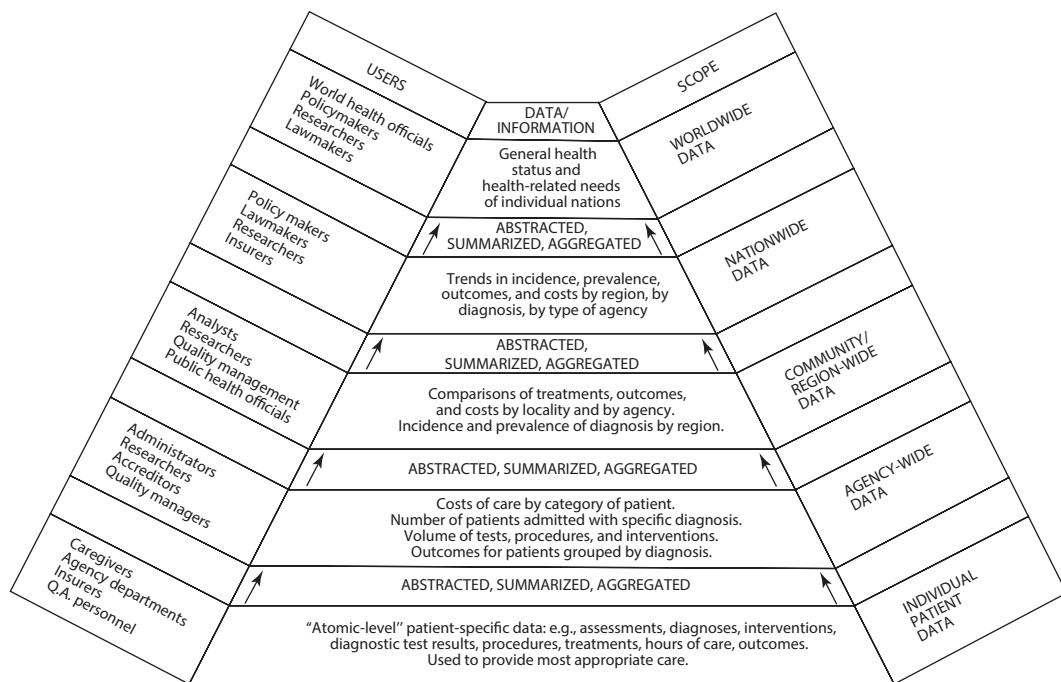

Types of data	System processes			
	Acquiring	Storing	Transforming	Presenting
Domain-specific	Downloading relevant scientific or clinical literature or practice guidelines	Maintaining information in electronic journals or files, searchable by key words	Linking related literature or published findings; updating guidelines based on research	Displaying relevant literature or guidelines in response to queries
Agency-specific	Scanning, downloading, or keying in agency policies and procedures; keying in personnel, financial, and administrative records	Maintaining information in electronic directories, files, and databases	Editing and updating information; linking related information in response to queries; analyzing information	Displaying on request continuously current policies and procedures; sharing relevant policies and procedures in response to queries; generating management reports
Patient-specific	Point-of-care entry of data about patient assessment, diagnoses, treatments planned and delivered, therapeutic goals, and patient outcomes	Moving patient data into a current electronic record or an aggregate data repository	Combining relevant data on a single patient into a cue for action in a decision-support system; performing statistical analyses on data from many patients	Displaying reminders, alerts, probable diagnoses, or suggested treatments; displaying vital signs graphically; displaying statistical results

systems useful in representing patient-centered care concepts are discussed in greater detail in ► Chap. 7. *Data transformation* (or *data processing*) comprises the methods by which stored data or information are acted on according to the needs of the end-user—for example, calculation of a pressure ulcer risk-assessment score at admission or calculation of critically ill patients' **acute physiology and chronic health evaluation (APACHE III)** scores. ■ Figure 17.2 illustrates the transformation (abstraction, summarization, aggregation) of patient-specific data for multiple uses. *Presentation* encompasses the forms in which information is delivered to the end-user after processing.

Transformed patient-specific data can be presented in a variety of ways. Numeric data may be best presented in chart or graph form to allow the user to examine trends, whereas

the compilation of potential diagnoses generated from patient-assessment data is better presented in an alphanumeric-list. Different types of agency-specific data lend themselves to a variety of presentation formats. Common among all, however, is the need for presentation at the point of patient care. For example, the integration of up-to-the-minute patient-specific data with agency-specific guidelines or parameters can produce alerts, reminders, or other types of notifications for immediate action. See ► Chap. 21, on patient-monitoring systems, for an overview of this topic. Presentation of domain information and knowledge related to patient care is most frequently accomplished through interaction with databases and **knowledge bases**, such as Medline or Micromedex. Commercial applications such as UpToDate™ are popular among clinicians because they provide easy

**Fig. 17.2** Examples of uses for atomic-level patient data collected once but used many times (Source: Reprinted with permission from Zielstorff et al. (1993).

© 1993 American Nurses Publishing, American Nurses Foundation/American Nurses Association, Washington, DC. Reproduced with permission.)

access to knowledge resources at the point of care. The **Infobutton**, developed at NewYork-Presbyterian Hospital, is an HL7 standard for context-aware knowledge retrieval (Del Fiol et al. 2012). Incorporated into EHRs, Infobuttons, along with associated management tools, can integrate data about the patient and the clinical context to provide immediate, point-of-care access to relevant knowledge resources (Cimino et al. 2013).

To support patient-centered care, information systems must be geared to the needs of all the clinicians involved in care. The systems should acquire, store, process, and present each type of information (patient-, agency-, and domain-specific) where, when, and how the information is needed by each clinician in the context of his or her professional domain. Systems designed for patient-centered care have the potential to go beyond supporting the collaborative, interdisciplinary care of individual patients. Through appropriate use of patient-specific information (care requirements), agency-specific information (clinicians and their responsibilities and agency

policies and procedures), and domain information (guidelines), such systems can greatly aid the coordination of interdisciplinary services for individual patients and the planning and scheduling of each caregiver's work activities. Patient acuity is taken into account in scheduling nursing personnel, but historically has most often been entered into a separate system rather than derived directly from care requirements as recorded in the EHR. Fully integrated, patient-centered systems—still an ideal today—would enhance our understanding of each patient's situation, needs, and values, improve decision-making, facilitate communications, aid coordination, and use clinical data to provide feedback for improving clinical processes.

Clearly, when other **clinical information systems** designed to support patient-centered care fulfill their potential, they will not merely replace oral and paper-based methods of recording and communicating. They will be an integral and essential part of the transformation of health care to apply evidence-based interventions in accordance with patient needs

and values. How far have we come toward the ideal? What must we do to continue our progress?

## 17.2 The Emergence of Patient-Centered Care Systems

---

Events in the first decade of the Twenty-first Century planted the seeds of transformative change in patient care and clinical informatics. Over 10 years, the shared ideal of health care began to move from the Twentieth Century “doctor knows best” model toward a new vision of health care based on interdisciplinary teams drawing on a variety of knowledge and information resources to collaborate with one another and with patients and families to resolve or alleviate health problems and to achieve health goals. Recursive and iterative developments grew from reports of the **National Research Council** and the **Institute of Medicine** (now known as the **National Academy of Medicine**); from government policies and initiatives; from changes in organizational and financial structures for health care delivery; and from advances in the informatics methods and technologies that have become integral to the provision, management, reimbursement, and improvement of health care. Much remains to be done to nurture continuing development, but with care and patience we can begin to harvest the benefits of better health care and better health for individuals and populations.

### 17.2.1 Publications of the National Academy of Sciences

---

With its seminal publication, *To Err is Human: Building a Safer Health System* (Kohn et al. 2000), the Institute of Medicine startled the world by estimating that clinical errors were killing up to 98,000 hospitalized Americans each year. The report called for a national focus to advance knowledge about safety, reporting efforts to identify and learn from errors, higher standards and expectations for

safety, and implementation of safe practices and systems within health care organizations.

The follow-on report, *Crossing the Quality Chasm: A New Health System for the 21st Century* (Committee on Quality of Health Care in America 2001), addressed the need for fundamental change in the health care delivery system. Shortcomings included inadequate focus on quality and clinical infrastructures not sufficiently developed to provide the full range of services needed by persons with chronic conditions. Significantly, the report placed the blame not on individual health care professionals, but on inadequate and broken systems of care.

*Crossing the Quality Chasm* outlined a call for action by government, payers, providers, and the public to embrace a statement of purpose for the health care system as a whole—to reduce illness and improve health and functioning—and to adopt a shared agenda to achieve health care that would be safe, effective, patient-centered, timely, efficient, and equitable. The report recommended the redesign of care processes to achieve continuity in care relationships; customization in accordance with patient needs and values; the sharing of knowledge, information, and decision-making with patients; evidence-based decision-making; safety as a system property; transparency of information to facilitate informed decision-making by patients and families; anticipation of patient needs; continuous decrease in waste; and cooperation among clinicians. The report gave considerable attention to informatics as an essential methodology to achieve these aims and called for a renewed national commitment to a national health information infrastructure, with the elimination of most hand-written clinical information by 2010.

In *Patient Safety: Achieving a New Standard for Care* (Committee on Data Standards for Patient Safety 2004), the Committee highlighted the fact that a national health information infrastructure—a foundation of systems, technology, applications, standards, and policies—is required for error prevention and capture of data that facilitate local

and global learning from adverse events, near misses, and hazards. The report emphasized the need for data interchange standards as an essential building block.

The **National Academies** followed these three reports with a number of others that explored in greater depth aspects of the problems and recommendations described within them and made further recommendations for public and private actions to improve health care and its costs and outcomes. The National Research Council (Stead & Lin 2009) published *Computational Technology for Effective Health Care: Immediate Steps and Strategic Directions*. This report noted that many health information technologies in the current marketplace lacked the functionality to achieve the goals of improving health care. The central finding was that computer scientists, experts in health and biomedical informatics, and clinicians would need to collaborate to create technologies that would provide cognitive support to clinicians, patients, and family members as they sought to understand, resolve, or alleviate health challenges. The report recommended that federal and state governments and clinicians join forces to require vendors to provide systems that offer such “meaningful” support.

In its **Learning Health System** series, the National Academy of Medicine’s Leadership Consortium for a Value & Science-Driven Health System synthesized the insights of a broad array of experts and explored the need for transformational change in the fundamental elements of health and health care. Multiple volumes reflect the fundamental role of informatics in a learning health system: *Clinical Data as the Basic Staple of Health Learning: Creating and Protecting a Public Good* (Institute of Medicine 2010), *Digital Infrastructure for the Learning Health System: The Foundation for Continuous Improvement in Health and Health Care – Workshop Series Summary* (Institute of Medicine 2011), *Digital Data Improvement Priorities for Continuous Learning in Health and Health Care – Workshop Summary* (Institute of Medicine 2013), and *Optimizing Strategies for Clinical Decision Support: Summary of*

*Meeting Series* (Tcheng et al. 2017). Several priorities for collaborative action from the last are of particular relevance to enable scalable patient-centered care systems: create a national **Clinical Decision Support (CDS)** repository, develop tools to assess CDS efficacy, publish performance evaluations, promote financing and measurement to accelerate CDS adoption, develop a multi-stakeholder CDS learning community to inform usability, and establish an investment program for CDS research.

### 17.2.2 Federal Government Initiatives

The Health Information Technology for Economic and Clinical Health (HITECH) Act provided an unprecedented federal investment in HIT through a series of initiatives aimed at ensuring that all Americans benefit from EHR-supported patient-centered care. Administered by the Office of the National Coordinator for Health Information Technology, the activities are designed:

- To support the health care workforce through Regional Extension Centers for technical assistance for implementation of EHRs and training initiatives to ensure meaningful use of EHRs
- To enable coordination and alignment within and among states (State Health Information Exchange Cooperative Agreement Program)
- To establish connectivity to the public health community in case of emergencies (Beacon Community Program)

In addition, two federal rules support meaningful use of EHRs. The Incentive Programs for EHRs rule from the Centers for Medicare & Medicaid Services (CMS) defines minimum requirements that hospitals and eligible professionals must meet through their use of certified technology to qualify for incentive payments. Criteria related to providing patients with an electronic copy of their own health information and ability to electronically

exchange key clinical information are particularly important to patient-centered care. The complementary Standards and Certification Criteria for Electronic Health Records rule defines the criteria for certification of the technology. Also relevant to patient-centered care are **NHIN Direct** and **NHIN CONNECT**, which support health information exchange to enable patient-centered care.

The Agency for Healthcare Research and Quality (AHRQ) has also invested in advancing patient-centered care through investments in HIT. A particular focus is promoting systems engineering approaches to improve patient safety through evaluation of clinical processes resulting in improved work and information flows. This is reflected in the AHRQ Patient Safety Learning Labs grant portfolio. For example, the Brigham and Women's Hospital project, *Making Acute Care More Patient-centered*, focused on developing tools and care processes to engage patient, family, and professional care team members in reliable identification, assessment, and reduction of patient safety threats in real time before they manifest into actual harm. Widespread adoption of EHR systems and web-based technologies makes it possible to reuse EHR data to create visual displays at the bedside to provide decision support to the care team, patients, and family. ■ Figure 17.3 is an example of a bedside screensaver display used at Brigham and Women's Hospital. The **icons** are driven by patient-specific information in the EHR. The display provides information to patients about their safety plan and provides decision support at the bedside related to patient-specific needs to professional and paraprofessional care team members.

Given these major investments in promoting EHR adoption and use for patient-centered care and research, the vision of every American reaping the benefits of EHRs is moving closer to reality. However, this will continue to be heavily influenced by associated changes in health care financial and organizational structures.

### 17.2.3 Financial and Organizational Structures in Health Care

The historical evolution of information systems that support patient care, and eventually patient-centered care, is not solely a reflection of the available technologies (e.g. Web 2.0, cloud computing). Societal forces—including delivery-system structure, practice model, payer model, and quality focus—have influenced the design and implementation of patient-care systems (■ Table 17.2).

#### ■ Delivery-System Structure

Authors have noted the significant influence of the organization and its people on the success or failure of informatics innovations (Massaro 1993; Campbell et al. 2006; Ash et al. 2007). Others have documented unintended consequences of implementation of HIT and called for applications of models of processes, such as Iterative Sociotechnical Analysis, that take into account health care organizations' workflows, social interactions, culture, etc. to further elucidate the relationship between organizations and technology (Harrison et al. 2007; Koppel et al. 2005; Ozbolt et al. 2012). As delivery systems shifted from the predominant single-institution structure of the 1970s to the **integrated delivery networks** of the 1990s to the complex linkages of the Twenty-First Century, the information needs changed, and the challenges of meeting those information needs increased in complexity. The **patient centered medical home (PCMH)**<sup>2</sup> (also known as primary care medical home, advanced primary care, and health care home) is a model of primary care that delivers care designed to be patient-centered, comprehensive, coordinated, accessible, and continuously improved through a systems-based approach to quality and safety (Patient Centered Medical Home Resource Center 2011).<sup>3</sup> AHRQ and others (Bates and

team. (© Brigham and Women's Hospital, Center for Patient Safety, Research and Practice. Reused with permission.)

Bitton 2010) have noted the seminal role of HIT (e.g., health information exchange, disease registries, alerts and reminders) to support tasks related to **National Committee on Quality Assurance** PCMH standards for enhancing access and continuity, identifying and managing patient populations, planning and managing care, providing self-care and community support, tracking and coordinating care, and measuring and improving performance (Patient Centered Medical Home 2011). **Accountable Care Organizations** (ACOs) focus on care of designated populations. A recent systematic review (Kaufman et al. 2019) reveals consistent associations between ACO implementation and outcomes across payer types and reduced inpatient use, reduced emergency department visits, and improved measures of preventive care and chronic disease management. See ► Chaps. 11, 15, and 18 for discussions of managing clinical information in consumer-provider partnerships in care, in the public health information infrastructure, and in integrated delivery systems.

#### ■ Professional Practice Models

Professional practice models have also evolved for nurses and physicians. In the 1970s, team nursing was the typical practice model for the hospital, and the nursing care plan—a document for communicating the plan of care among nursing team members—was most frequently the initial computer-based application designed for use by nurses. The 1990s were characterized by a shift to interdisciplinary-care approaches necessitating computer-based applications such as critical paths to support case management of aggregates of patients, usually with a common medical diagnosis, across the **continuum of care**. The Twenty-First Century sees advanced practice nurses increasingly taking on functions previously provided by physicians while maintaining a nursing perspective on collaborative, interdisciplinary care. This trend is likely to accelerate given the recommendations for facilitating full scope of practice for nurses and advanced practice nurses (e.g., certified nurse midwives, nurse practitioners) in the 2010 Institute of Medicine

**Table 17.2** Societal forces that have influenced the design and implementation of patient-centered systems

	1970s	1980s	1990s	2000s	2010s
Delivery-system structure	Single institution	Single organization	Integrated delivery systems		Patient centered medical home Virtual care
Professional-practice model	Team nursing	Primary nursing	Patient-focused care, multi-disciplinary care, case management	Patient-centered care	Expansion of nurse and advanced practice nurse roles to legal scope of practice
	Single or small group physician practice	Group models for physicians	Variety of constellations of physician group practice models		
Payer model	Fee for service	Fee for service	Capitation	CMS P4P hospital initiative	Affordable Care Act of 2010
		Prospective payment	Managed care		Accountable Care Organizations Risk-bearing, coordinated care models
		Diagnosis-related groups			
Quality focus	Professional Standards Review Organizations (PSROs)	Continuous quality improvement	Risk-adjusted outcomes	Patient safety	Value-driven health care
		Retrospective chart audit	Joint Commission on Accreditation of Health Care Organization (JCAHO)'s agenda for change	Benchmarking	Learning organizations
	Practice guidelines				
	Critical paths/ care maps			Consumer-driven	
	Health Employer Data and Information Set (HEDIS)

report on *The Future of Nursing: Leading Change, Advancing Health* (Committee on the Robert Wood Johnson Foundation Initiative on the Future of Nursing at the Institute of Medicine 2010). These changes broaden and diversify the demands for decision support, feedback about clinical effectiveness, and quality improvement as a team effort.

Physician practice models have shifted from single physician or small group offices to complex constellations of provider organizations. The structure of the model (e.g., staff model **health-maintenance organization (HMO)**, captive-group model health-maintenance organization, or independent-practice association) determines the types of relationships among the physicians and the organizations. These include issues—such as location of medical records, control of practice patterns of the physicians, and data-reporting requirements—that have significant implications for the design and implementation of patient-care systems. In addition, the interdisciplinary and distributed care approaches of the 1990s and the 2000s have given impetus to system-design strategies, such as the creation of a single patient problem list, around which the patient-care record is organized, in place of a separate list for each provider group (e.g., nurses, physicians, respiratory therapists). While a shared single patient problem list remains a goal of patient-centered care, few implementations have achieved successful integration of the medical problem list with the problem list

from other health professions, in particular nursing, due to the persistence of siloed EHR terminology management (Collins, Bavuso et al. 2017; Collins, Klinkenberg-Ramirez et al. 2017; Collins, Rozemblum et al. 2017).

In the 2010s the use of shared clinical **dashboards** accelerated the operationalization of known patient-centered best practices, such as interdisciplinary clinical rounding and safety checklists, to drive increased situational awareness and promote common ground in relation to patient goals and preferences and prevention of harm (Collins, Gazarian et al. 2014; Mlaver et al. 2017). These shared, interdisciplinary, team-based dashboards are typically configured to a particular practice and specialty area (e.g., cardiac ICU, emergency department) or a clinical quality improvement strategic initiative (e.g., optimizing length of stay, promoting effective and early discharge planning) (Collins, Hurley et al. 2014). In the ambulatory setting shared dashboards are also used and configured to drive population health initiatives.

#### ■ Payer Models

Changes in payer models have been a significant driving force for information-system implementation in many organizations. With the shift from fee for service to prospective payment in the 1980s, and then toward capitation in the 1990s, information about costs and quality of care has become an essential commodity for rational decision-making in the increasingly competitive health care mar-

ketplace. Because private, third-party payers often adopt federal standards for reporting and regulation, health care providers and institutions have struggled in the early 2000s to keep up with the movement toward data and information system standards accelerated by the **Health Insurance Portability and Accountability Act (HIPAA)**<sup>4</sup> and the initiatives to develop a National Health Information Network. With the advent of pay for performance (P4P), CMS has eliminated reimbursement for preventable conditions (e.g., catheter-associated urinary tract infections) that occur during hospitalizations (“CMS P4P”). In this decade, there is no doubt that the implementation of the highly controversial Affordable Care Act of 2010 and evolving ACOs will profoundly impact patient-centered care and the information systems needed to support it.

#### ■ Quality Focus

Demands for information about quality of care have also influenced the design and implementation of patient-care systems. The quality-assurance techniques of the 1970s were primarily based on retrospective chart audit. In the 1980s, continuous quality improvement techniques became the modus operandi of most health care organizations. The quality-management techniques of the 1990s were much more focused on concurrently influencing the care delivered than on retrospectively evaluating its quality. In the Twenty-first Century, patient-centered systems-based approaches—such as practice guidelines, alerts, and reminders tailored on patient clinical data and, in some instances, genomic data (i.e., personalized medicine)—are an essential component of **quality management**. In addition, institutions must have the capacity to capture data for benchmarking purposes and to report process and outcomes data to regulatory and accreditation bodies, as well as to any voluntary reporting programs to which they belong. Increasingly, concurrent feedback about the effectiveness

of care guides clinical decisions in real time, and “dashboards” are used to display indicators related to different dimensions of quality.

**Data science** approaches using clinical data with a quality focus greatly expanded in the 2010s (Bates et al. 2014; Hruby et al. 2016). While much of this work has focused only on the subset of data within the EHR that are consistently structured and coded, such as medical diagnoses, allergies, and medication orders, there are increasing efforts to process and derive value from additional data sources, such as nursing assessment data and narrative notes (Klann et al. 2018) (see ► Chap. 8). The use of high volume clinical **metadata**, or data about the clinical data, also provides value for quality purposes, such as developing health-care process models of care delivery processes, for a richer understanding of patient centered workflows and evaluation of best practices and gaps in care than previously feasible (Hripcsak & Albers 2013; Collins & Vawdrey 2012; Collins et al. 2013).

Of note, while advances in natural language processing continue, many of the computable processes outlined above, such as practice guidelines, alerts, and reminders, still require structured data capture, which typically requires manual data entry by clinicians (Collins, Couture et al. 2018). Evaluation of the value and downstream uses of *manually* captured structured data is an important consideration when configuring clinical systems to decrease burden on the clinician and promote ‘top of license’ practice. Data science approaches for continuous knowledge development are seen as an essential aspect of a Learning Health System. Innovations related to clinical data capture, such as increased capabilities and implementations of device-integrated data and voice-recognition tools, are expected to increase the volume, veracity, variety, and velocity of clinical data for data science and quality purposes. In turn, automated data capture promises to decrease clinician data entry burden and provide greater opportunity for clinical data consumption, interpretation, and decision-making tailored to patient preferences by the care team as part of a patient-centered system.

### 17.2.4 Advances in Patient-Centered Care Systems

The design and implementation of patient-care systems, for the most part, occurred separately for hospital and ambulatory-care settings. Early patient-care systems in the hospital settings included the University of Missouri-Columbia System (Lindberg 1965), the Problem-Oriented Medical Information System (PROMIS) (Weed 1975), the TriService Medical Information System (TRIMIS) (Bickel 1979), the Health Evaluation Logical Processing (HELP) System (Kuperman et al. 1991), and the Decentralized Hospital Computer Program (DHCP) (Ivers et al. 1983). Among the earliest ambulatory-care systems were the Computer-Stored Ambulatory Record (COSTAR), the Regenstrief Medical Record System (McDonald 1976), and The Medical Record (TMR). For a comprehensive review, see Collen (1995).

According to Collen (1995), the most commonly used patient-care systems in hospitals of the 1980s were those that supported nursing care planning and documentation. Systems to support capture of physicians' orders, communications with the pharmacy, and reporting of laboratory results were also widely used. Some systems merged physician orders with the nursing care plan to provide a more comprehensive view of care to be given. This merging, such as allowing physicians and nurses to view information in the part of the record designated for each other's discipline, was a step toward integration of information. It was still, however, a long way from support for truly collaborative interdisciplinary practice.

Early ambulatory-care systems most often included paper-based patient encounter forms. Some used a computer-scannable mark-sense format while others required clerical personnel to type the data into the computer. Current desktop, laptop, or handheld systems use keyboard, mouse, touchpad, or pen-based entry of structured information, with free text kept to a minimum. Current systems also provide for retrieval of reports and past records. Some systems provide decision support or alerts to

remind clinicians to provide needed care, such as immunizations or screening examinations, and to avoid contraindicated orders for medications or unnecessary laboratory analyses. The best provide good support for traditional medical care. Support for comprehensive, collaborative care that gives as much attention to health promotion as to treatment of disease presents a challenge not only to the developers of information systems but also to practitioners and health care administrators who must explicate the nature of this practice and the conditions under which agencies will provide it.

Patient-care information systems in use today represent a broad range in the evolution of the field. Versions of some of the earliest systems are still in use, although most organizations have migrated to commercially available EHR systems. Internally developed systems were generally designed to speed documentation and to increase legibility and availability of the records of patients currently receiving care. As payment models shifted towards population health and value-based care, numerous organizations and providers merged to form healthcare networks. After weighing the costs and benefits associated with further developing the internally developed EHR system and expanding it to newly acquired healthcare providers and sites within their network, many organizations made the decision that the costs and resource requirements for long-term investment in the legacy EHR system were not sustainable. For some organizations this was a difficult decision because the internally developed legacy EHR systems had demonstrated positive outcomes in terms of improved quality and safety. However, substantial resources were required to support continuous development and modification of those systems.

The 2009 enactment of the HITECH Act and its requirements for meaningful use of EHR systems caused many of the commercially available EHR systems to include (or to plan to include) the core functionality needed to achieve the conditions of certification and to meet the population health and reporting requirements of the HITECH Act. Many

legacy EHR systems had inadequate functionality to enable compliance with the new regulations, nor could they support emerging value-based care models. Migration to a single commercial enterprise EHR helped to merge and consolidate clinical data to a single instance (e.g., one patient, one record) regardless of where a patient was seen within the expanding healthcare networks.

More recently developed systems attempt with varying success to respond to the edict “collect once, use many times.” Selected items of data from patient records are abstracted manually or electronically to aggregate databases where they can be analyzed for administrative reports, for quality improvement, for clinical or health-services research, and for required patient safety and public health reporting. Such functionality is a key aspect of the federal requirements for meaningful use and interoperability. See ► Chap. 19 for a full discussion of public health informatics.

Some recently developed systems offer some degree of coordination of the information and services of the various clinical disciplines into integrated records and **care plans**. Data collected by one caregiver can appear, possibly in a modified representation, in the “view” of the patient record designed for another discipline. When care-planning information has been entered by multiple caregivers, it can be viewed as the care plan to be executed by a discipline, by an individual, or by the interdisciplinary team. Some patient-care systems offer the option to organize care temporally into clinical pathways and to have variances from the anticipated activities, sequence, or timing reported automatically. Others offer a patient “view” so that individuals can view and contribute to their own records. For example, patients hospitalized for cardiac conditions can review selected aspects of their records and enter data about their symptoms such as pain ratings into CUPID (Computerized Unified Patient Interaction Device), an iPad-based application (Vawdrey et al. 2011), or about their goals of care (Dykes et al. 2017). Today, care plans are generally limited to one discipline, disease, or care setting. Even after a decade of HITECH funding, a truly integrative electronic care plan

that is comprehensive, cohesive, dynamic, and oriented around actionable patient goals and preferences is still not a reality. The concept of **longitudinal care plans** (LCPs) to support care coordination is referenced in the ACA and HITECH Acts and the ensuing regulations of **Meaningful Use** Stages 1 and 2. This legislation contained financial incentives and penalties, describing implementing LCPs as necessary and dependent on technical interoperability (McDonald et al. 2012). CMS also uses plans of care as part of their rules for eligible providers and facilities that serve Medicare patients with chronic conditions, and for performance-based incentive models (Agency for Healthcare Research and Quality 2014). However, there remains no consensus or definition of an LCP’s contents, nor are there best practices for collaborating, updating, and reconciling the care plan across settings and with the patient and family (Dykes et al. 2014).

Electronic documentation of clinician progress notes has lagged behind other functions in EHRs (Doolan et al. 2003). The process of entering notes may occur through dictation, selecting words and phrases from structured lists, use of templates, and typing free text. Amid concerns that salience may be lost in electronic notes (Siegler 2010), Johnson et al. (2008) advocated for a hybrid approach that combines semi-structured data entry and natural language processing within a standards-based and computer-processible document structure. Thus, ability for data re-use is preserved while maintaining clinician efficiency and expressivity. Some progress has been made with sharing EHR notes with patients. **OpenNotes** is a national initiative to share clinician notes with patients. Early research indicates that clinician note transparency supports patient-centered care, empowers informal caregivers, and engages less educated and diverse patients (Chimowitz et al. 2018).

The publication of the Institute of Medicine’s reports *To Err is Human* (2000) and *Crossing the Quality Chasm* (2001) resulted in increasing demands from health care providers for information systems that reduce errors in patient care. Information system vendors

are responding by developing such systems themselves and by purchasing the rights to patient care systems developed in academic medical centers that have demonstrated reductions in errors and gains in quality of care and cost control. **Closed loop** medication systems use technologies such as bar codes and decision support to guard against errors throughout the process of prescribing, dispensing, administering, and recording and have been identified as a key intervention to improve medication safety. In a before-and-after evaluation of the closed loop electronic medication administration system at Brigham and Women's Hospital, investigators found a significant reduction in the rates of transcription errors, medication errors, and potential adverse events (Poon et al. 2010). In other contexts, decision support systems offer **clinical practice guidelines**, protocols, and order sets as a starting point for planning individualized patient care; providing alerts and reminders; using knowledge bases and patient data bases to assess orders for potential contraindications; and offering point-and-click access to knowledge summaries and full-text publications. See ► Chap. 26 for more information about these systems.

Many health care organizations have substantial investment in legacy systems and cannot simply switch to more modern technology. Finding ways to phase the transition from older systems to newer and more functional ones is a major challenge to health informatics. To make the transition from a patchwork of systems with self-contained functions to truly integrated systems with the capacity to meet emerging information needs is even more challenging (see ► Chap. 16). Approaches to making this transition are described in the Journal of the American Medical Informatics Association (Stead et al. 1996). More recently, some institutions have applied Web 2.0 approaches to create configurable user interfaces to legacy systems. For example, MedWISE integrates a set of features that supports custom displays, plotting of selected clinical data, visualization of temporal trends, and self-updating templates as mechanisms for facilitating cognition dur-

ing the clinical decision making and documentation process (Senathirajah, Bakken, & Kaufman 2014; Senathirajah, Kaufman, & Bakken 2014).

If patient-centered care systems are to be effective in supporting better care, health care professionals must possess the informatics competencies to use the systems. Consequently, many are integrating informatics competencies into health science education (See ► Chap. 25). For example, the Quality and Safety Education for Nurses initiative has named and described necessary competencies and associated curriculum to support patient-centered care, including competencies related to quality, safety, team work, and collaboration (Cronenwett et al. 2009). Recently, informatics competencies for nursing leaders were validated (Yen et al. 2017).

To what degree do patient-care disciplines need to prepare their practitioners for roles as informatics specialists? To the degree that members of the discipline use information in ways unique to the discipline, the field needs members prepared to translate the needs of clinicians to those who develop, implement, and make decisions about information systems. If the information needs are different from those of other disciplines, some practitioners should be prepared as system developers.

The mere existence of information systems does not improve the quality of patient care. The adoption and use of advanced features (such as CDS) that are sensitive to both workflow and human factors are needed to improve the quality of care (Stead & Lin 2009; Zhou et al. 2009). Recent safety reports, public policy, and reimbursement incentives raise awareness of the need for patient-centered care systems. Because traditional requirements for EHRs were provider-centric, existing information systems rarely provide the comprehensive suite of advanced features needed to support patient-centered care. However, the ability of systems to support patient-centered care is essential for achieving the vision of health care reform. What are the requirements for patient-centric information systems? How do these requirements drive the design of systems that will support patient-centered care?

### 17.3 Designing Systems for Patient-Centered Care

In the second decade of the Twenty-first Century, informaticians and clinicians increasingly share a vision for systems that support patient-centered care practices such as interdisciplinary care planning, care coordination, quality reporting, and patient engagement. This evolution is fueled in part by meaningful use requirements that aim to engage patients and families in their health care and to improve care coordination and the overall quality of care provided. Traditional EHR functionality must be expanded to support new features, functions, and care practices including seamless communication, interdisciplinary collaboration, and patient access to information. To optimize human and organizational factors and the integration of systems and workflow, these features must be built into information systems as core requirements, rather than as an afterthought.

The *Principles to Guide Successful Use of Health Care Information Technology* described by the National Research Council (Stead & Lin 2009) provide a comprehensive framework for defining a set of core requirements that will support the design of systems for patient-centered care. This framework defines nine principles related to both evolutionary (i.e., iterative, long-term improvements) and radical (i.e., revolutionary, new-age improvements) changes occurring in the United States' health care system. The principles and associated system design prerequisites are included in [Table 17.3](#).

### 17.4 Current Research Toward Patient-Centered Care Systems

Friedman (1995) proposed a typology of the science in medical informatics. His four categories build from fundamental conceptualization to evaluation as follows:

- Formulating models for acquisition, representation, processing, display, or transmission of biomedical information or knowledge

- Developing innovative computer-based systems, using these models, that deliver information or knowledge to health care providers
- Installing such systems and then making them work reliably in functioning health care environments
- Studying the effects of these systems on the reasoning and behavior of health care providers, as well as on the organization and delivery of health care

While the Friedman typology continues to be useful more than 20 years after its inception, we propose extending the second and third categories in [▶ Sects. 17.4.2 and 17.4.3](#) to expand the focus from clinical informatics as a provider-centric discipline to a discipline that enables and supports patient-centric care. Following are examples of recent research with implications for patient-centered care.

#### 17.4.1 Formulation of Models

For several decades, standards development organizations (SDOs) and professional groups alike have focused on the formulation of models that describe the patient care process and the formal structures that support management and documentation of patient care. The efforts of SDOs are summarized in [▶ Chap. 8](#). Early SDO efforts focused primarily on representing health care concepts such as professional diagnoses (e.g., medical diagnoses, nursing diagnoses) and actions (e.g., procedures, education, referrals). These efforts were complemented by professional efforts such as those of the Nursing Terminology Summit (Ozbolt 2000). As a result of multi-national efforts, SNOMED CT became an international standard that provides a formal model for concepts that describe clinical conditions and the actions of the multidisciplinary health care team (International Health Terminology Standards Development Organization 2011). In addition, SNOMED CT subsets have been developed for specific domains such nursing problems (Matney et al. 2012). Toward the goal of patient-centered care, attention has also been paid to approaches for formal

**Table 17.3** Principles to guide successful use of health care information technology

	Principle	System design prerequisites
Evolutionary change	1. Focus on improvements in care—technology is secondary	Gaps in patient-centered care are clearly defined and operationalized. Health care IT is employed to enable the process changes needed to close gaps in patient-centered care.
	2. Seek incremental gain from incremental effort	An organization's portfolio of health care IT projects has varying degrees of investment. Each project is linked to measurable process changes to provide ongoing visible success with closing gaps in patient-centered care.
	3. Record available data so they can be used for care, process improvement, and research	Health care IT systems support auto capture of data about people, processes, and outcomes at the point of care. Data are used in the short term to support incremental improvements in patient-centered care processes. An expandable data collection infrastructure is employed that is responsive to future needs that cannot be anticipated today.
	4. Design for human and organizational factors	Clear consideration is given to sociological, psychological, emotional, cultural, legal, economic, and organizational factors that serve as barriers and incentives to providing patient-centered care. Health care IT should eliminate the barriers and enable the incentives, making it easy to provide patient-centered care.
	5. Support the cognitive functions of all caregivers, including health professionals, patients, and their families	Health care IT systems include advanced clinical decision support for high-level decision-making that is sensitive to both workflow and human factors.
Radical change	6. Architect information and workflow systems to accommodate disruptive change	Health care IT systems are designed using standard interconnection protocols that support the patient-centered care processes and roles of today while accommodating rapidly changing requirements dictated by new knowledge, care venues, policy, and increasing patient engagement.
	7. Archive data for subsequent re-interpretation	Health care IT systems support archival of raw data to enable ongoing review and analysis in the context of advances in biomedical science and patient-centered care practices.
	8. Seek and develop technologies that identify and eliminate ineffective work processes	Health care IT system design is preceded by a thorough investigation of current and future state work processes of all stakeholders (including patients and their families). Health care IT systems support efficient workflows that leverage ubiquitous access to information and communication and are not constrained by existing care venues or provider-centric practice patterns.
	9. Seek and develop technologies that clarify the context of data	Health care IT systems facilitate patient-centered care by presenting information in context with patient values and preferences and in a format that is understandable and actionable.

representation of terms that patients use to describe their problems and actions (Doing-Harris and Zeng-Treitler 2011).

In more recent years, the focus has turned to the development of **information models** (e.g., clinical elements model) (Oniki et al. 2016) and formal document structures that support sharing of data across heterogeneous information systems and care coordination. In terms of formal document structures, **Logical Observation Identifiers Names and Codes (LOINC)** provides a formal naming convention for document titles and sections (Hyun et al. 2009; Rajamani et al. 2015) and documents are represented according to the HL7 Consolidated **Clinical Document Architecture (C-CDA)** standard including the Release 2 Care Plan and the **Continuity of Care Document (CCD)**. Matney and colleagues illustrated the application of the C-CDA to support the nursing process (Matney, Warren et al. 2016; Matney, Dolin et al. 2016). A CCD designed specifically for low socioeconomic status persons living with HIV/AIDS (PLWH) enrolled in a special needs plan was implemented for viewing by PLWH, their clinicians, and case managers to promote coordination and quality of care (Schnall, Cimino et al. 2011; Schnall, Gordon et al. 2011). More recently, a set of scalable, standards-based approaches has been developed to support interaction of external systems with the native functions of vendor-based EHRs. The **Fast Health Interoperability Resource (FHIR)**, an HL7 standard, has gained traction as a mechanism for information exchange using a well-defined and limited set of resources. Of particular relevance to patient-centered care, Lee and colleagues (2016) developed a FHIR profile for cross-system exchange of a full pedigree-based family health history for applications used by clinicians, patients, and researchers. Built upon FHIR, the **Substitutable Medical Applications and Reusable Technologies (SMART)** platform enables EHR systems to behave as ‘iPhone-like platforms’ through an application programming interface and a set of core services that support easy addition and deletion of third party apps, such that the core system is stable and the apps are substitutable (Mandel et al. 2016). **CDS Hooks** is designed to invoke exter-

nal CDS services from within the EHR workflow based upon a triggering event.<sup>5</sup> Services may be in the form of (a) *information cards* – provide text for the user to read; (b) *suggestion cards* – provide a specific suggestion for which the EHR renders a button that the user can click to accept, with subsequent population of the change into the EHR user interface; and (c) *app link cards* – provide a link to an app.

#### 17.4.2 Development of Innovative Systems

For the purposes of developing innovative patient-centered care systems, the second category of the Friedman Typology described in ▶ Sect. 19.4 is expanded to address the use of models that deliver information or knowledge to both health care providers *and* patients. Consumers regularly use information and communication technology to support decision making in all aspects of their lives. However, access to tools to support health care decision making is suboptimal (Krist and Woolf 2011). Krist et al. (2010) proposed five levels of functionality for patient-centered health information systems.

- Level 1: Collects patient information related to health status, behaviors, medications, symptoms, and diagnoses (e.g., electronic version of traditional paper records maintained by patients)
- Level 2: Integrates patient information with clinical information (e.g., personal health record tethered to an EHR)
- Level 3: Interprets information to provide context in an appropriate level of health literacy
- Level 4: Provides tailored recommendations based on patient information, clinical information, and evidence-based guidelines
- Level 5: Facilitates patient decision-making, ownership, and action

The levels of functionality needed to support patient-centered health information

5 ▶ <https://cde-hooks.org/> (Accessed 5/31/18).

systems relate directly to several of the *Principles to Guide Successful Use of Health Care Information Technology* described by the National Research Council (Stead & Lin 2009) and outlined in ► Sect. 17.3; specifically principles 5, 8 and 9 (see ■ Table 17.3).

Partners Health Care System in Boston, MA, developed Patient Gateway, a secure patient portal serving over 65,000 patient users from primary and specialty care practices affiliated with the Dana Farber Cancer Institute, Brigham and Women's Hospital, and Massachusetts General Hospital. Patient Gateway is a tethered **personal health record** (see ► Chap. 11) that provides functionality in line with the five levels described by Krist and Woolf. For example, tools for management of chronic illness are used by patients and providers to promote adherence with evidence-based health maintenance guidelines and to improve collaboration on diabetes self-management plans (Grant et al. 2006; Wald et al. 2009). Research on patient response and satisfaction with the Patient Gateway suggests that patients appreciate the ability to communicate electronically with providers, they welcome greater access to their health information including test results, and they believe that Patient Gateway enables them to better prepare for visits (Grant et al. 2006; Schnipper et al. 2008; Wald et al. 2009). Evaluations of patient satisfaction with personal health records with similar levels of functionality at other sites, including Geisinger Health System (Hassol et al. 2004), Group Health Cooperative (Ralston et al. 2007), and Virginia Commonwealth University (Krist et al. 2010), are consistent with the results reported at Partners Health Care System.

While traditionally patient portals have been associated with ambulatory care, some health care systems are providing modules within their patient portals to inform and activate patients and family during an acute hospitalization and associated transitions (Grossman et al. 2018). Early research indicates that in addition to the features commonly found in ambulatory patient portals (e.g., medications, labs, educational content, scheduling features), the acute care modules provide patient access to the plan of care,

daily schedules, and direct care team communication. Some inpatient portals support patient-generated content such as notes, patient-provider messaging, and patient feedback related to their care plan or discharge plan. Research is needed on the use of acute care portals to explore their impact on patients' abilities to successfully navigate information-rich acute care hospitalizations and to examine the effects of portal use on patient activation, engagement, and the overall quality of care (Grossman et al. 2018).

The involvement of users has been identified as fundamental to well-designed systems that are usable and useful in the context of busy patient care workflows (Rahimi et al. 2009). Some examples of development activities where user involvement is needed are content standardization, workflow modeling, and **usability testing**.

- *Content standardization*: Content standardization includes identifying EHR content needed to support documentation of care provided and identification of data needed for reuse (e.g., decision support, quality reporting, and research). Content that is shared across disciplines and patients is identified. Content is modeled using standards to ensure data reuse and interoperability (Principle 3, ■ Table 17.3) (Chen et al. 2008; Dykes et al. 2010; Kim et al. 2011).
- *Workflow modeling*: Sound modeling of the clinical workflow that underlies an electronic system is essential to designing systems that are usable by care team members (Peute et al. 2009). Workflow models are based on observations of current state clinical workflows including interactions with patients, staff, equipment, and supplies. Understanding of workflow interactions, including current state inefficiencies, informs effective and efficient future state workflows, use-case development, and system prototypes (Rausch & Jackson 2007; Mlaver et al. 2017). Workflow modeling of patient-centered systems includes clear evaluation of ways to use technology to identify and eliminate ineffective work processes (Principle 8, ■ Table 17.3). Design of new systems is an opportunity

to provide ubiquitous access to information and communication by all care team members including patients. Applying these principles in workflow modeling assures that future state workflows are not constrained by existing care venues or provider-centric practice patterns.

- *Usability testing*: A key lesson learned from Computerized Physician Order Entry implementations is that electronic systems with poor usability interfere with clinical workflow. The unintended consequences of poorly designed systems are well known, and some widely disseminated papers (Ash et al. 2004, 2009; Koppel et al. 2005) have called into question the safety of using such systems with patients. Examples of common usability problems include overly cluttered screen design, poor use of available screen space, and inconsistencies in design. Involving end-users in design and enforcing usability design standards when building clinical systems prevents implementing systems that are difficult to use and interfere with, rather than support, patient-centered care (Principles 4, 5 and 8, ■ Table 17.3).

Innovative systems to support patient care often take advantage of information entered in one context for use in other contexts.

For example, the Brigham and Women's Hospital Patient Safety Learning Lab in Boston developed a provider checklist and a patient-centered toolkit that used information from the order entry, scheduling, flow-sheets (nursing documentation), and other systems to auto-populate a suite of tools used by clinicians and patients to improve team communication and patient safety. The iterative, participatory development process led to tools that are used every day in the medical intensive care units and that demonstrated significant reductions in adverse events and improvement in patient and family satisfaction (Mlaver et al. 2017).

The principle of entering information once for multiple uses also drove development of the bedside displays for inpatients and the care team at Brigham and Women's Hospital (Duckworth et al. 2017). A patient safety

plan dashboard was developed that captures disparate data from the EHR and presents a personalized display as the screensaver on the bedside computer workstation. The dashboard aligns all care team members, including patients and families, in the safety plan. The screensaver content includes icons that provide actionable alerts related to patient-specific safety concerns. These bedside displays combine data from many sources to support the integrated care of physicians, nurses, and family members.

At Partners Health Care System, system developers are working with clinical teams to identify system requirements, to iteratively develop, and to test patient-centric systems that integrate decision support into the clinical workflow. For example, Dykes et al. (2010) developed a fall prevention toolkit that reuses fall risk assessment data entered into the clinical documentation system by nurses and automatically generates a tailored set of tools that provide decision support to all care team members, including patients and their family members at the bedside (Dykes et al. 2009). The fall prevention toolkit logic was developed from focus groups of professional and para-professional caregivers (Dykes et al. 2009), and of patients and family members (Carroll et al. 2010). As nurses complete and file the routine fall risk assessment scale, the documentation system automatically generates a tailored bed poster that alerts all team members about each patient's fall risk status and patient-appropriate interventions to mitigate risk. In addition, a patient education handout is generated that identifies why each individual patient is at risk for falls and what the patient and family members can do while in the hospital to prevent a fall. The icons used in the Fall TIPS poster and patient education handout have been developed and validated using a participatory design process with clinicians and patients (Leung et al. 2017; Hurley et al. 2009). In a randomized control trial of over 10,000 patients, the toolkit was associated with a 25% reduction in falls (Dykes et al. 2010). The Fall TIPS toolkit reduced falls by leveraging HIT to complete the three-step fall prevention process: (1) conduct fall risk assessments, (2) develop tailored fall prevention plans with

evidence-based interventions, and (3) consistently implement the plan. We learned that Fall TIPS was most effective at reducing falls and related injuries when patients and family were engaged in all three steps of the fall prevention process (Dykes et al. 2017).

### 17.4.3 Implementation of Systems

Much has been written about HIT failures and associated costs and consequences (Bloxham 2008; Booth 2000; McManus & Wood-Harper 2007; Ornstein 2003; Rosencrance 2006). Higgins and associates (see Rotman et al. 1996) described the lessons learned from a failed implementation of a computer-based physician workstation that had been designed to facilitate and improve ordering of medications. Those lessons are not identical to, but are consistent with, the recommendations of Leiner and Haux (1996) in their protocol for systematic planning and execution of projects to develop and implement patient-care systems. While long term follow-up of a vendor EHR implementation with advanced CDS identified lower prescribing error rates, achieving prior levels of perceived prescribing efficiency took nearly 2 years (Abramson et al. 2013, 2016).

In response to evidence of unintended consequences and clinicians voicing concerns after system implementations, the **American Medical Informatics Association (AMIA)** EHR 2020 Task Force on the Status and Future Directions of EHRs published a report in 2015 that outlined 10 recommendations that span five areas. These recommendations are in response to current barriers to quality care delivery experienced at many organizations after EHR system implementations. The five areas addressed were: simplify and speed documentation, refocus regulation, increase transparency and streamline certification, foster innovation, and support person-centered care delivery. Specific recommendations discussed decreasing documentation burden, improving the designs of interfaces so that they support and build upon how people think (i.e., cognitive-support design), and promoting the integration of EHRs into the full social context of care, moving beyond acute

care and clinic settings to include home health, specialist care, laboratory, pharmacy, population health, long-term care, and physical and behavioral therapies (Payne et al. 2015).

Several studies have quantified documentation burden. In one setting, resident physicians spent 85 minutes per day authoring and viewing notes (Hripcsak et al. 2011). In another setting, on average, nurses perform 631–662 manual flowsheet data entries per 12-hour shift (excluding device integrated data), averaging to one data point every 0.82–1.14 minutes in acute care (Collins, Couture et al. 2018). Further, EHR log file analyses indicate nurses spend 21.4–38.2 minutes per day authoring notes, on average (Collins, Couture et al. 2018), yet fewer than 20% of nursing notes were read by physicians, and only 38% were read by other nurses (Hripcsak et al. 2011). There is an overall lack of standardization and consistency of data definitions within EHRs, leading to a proliferation of data elements that contribute to EHR burden and inhibit interoperability and automated reporting (Zhou et al. 2016; Collins, Bavuso et al. 2017; Collins, Klinkenberg-Ramirez et al. 2017; Collins, Rozemblum et al. 2017). Methods to increase consistency of data definitions have been published, but are often minimally implemented due to project timelines and limited resources (Collins et al. 2015, Collins, Bavuso et al. 2017, Collins, Klinkenberg-Ramirez et al. 2017, Collins, Rozemblum et al. 2017). Efforts by national organizations to improve consistency of data definitions include the American Medical Association's Integrated Health Model Initiative<sup>6</sup> and collaborations between the Office of the National Coordinator for Health Information Technology (ONC) and CMS.<sup>7</sup>

As these experiences demonstrate, the implementation of patient-care systems is far more complex than the replacement of one technology with another. Such systems

6 AMA. Integrated Health Model Initiative, 2018. [▶ https://ama-ihmi.org](https://ama-ihmi.org) (Accessed 9/25/18).

7 ONC/CMS Reducing Clinician Burden Meeting. February 22, 2018. [▶ https://www.healthit.gov/news/events/onccms-reducing-clinician-burden-meeting](https://www.healthit.gov/news/events/onccms-reducing-clinician-burden-meeting) (Accessed 9/25/18).

transform work and organizational relationships. If the implementation is to succeed, attention must be given to these transformations and to the disruptions that they entail. Southon et al. (1997) provided an excellent case study of the role of organizational factors in the failed implementation of a patient-care system that had been successful in another site.

To realize the promise of informatics for health and clinical management, people who develop and promote the use of applications must anticipate, evaluate, and accommodate the full range of consequences. In early 2003, these issues came to the attention of the public when a large academic medical center decided to temporarily halt implementation of its CPOE system due to mixed acceptance by the physician staff (Chin 2003; Ornstein 2003). A case series study by Doolan et al. (2003) identified five key factors associated with successful implementation: (1) having organizational leadership, commitment, and vision; (2) improving clinical processes and patient care; (3) involving clinicians in the design and modification of the system; (4) maintaining or improving clinical productivity; and (5) building momentum and support amongst clinicians. A collaboration of ten AMIA working groups and the **International Medical Informatics Association** Working Group on Organizational and Social Issues cosponsored a workshop to review factors that lead to implementation failure. These include poor communication, complex workflows, and failure to engage end-users in clearly defining system requirements. Recognizing that the problems encountered in failed implementations tend to be more administrative than technical, they recommended the following set of managerial strategies to overcome implementation barriers (1) provide incentives for adoption and remove disincentives; (2) identify and mitigate social, IT, and leadership risks; (3) allow adequate resources and time for training before and after implementation, including ongoing support; and (4) learn from the past and from others about implementation successes and failures and about how failing situations were turned around (Kaplan and Harris-Salamone 2009).

In 2014, the SAFER (Safety Assurance Factors for Electronic Health Record Resilience) Guides were first published to facilitate proactive risk assessments of EHR safety and usability related policies, processes, procedures, and configurations at healthcare organizations (Ash et al. 2016). These guides are endorsed by the ONC and available at ► [HealthIT.gov](http://HealthIT.gov). The SAFER Guides include nine guides organized into three broad groups: foundational guides, infrastructure guides, and clinical process guides. Recent evaluations indicate that health organizations would benefit from broader implementation of these guides and principles of safety and usability (Ash et al. 2016; Sittig et al. 2018).

For the purposes of promoting successful implementation of patient-centered systems, the third category of the Friedman typology is expanded to provide access to information to all team members including patients and their families or caregivers outside of traditional health care settings as follows: *Installing such systems and then making them work reliably in functioning health care environments and other settings where information is needed to promote health and wellbeing*. The majority of self-management occurs outside traditional health care settings. As noted in ► Table 17.3, a prerequisite for patient-centered systems is that they support efficient workflows with ubiquitous access to information and communication and that the systems are not constrained by existing care venues or provider-centric practice patterns (Principle #8). Clinical workflows are highly complex and data-rich, requiring formal analysis and evaluation before and after system implementation. For example, a time-motion study found that, on average, nurses engage in 31 communications and 52 hands-on tasks per hour, and multi-task 18.63% of the time (Yen et al. 2016). Strategies to involve users in system design or selection and customization will support successful implementation of systems that meet user expectations (Burley et al. 2009; Rahimi et al. 2009; Saleem, Russ, Justice et al. 2009; Saleem, Russ, Sanderson et al. 2009). User involvement in defining future workflows contributes to a shared understanding about the impact of information systems on clinical tasks and workflows (Leu et al. 2008).

Careful attention to the *Principles to Guide Successful Use of Health Care Information Technology* during system design will support successful implementation. For example, the principles related to evolutionary health care changes keep the focus on designing and implementing usable systems that enable patient-centered care practices. Principles related to radical change focus on development of flexible, adaptable systems that are architected to accommodate disruptive change and iterative development based on end-user feedback.

#### 17.4.4 Effects of Clinical Information Systems on the Potential for Patient-Centered Care

Electronic health records and CPOE systems are intended to support safe, evidence-based, patient-centered care by examining patient-specific information, agency-specific information, and domain-specific information in the clinical context and proposing appropriate courses of action or alerting clinicians to potential dangers. Many current systems, however, fail to follow design principles that take into account the real contingency-driven, non-linear, highly interrupted, collaborative, cognitive, and operational workflow of clinical practice (Ash et al. 2004). These flaws can lead to errors in entering and retrieving information, cognitive overload, fragmentation of the clinical overview of the patient's situation, lack of essential operational flexibility, and breakdown of communication. Physicians, in particular, have found themselves chagrined by changes in the power structure as they have devoted more time to entering information and orders while other members of the health team have gained greater access to information and the concomitant capacity to make certain decisions without consulting the physician. Clinicians across the range of professions have expressed concern about the decrease in face-to-face communication with its verbal and non-verbal richness, negotiation, and redundant safety checks as more and more clinical information is exchanged via the com-

puter (Campbell et al. 2006; Ash et al. 2007). These and other unintended consequences of EHRs and CPOE systems are the subject of ongoing research. Detecting and finding ways to prevent or mitigate the adverse, unintended consequences of these systems will be critical for supporting patient-centered care.

A number of unintended consequences stem from the incompatibility of system design with the clinician's cognitive workflow. For example, systems that make it difficult to find and retrieve information can interfere with patient-centered care. In a hospital preparing to implement a commercial CPOE system, investigators compared the efficiency, usability, and safety of information retrieval using the vendor's system, the current paper form, and a prototype CPOE developed on principles of **User Centered Design**. They found the prototype system to be similar to the paper form and both to be significantly superior to the vendor's system in efficiency, usability, and safety (Chan et al. 2011).

Other unintended consequences arise from over-reliance on the information system because of limited understanding of its design and capacities. To date, many CDSS are somewhat limited in their ability to incorporate patient-specific data into their decision algorithms. A synthesis of 17 systematic reviews conducted with sound methodology found that CDSS often improved providers' performance, especially in medication orders and preventive care. The reviewers noted, "These outcomes may be explained by the fact that these types of CDSS require a minimum of patient data that are largely available before the advice is (to be) generated: at the time clinicians make the decisions" (Jaspers et al. 2011, p. 327).

On the other hand, many systems offer functionalities that support patient-centered care. An important component of patient-centered care is the application of evidence in a plan of care tailored to the patient's needs. To increase the use of evidence-based order sets, investigators at Sinai-Grace Hospital in Detroit, Michigan embedded into the general admission order set specific, evidence-based order sets for the most common primary and secondary diagnoses for patients admitted to

their medical service. The result was a fivefold increase in the use of evidence-based order sets in the 16-month period following implementation (Munasinghe et al. 2011).

As in the examples above, most systems to support the cognitive workload have been directed toward physicians. Patient-centered care requires a broader perspective. A study of the information needs of case managers for PLWH found that the most frequent needs were for patient education resources (33%), patient data (23%), and referral resources (22%) (Schnall, Cimino et al. 2011). The investigators recommended that targeted resources to meet these information needs be provided in EHRs and continuity of care records through mechanisms such as the **Infobutton Manager**.

Key to patient-centered care is communication among all the health care professionals on the patient's team. A study at one academic medical center (Hripcsak et al. 2011) reviewed EHRs of hospitalized patients, along with usage logs, to make inferences about time spent writing and viewing clinical notes and patterns of communication among team members. In this setting, the core team for each patient consisted of one or more attending physicians, residents, and nurses, with social workers, dietitians, and various therapists joining the team later. Results showed that clinical notes were more likely to be reviewed within the same professional group, with attending physicians and residents viewing notes from nurses or social workers less than a third of the time. The investigators proposed that it might be useful to develop ways for EHRs "to summarize information and make it readily available, perhaps with the ability of the author to highlight information that may be critical and that has a high priority for communication" (p. 116) (Hirsch et al. 2014). They also noted that their study was limited to communications within the EHR and did not take into account face-to-face or telephone communications that might have occurred, especially in urgent situations. They suggested further research involving direct observation of clinicians, time-motion analyses, and think-aloud methods to develop deeper knowledge of how clinicians communicate about patient care, especially across the professions.

The quality of documentation tools can have a profound effect on whether information, even if communicated face-to-face, is acted upon in clinical care (Collins et al. 2011). In a neurovascular intensive care unit, therapeutic goals for patients were stated during daily interdisciplinary rounds. In this setting, the interdisciplinary team treated the attending physician's note as a common patient-focused source of information. Although the attending physician's note contained 81% of the stated ventilator weaning goals, it included only 49% of the stated sedation weaning goals. Overall, nearly a quarter of stated goals were not documented in the note. If a goal was not documented, it was 60% less likely to have a related action documented. Nurses' documentation rarely mentioned the goals, even if actions recorded were consistent with the goals as stated during rounds. Notably, the nurses' structured documentation system did not support sedation-related goals, even though sedation weaning was a nursing responsibility in this setting. The authors noted that the frequent omission of sedation goals from the attending physician's note might be because this nursing function was not a billable goal or act. They also expressed concern that the omission from the EHR of evidence of important clinical judgments nurses make could impair patient safety, quality improvement, and development of nursing knowledge. Thus, in this example, although the interdisciplinary team was collaborating in setting and reaching therapeutic goals, deficiencies in their processes and in the nurses' documentation system limited their achievement of patient-centered care.

A study at Vanderbilt University Medical Center also demonstrated both strengths and shortcomings in the ability of a clinical information system to support patient-centered care. Attending physicians in the Trauma and Surgical ICUs established protocols for Intensive Insulin Therapy that were built into a CDSS to advise nurses on insulin doses based on a patient's blood glucose and insulin resistance trends. In 94.4% of studied instances, nurses administered the recommended dose. When nurses overrode the recommended dose, they overwhelmingly administered less insu-

lin than the recommended dose, leading to a higher incidence of hyperglycemia than when the recommended dose was administered. Nurses appeared more concerned about hypoglycemia than hyperglycemia and to consider the patient's blood glucose but not the insulin resistance trend. They also noted that their workflow was impeded by the need to record information about the blood glucose, insulin dose, and primary dextrose source in two places—the CPOE that included the CDSS and the separate nurse charting system. The investigators' recommendations included displaying information about insulin resistance trends on screen (provided that this did not produce clutter and confusion) and developing clinical information systems that do not require double documentation. Strengths of this example for supporting patient-centered care include the collaboration of physicians and nurses in maintaining blood glucose in the desired range based on patient data. Shortcomings include the failure to present nurses with information about the patient's insulin resistance trend to aid their decision-making and the requirement that they record the same data in two places, thereby reducing time for direct patient care (Campion Jr et al. 2011).

Patient-centered care systems not only support the cognitive work and communications of clinicians; they also take into account the resources patients and families use to manage their health concerns. Increasingly, patients and family members engaged in promoting their own health turn to social networking sites on the Internet. While research on the impact of social networking sites on patient-related outcomes is in its infancy, early research indicates that social networking sites are used by patients and family members to get informational and social support for day-to-day management of chronic illnesses such as diabetes and heart failure (Mogi et al. 2017; Partridge et al. 2018). Several studies indicate that the primary objectives for using social networking sites were to request information, to provide information to others with similar conditions, to express emotion about one's own condition, to provide emotional support to others, and to promote a specific product (Greene et al. 2011; Mogi et al. 2017). Many

health care professionals recognize the potential of social networking sites for the peer support that patients gain from participation, but they have concerns about the accuracy of the content that is offered on these sites. Available research indicates great variability in the accuracy and effectiveness of the clinical content offered on **social networking sites** (Greene et al. 2011; Mogi et al. 2017). One study found that approximately one-third of the posts on health-related social networking sites could be classified as an advertisement of a non-FDA-approved remedy or cure (Greene et al. 2011). It was also noted that requests for personal information were not uncommon, potentially making participants vulnerable to solicitations from product manufacturers or vendors. Clinicians should be aware of the social networking sites related to their area of expertise. Discussing social networking options with patients, including the advantages and disadvantages and the potential benefits and problems, can help patients to be more judicious consumers of social networking sites.

In patient-centered care, personal health records (see ► Chap. 13) are often viewed as a means of communication between patients and providers and as a method of engaging patients in understanding and acting in the interests of their own health. A 2016 international study to understand perspectives on sharing data with patients categorized countries that are focused on encouraging patients to receive access to their clinical data, within the following stages of maturity: Established, Emerging, and Limited. Countries with “Established” levels of maturity for sharing patient data had been focused on this work since the early 2000s and included Israel, England, Canada, Australia, and the United States (Prey et al. 2016). Expanded efforts to share patient data led to “Emerging” status for Austria, Argentina, Brazil, the Netherlands, Portugal, South Korea, Switzerland, and Uruguay. Iran, Japan, and Kenya were described as focused on EHR implementation with “limited” patient engagement and the potential for increased focus on patient engagement in the future. In 2013, ONC announced the Blue Button initiative, promoting patients' legal rights to receive their personal health informa-

tion and recognizing sites that enable consumers to download their health records. A 2017 ONC Data Brief reported that 52 percent of individuals have been offered online access to their medical record in the United States and over half of those individuals viewed their record within the past year, the equivalent of 28 percent of individuals nationwide (Patel & Johnson 2018).

Most of the clinical data being shared through portals is structured, coded information such as problem lists, allergies, medication lists, appointments, and laboratory results. Sharing of narrative notes is not widespread, but, as noted previously, the OpenNotes project has demonstrated the successful sharing of notes with patients. To date, over 28 million patients have online access to notes, and the network of providers participating in this project continues to grow.<sup>8</sup>

Patient portals, which evolved as a mechanism to access personal health data and populate personal health record platforms, began to take hold in the 2000s. Several pilots during this time, such as the Military Health System's MiCare portal in 2008, resulted in critical learnings and informed optimization of portal functionality over the following decade. Lessons learned include the following: (1) transfer of data upon specific patient request is more efficient than automatic transfer; (2) patient representatives prefer instant access to all their data, while many providers prefer an embargo time, particularly for release of sensitive results data; (3) inefficient provider access to personal health records and siloed repositories with incomplete information might pose the danger of ill-informed clinical decisions; and (4) giving patients the power to determine what medical information to share with the provider could similarly lead to clinical decisions made in the absence of vital information, with resulting harm to patients. The MiCare pilot concluded that while there is broad agreement on desired functionalities for portals, challenging tensions remain between patients' desire for access to and control of health information and providers'

needs for full information about the patient and for appropriate opportunities for ethical disclosure of information to patients. Over the following decade throughout the 2010s, core functionality for portals continued to expand and mature. Common features now include secure messaging, prescription renewals and refills, appointment requests online, online bill pay, referral requests, medication reminders, links to reference materials, use of low health literacy terms, and increasing access to several types of clinical data. Clinical data released in portals include routine and sensitive laboratory results, genetic test results, medications, encounter information, allergies, immunizations, radiology and other diagnostic reports, problem lists, discharge summaries, and clinical notes. In many organizations embargo periods for releasing results have lessened or been eliminated, although variability remains.

As portal functionalities expanded and were optimized, acute care patient portals (portal access tailored to the hospital setting) began to emerge. Although some clinicians feared that patient portal access to data during a hospitalization would burden them with excessive patient inquiries, their fears were no more realized than were those of clinicians wary of the OpenNotes project (Collins, Bavuso et al. 2017; Collins, Klinkenberg-Ramirez et al. 2017; Collins, Rozemblum et al. 2017). User-centered design with patients and families and other key clinician and administrative stakeholders specified that acute care portals could provide value by humanizing the patient-clinician connection, facilitating the maintenance and sharing of verbal communication, and promoting ubiquitous and equitable access to information. Key features specified for portals in the acute care setting are the provision of clinical data, messaging with clinicians, glossary of clinical/hospital terms, patient education resources, patient diary, patient notepad for reminders, resources that support family involvement, and tiered displays for information-dense clinical data. New clinical workflows are required to integrate portals within the acute care setting, and these are facilitated by active clinician engagement and demonstration of improved patient outcomes and satisfaction (Collins, Bavuso et

---

al. 2017; Collins, Klinkenberg-Ramirez et al. 2017; Collins, Rozemblum et al. 2017). Patient portals are increasing, but not yet in routine use, in the acute and post-acute setting.

In 2018, 7 key focus areas were identified for sociotechnical and evaluation research related to patient engagement and portal use in the acute and post-acute care settings. These identified research areas were (1) standards for interoperability, functionality, and patient-driven use case models; (2) appropriate access and policies for privacy and security; (3) user-centered design; (4) implementations that integrate with workflows for sustainable adoption; (5) data and content management and visualizations with inclusion of novel data sources (e.g., multimedia tools, safety reporting platforms, **social determinants of health** [SDOH] data); (6) CDS for patients and care partners; and (7) systematic evaluation of process, balance, and outcomes measurement (Collins, Dykes et al. 2018).

Importantly, patients expect that patient portals across ambulatory and acute care settings are seamless and integrated for ease of access within the patient's control. Seamless data access within the patient's control is not yet broadly realized, but several technical and policy initiatives offer promising paths that were not possible previously. The federal 21st Century Cures Act (Cures Act) includes provisions to improve patients' access to their health data and simplification of the patient's ability to electronically share their information. Aligned with those provisions, there are ongoing interoperability efforts with a primary focus on connecting mobile health apps and devices to EHRs using open **application programming interfaces** (APIs) to allow individuals to collect, manage, and share their health information. ONC, aligned with the Cures Act, promotes policy choices that will give consumers, clinicians, and innovators more options for getting to and using health information with specific HIT certification criteria that call for the development of modern APIs that do not require "special effort" to access and use (Rucker 2018). ONC promotes the use of the FHIR standard for representing clinical data with APIs.

Electronic health records and other computer-based information resources can influence the provision of patient-centered care even when the patient and the provider are in the same room. A study of computer use during acute pediatric outpatient visits found that female physicians were more likely than males to be communicating with patients and families while using the computer (Fiks et al. 2011). A recent study in ambulatory care revealed that although providers reported improvements attributable to EHRs (e.g., communication between providers, review of results with patients, and review of follow-up to testing results with patients), they perceived a negative effect on patient-provider connection (Sandoval et al. 2016). An observational study involving 20 primary care physicians and 141 of their adult patients showed how the inclusion of the computer in the clinical consultation can help patients shift the balance of power and authority toward shared decision-making and patient-centered care (Pearce et al. 2011). This Australian study found that about one-third of the patients actively included the computer as a party to the consultation, drawing the physician's attention to it as a source of information or authority. They concluded, "*In the future, computers will have greater agency, not less, and patients will involve themselves in the three-way consultation in more creative ways—for example, through online communication, or through the plugging into computers of their own electronic records, creating a situation where they co-own the information in the computer .... By democratizing and commoditizing information flows and authority in the consultation, we may in fact create truly patient-centered medicine, with the patient directing the action*" (p. 142).

As these examples illustrate, the complexity of collaborative, interdisciplinary, patient-centered care poses serious challenges to the design of clinical information systems. Many systems fall short in supporting cognitive work, even from a clinician-centric perspective. Supporting communications among clinicians, between clinicians and patients, and among patient and family support groups presents myr-

technical and ethical problems. Still, researchers and clinicians increasingly share a vision of patient-centered care that drives them to push the frontiers and develop support for this emerging model of care.

## 17.5 Outlook for the Future

Social and political forces have begun to transform health care in the United States, and HIT is advancing to support the changes. The transformation is rapid, disruptive, and not always smooth, but mandates and incentives are aligning with social and economic imperatives to maintain progress.

To meet demands for patient-centered care, changes must occur in clinician practice patterns and processes, in the organization and management of health services, and in the education of health care professionals and the public. To support patient-centered care, clinicians, informatics professionals, and computer scientists must develop health information and communication technologies that support collaboration; cognitive processes and operational workflow; communication and shared decision making between and among clinicians, patients, and family members; and trustworthy tools for the management of personal and family health.

Transformational change is daunting, and resistance is inevitable. Still, the chances for success have never been better. The vision of health care articulated by the National Academies of Sciences is guiding policy, research, and practical action by government agencies, health care providers, and the public.

### ? Questions for Discussion

1. What is the utility of a linear model of patient care as the basis for a decision-support system? What are two primary limitations? Discuss two challenges that a nonlinear model poses for representing and supporting the care process in an information system.
2. Compare and contrast additive, clinician-centered versus coordinated, patient-centered models of interdisciplinary patient care. What are the advantages and disadvantages of each model as a mode of care delivery? What are the broad implications for design of information systems to support clinician-centered versus patient-centered models of care?
3. Imagine a patient-care information system that assists in planning the care of each patient independently of all the other patients in a service center or patient-care unit. What are three advantages to the developer in choosing such an information architecture? What would be the likely result in the real world of practice? Does it make a difference whether the practice setting is hospital, ambulatory care, or home care? What would be the simplest information architecture that would be sufficiently complex to handle real-world demands? Explain.
4. Zielstorff et al. (1993) proposed that data routinely recorded during the process of patient care could be abstracted, aggregated, and analyzed for management reports, policy decisions, and knowledge development. What are three advantages of using patient care data in this way? What are three significant limitations?
5. Over the past decade, many of the patient-care information systems designed in the 1970s have been replaced by vendor-based systems. What role have public policy and payment models had in driving this change? How do the practice models, payer models, and quality focus of today differ from those of the past? What differences do these changes require in information systems? What are two advantages and two disadvantages of the older, internally developed legacy systems versus vendor-provided systems?
6. What challenges exist in modeling information for patient-centered care? What considerations are important in designing patient-facing health information and communication technologies?

# Population and Public Health Informatics

*Martin LaVenture, David A. Ross, Catherine Staes,  
and William A. Yasnoff*

## Contents

- 18.1 Chapter Overview – 614**
- 18.2 What Is Public Health? – 614**
  - 18.2.1 Public Health Versus Population Health – 617
- 18.3 Public Health Informatics – 618**
- 18.4 Examples of Public Health Informatics Challenges and Opportunities – 619**
  - 18.4.1 Overview of Public Health Information Systems in the U.S. – 619
  - 18.4.2 Immunization Information Systems: A Public Health Informatics Exemplar – 624
  - 18.4.3 Global Health Perspective and Opportunities – 631
- 18.5 Public and Population Health Informatics Conclusion – 632**
- References – 635**

## Learning Objectives

After reading this chapter you should know the answers to these questions:

- What are the three core functions of public health, and how do they influence informatics requirements to achieve public health goals?
- What is the difference and relationship between public health and **population health**?
- What are the differences between **public health informatics** and other informatics specialty areas?
- What are the ways populations can be defined and how does that impact public health informatics?
- What are the categories and specific characteristics of informatics systems that are typically deployed in public health?
- What are the variations in the types of public health information systems needed at a local, regional, state, or national level?
- What factors influence the use of immunization information systems (IIS) and how can this model apply to other areas of the health system?
- What are some of the characteristics and factors that allow a public health information system to work in other countries but not in the U.S.?

## 18.1 Chapter Overview

The science and practice of Biomedical Informatics supports public health in its efforts to *promote* the health of populations, *prevent* disease and unhealthy exposures and behaviors, and *protect* populations exposed to human-caused or natural disasters. To optimize **population health**, one must address factors beyond the genetic and biologic make-up of individuals, such as the environment, behaviors, socio-economic status, occupation, access to care, and other influencers of health status. Although much of the variation in health status can be attributed to the zip code of one's residence, (Dwyer-Lindgren et al.

2017) behaviors (e.g., smoking and physical activity) are root determinants for the most common causes of death (Schroeder 2007). Public health measures leading to improved access to safe water and sanitation, nutrition, immunizations, and preventive care (particularly for pregnant women and children) are responsible for 25 of the 30 years gained in life expectancy in the US during the 20th Century (Bunker et al. 1994). Thus, effective improvement of the health status of populations requires the effective application of informatics strategies beyond the clinical care setting.

In this chapter, we first briefly describe public health science, the differences between “population health” and “public health,” and explain key differences between clinical and public health practice that influence the needs and requirements for informatics-related interventions. Next, we define “**population and public health**” **informatics** as the systematic application of informatics methods and tools to support public health goals and outcomes, regardless of the setting. Finally, we describe specific example systems and applications that illustrate key challenges and opportunities.

## 18.2 What Is Public Health?

**Public health** is a complex discipline focused on promoting and protecting the health of people and communities where they live, learn, work and play (**American Public Health Association (APHA) 2018<sup>1</sup>**). Public health practice is guided by social justice and the needs of all persons within a population, not simply those accessing healthcare delivery systems. While medical care focuses on the detection, treatment, and management of injury and disease, public health practice and research involves a broad array of disciplines and diverse activities with an overarching emphasis on primary prevention, intervening at the earliest possible place in the

1 American Public Health Association, What is public health; Retrieval 10/12/2018: ► <https://www.apha.org/what-is-public-health>

causal chain leading to disease or disability. Prevention activities span improved access to safe food, clean water, air, and sanitation, vaccines, safe roadways and workplaces, and so forth – all in an effort to improve the health of communities, however defined. Public health achievements have been associated with major gains in life expectancy (CDC 1999<sup>2</sup>), and investment in disease prevention can yield significant cost savings and a healthier and less costly life (Trust for America's Health 2020<sup>3</sup>). Despite these achievements, global public health is challenged by the increasing mobility of populations and ongoing threats to security and safe environments which can result in regional outbreaks becoming pandemics (e.g. COVID-19).

It is useful to conceptualize public health in terms of three core functions: assessment, policy development, and assurance (Institute of Medicine (IOM) 1988). *Assessment* involves monitoring and tracking the health status of populations including identifying and controlling disease outbreaks. By relating health status to a variety of demographic, geographic, environmental, and other factors, it is possible to develop and test hypotheses about the etiology, transmission, and risk factors that contribute to health problems in a population and to develop and implement control strategies that contribute to improvements in population health.

*Policy development*, the second core function of public health, uses the results of assessment activities and etiologic research in concert with local resources, values and culture (as reflected via citizen input) to recommend public policies and interventions that improve health status. For example, the

relationship between fatalities in automobile crashes and ejection of passengers from vehicles led to recommendations, and eventually laws, mandating seat belt use which contributed to a subsequent decrease in morbidity and mortality from automobile crashes.

Advances in information technology and widespread use of the internet, including social media sites and on-line discussion forums, as well as use of mobile apps, provide new opportunities for public health policy development. Given that public health is primarily a governmental activity, it depends upon and is informed by the consent of those governed. Policy development in public health is (or should be) based on science, but it is also guided by the values, beliefs, and opinions of each society it serves. Public health officials who wish to promote certain healthy behaviors, or to promulgate regulations (e.g., concerning fluoridated water, e-cigarettes, bicycle helmets, social distancing and so forth) would do well to tap into the online marketplace of ideas—both to understand the opinions and beliefs of their citizenry, and to inform and influence citizens to engage in those healthy behaviors.

*Assurance*, the third core function of public health, refers to the duty of public health agencies to assure their constituents that services necessary to achieve agreed upon goals are available. The services in question (including medical care) may be provided directly by the public health agency or by encouraging or requiring (through regulation) other public or private entities to deliver the services. For example, in some communities, local public health agencies provide direct clinical care to underserved or at-risk populations. The health department in Multnomah County, Oregon follows this model and offers health care services in multiple primary care clinics, schools, community sites and in people's homes. In other communities (e.g., Tacoma-Pierce County, Washington), local public health agencies have sought to minimize or eliminate direct clinical care services, instead working with and relying on community partners to provide such care. While there is great variation across jurisdictions, the fundamental function is unchanged: to assure that all

- 2 Centers for Disease Prevention and Control. (1999). Ten great public health achievements – United States, 1900–1999. *MMWR*; 48(12);241–243. Retrieval 10/02/2018: <https://www.cdc.gov/mmwr/preview/mmwrhtml/00056796.htm>
- 3 Trust for America's Health. (2020). Prevention for a healthier America: investments in disease prevention yield significant savings, stronger communities. Retrieval 1/25/2020: <http://www.tfah.org/wp-content/uploads/2020/04/TFAH2020PublicHealthFunding.pdf>

members of the community have adequate access to needed services, especially preventive care services and testing and diagnostic services in the context of an outbreak such as COVID-19.

The assurance function is frequently associated with clinical care, but also refers to assurance of the conditions that allow people to be healthy and free from avoidable threats to health—which include access to clean water, a safe food supply, responsive and effective public safety entities, and so forth.

This “core functions” framework is useful for describing the fundamental, overarching responsibilities of public health. The three core functions are operationalized through a set of ten essential public health services (■ Table 18.1) (Department of Health and Human Services (DHHS) 1994<sup>4</sup>). Although there is great variation in capacity to implement the ten services, they represent types of activities that public health agencies use to achieve their mission to assure conditions in which people can be healthy.

Whether one views public health through the lens of the three core functions or the ten essential services, managing and using information is a fundamental activity for public health effectiveness. For example, assessment, and several of the essential public health services, rely heavily on **public health surveillance**, the ongoing collection, analysis, interpretation, and dissemination of data to guide public health actions. The data may concern health conditions (e.g., breast cancer, communicable diseases, obesity), threats to health (e.g., smoking prevalence, drug overdose), healthcare delivery and quality (e.g., immunization rates or reports of health system quality monitoring), healthcare capacity (e.g., availability of immunization or medications, emergency or intensive care services, or other critical needs for delivering required care for a population), or other events (e.g., births) to guide public health action.

■ **Table 18.1** Ten essential services of public health (DHHS 1994)

1. Monitor the health status of individuals in the community to identify community health problems
2. Diagnose and investigate community health problems and community health hazards
3. Inform, educate, and empower the community with respect to health issues
4. Mobilize community partnerships in identifying and solving community health problems
5. Develop policies and plans that support individual and community efforts to improve health
6. Enforce laws and rules that protect the public health and ensure safety in accordance with those laws and rules
7. Link individuals who have a need for community and personal health services to appropriate community and private providers
8. Ensure a competent workforce for the provision of essential public health services
9. Research new insights and innovate solutions to community health problems
10. Evaluate the effectiveness, accessibility, and quality of personal and population-based health services in a community

*Source.* Department of Health and Human Services. (1994). Essential public health functions. *Public Health in America*. Retrieval 08/12/2018: ► <http://www.health.gov/phfunctions/public.htm>

Public health surveillance data are often used to define priorities for public health actions, either to guide a public health response or policy development. Surveillance data may serve short-term needs (e.g., to respond to an acute infectious disease outbreak or pandemic such as COVID-19) or longer-term needs (e.g., to determine leading causes of premature death, injury, or disability), and are increasingly more available for querying and visualization through state and federal public health web sites (e.g., data.gov). Surveillance data are used by epidemiologists and researchers and can impact public understanding of health threats. For example, data

4 Department of Health and Human Services. (1994). Essential public health functions. *Public Health in America*. Retrieval 08/12/2018: ► <http://www.health.gov/phfunctions/public.htm>

used to manage the COVID-19 pandemic or data used to visualize the increasing prevalence of obesity in the U.S. over time both contributed to the tremendous energy and public focus brought to bear on these problems. Similarly, mortality data has been critical for understanding the evolving drug overdose epidemic in the U.S. (Seth et al. 2018). As is often the case though, no single data system provides all information required to appropriately tailor the public health response, particularly at a local level. For example, in addition to mortality data, more timely and comprehensive nonfatal and fatal overdose data are needed; therefore, other systems (such as **bio-surveillance**, **syndromic surveillance** systems or an unintentional drug overdose reporting system) can be used to identify overdoses and emerging threats in local communities or improve collection of toxicology data to identify specific drugs involved (Seth et al. 2018).

While the core functions of public health described in the IOM framework have not changed for many years, rapid advances in technology and sources of data are changing the practice of public health. For example, there are (a) new data sources and methods to assess and understand the prevalence of disease in communities, the impact of public health response actions (e.g. contact tracing or stay at home orders associated with COVID-19), and the health status and determinants of disease in populations, (b) improved analytical and visualization software (e.g., **geographic information systems (GIS)**), and (c) improved ability to integrate and/or share health data across systems (Overhage et al. 2008). Informatics is therefore a foundational science for public health practice.

### 18.2.1 Public Health Versus Population Health

The phrase “population health” is increasingly used by researchers, practitioners, and policymakers in health care, public health, and other fields (Stoto 2013). For the purpose of conceptualizing population versus public health informatics, a helpful working defini-

tion for population health was proposed by Kharrazi et al. (2017):

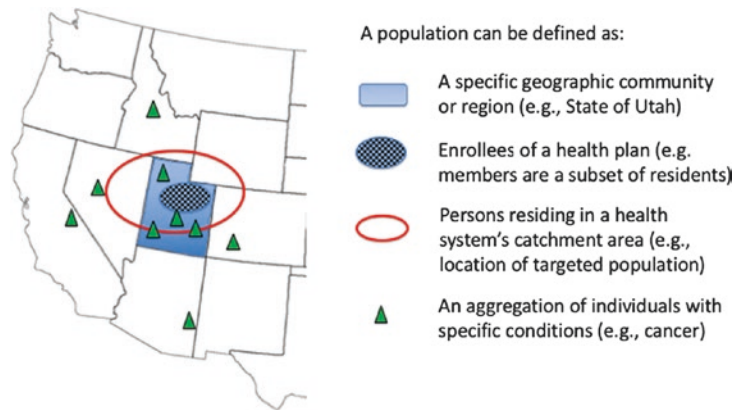

- » *Population health comprises organized activities for assessing and improving the health and well-being of a defined population. Population health is practiced by both private and public organizations. The target “population” can be a specific geographic community or region, or it may represent some other “denominator,” such as enrollees of a health plan, persons residing in a provider’s catchment area, or an aggregation of individuals with special needs. The difference between population health and public health is subtle, and there is not always a full consensus on these definitions. That said, public health services are typically provided by government agencies and include the “core” public health functions of health assessment, assurance, and policy setting. In the United States, most actions of public health agencies represent population health, but a considerable proportion, if not the majority, of population health services are provided by private organizations. (Kharrazi et al. 2017).*

Public health is typically focused on populations defined by a specific geographic community or region (■ Fig. 18.1). It may also leverage healthcare systems to implement strategies that meet public health goals such as the reporting and management of infectious diseases or administration of vaccine.

While “population health” means different things to different groups, it is always based on the underlying assumption that multiple common factors impact the health and well-being of specific populations, and that focused interventions early in the causal chain of disease will prevent morbidity and mortality and may also save resources.

In the context of health care reform, a population perspective has led to increased efforts to incorporate social and other determinants of health into medical care practice. This may include documenting this information in the **electronic health record (EHR)** in order to improve clinical decision making, and to better understand the health status of the community served. This has also led healthcare

**Fig. 18.1** The definition of a “population” varies according to need. (Courtesy of Catherine Staes, PhD, MPH, RN)

organizations to implement innovative strategies to improve health and reduce costs, such as providing housing, air conditioners, and/or transportation.

In the context of public health, a population perspective has always existed. However, now there are new opportunities to leverage data sources not traditionally used by public health (e.g., social media) and to use the information in EHRs to meet public health goals. For example, an EHR-based **clinical decision support system (CDSS)** and quality monitoring can be used to promote and monitor public health goals (e.g., improved cancer screening and immunization coverage, or early detection of health threats such as lead in water or an individual exposed to an infectious disease) among persons accessing clinical care.

### 18.3 Public Health Informatics

Public health informatics was first defined as the “systematic application of information science, computer science, and technology to public health practice, research, and learning” (Friede et al. 1995; Yasnoff et al. 2000). It is distinguished by its focus on populations (versus the individual), its orientation to prevention (rather than diagnosis and treatment), and its governmental context because it nearly always involves government agencies. It is a complex domain that is the focus of another

entire textbook in this series (Magnuson and Dixon 2020).

The **Centers for Disease Control and Prevention (CDC)** has characterized public health informatics as developing and deploying methods for achieving a public health goal faster, better, or at lower cost by leveraging computer science, information science, or technology (Savel and Foldy, 2012). Public health systems are implemented across a wide range of settings (large and small, urban and rural) with variable infrastructure and capabilities, and for a workforce with a wide range of informatics experience and skills and access to technical resources and support. Given this complex context, we define public health informatics as:

» *The systematic application of informatics methods and tools to support public health goals and outcomes, regardless of the setting.*

The differences between public health informatics and other informatics specialty areas parallel the contrast between public health and medical care itself. Public health focuses on the health of the community as opposed to that of the individual patient. In the medical care system, individuals with specific diseases or conditions are the primary concern. In public health, the information and unit of analysis often relates to the community and may, for example, include sharing of information (such as disclosure of the disease status of an individual) to prevent further

spread of illness or isolating individuals to protect others. In addition, information about environmental and other factors (e.g., air and water quality, animal health, etc.) is also part of the public health domain. Finally, the focus on prevention and assessing health status across a population, rather than responding to diagnosis and treatment of individuals, necessitates the use of standards for health information exchange and large-scale analysis of data across multiple health systems.

## 18.4 Examples of Public Health Informatics Challenges and Opportunities

This section provides a high-level overview of the scope and function of information systems that support public health practice to illustrate the value (and challenges) of informatics methods and tools for optimizing public health outcomes. Public health practice and **epidemiology** have always been data-intensive endeavors; however, new opportunities to apply informatics-based strategies have arisen with the advances in computer technologies, increased use of EHRs and social media, and new techniques for mining data, delivering decision support, processing natural language, and system architectures that use standards to support interoperability. When considering how to apply informatics to address a public health need, it is important to understand the current “business” of public health and the history of systems that have successfully achieved their goals.

We first present an overview of the array of heterogeneous systems and applications used in the U.S. across the approximately 3000 local and 56 state and territorial health departments, and at the federal public health level, and describe informatics opportunities and challenges. Second, we focus on a robust, nationwide public health system built on informatics principles: immunization registries. Third, we describe a global public health informatics challenge and illustrate how successful informatics solutions can be applied in

the context of the community/country where they are implemented.

### 18.4.1 Overview of Public Health Information Systems in the U.S.

#### ■ Context

The fundamental science of public health is **epidemiology**, which is “*the study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems*” (Last 2001). As a consequence, public health information systems may collect, use and report data at the level of **an event, a person, or a population**, and may address a broad spectrum of topics along the causal chain of factors that impact health status. Public health efforts focus early in the causal chain to affect outcomes (Stiefel and Nolan 2012). For example, public health information systems may monitor exposures and risk factors, health events (e.g., vaccinations), persons with injuries or infectious or chronic disease, and other topics relevant for (a) understanding public health threats, and (b) designing and evaluating interventions. These information systems must support prevention and control efforts targeted at individuals and populations and, typically, also allow aggregate analysis to describe populations. For example, during the COVID-19 pandemic, public health authorities monitored laboratory tests and reported positivity rates and total tests performed, persons infected and hospitalized, and indicators of healthcare system capacity to respond to medical needs in a community. In contrast, nearly all medical information systems focus exclusively on supporting the processes of care for individuals. For example, EHRs and clinical laboratory systems are optimized so clinicians can quickly identify lab results for a specific individual, whereas public health practitioners want information about the patterns of antibiotic resistance over time and across multiple clinics relevant for the population in their jurisdiction. Public health

information systems should be optimized to collect relevant data, visualize and recognize epidemiology-relevant patterns, and identify emerging threats.

The “business” of public health involves a heterogeneous range of activities performed by a broad range of settings, including private but mostly government-based organizations. In the U.S., public health is organized across different levels of government, with each level having its own unique role. In a very general sense, information at the local level is required to take action in response to individual events (thus requiring personal identifiers) and to implement policies that impact populations, while information at the state level shifts towards monitoring events and supporting public health programs, and finally, information at the federal level focuses on national-level monitoring, policy development, funding of public health activities, and regulatory compliance (thus not requiring personal identifiers). In contrast, most other countries around the world have public health systems that are more centralized, which reduces barriers to information sharing and population-level analytics.

#### ■ Systems at different levels of government in the U.S.

##### *Local (City/County/Tribal) Public Health Practice*

In the U.S., there are approximately 3000 city and county local health departments dedicated to promoting and protecting the health of people and animals in their community, and additional tribal jurisdictions each with their own public health organizations. At the local level, the work of public health often involves direct interaction with individuals or businesses in the community. Local health departments (LHDs) collect data to serve the needs of individuals, e.g., to support client follow up in LHD clinics. It is typical for local health department staff (e.g., a public health nurse, epidemiologist, or environmental health specialist) to investigate and gather identifiable person-specific information. This information is needed to ensure that infected persons are properly treated and that exposed

individuals receive prophylaxis or follow-up, or that control measures are properly implemented particularly in settings where transmission may occur (e.g., in day care, long term care or food service settings). Unlike clinical systems, the systems used by LHD staff must support contact tracing, identification of exposed individuals, and management of isolation, follow-up testing and other control measures. During outbreaks of highly contagious infections such as measles or COVID-19, these systems are critical for supporting LHD activities. In addition, LHDs need to summarize data across their jurisdiction. Each LHD operates under the legal and policy framework of their respective state or territorial health department.

Information systems at the local public health level vary tremendously, depending on the size of the jurisdiction, funding levels, and the activities the local agency is required to perform. For example, the scope of practice for a rural health department with four staff members is very different from the multi-thousand employee New York City Health Department. In view of this variation, it is not surprising that information systems also range from simple spreadsheets to complex electronic record systems. The effective application of informatics principles to functions and data is currently often limited, but the ecosystem is advancing. For example, it is becoming more common for state-based surveillance systems to be web-based and support local information needs as well. For example, the systems to manage persons with sexually transmitted infections, tuberculosis, or COVID-19 may be state-wide systems that allow access for local public health staff to perform case management and investigations.

##### *State Public Health Practice*

In the U.S., there are 56 state and territorial health departments charged to carry out the responsibility of the laws and policies of their respective jurisdictions. Each state and territory has a health officer who usually reports to the governor and is tasked with leading the health agenda. The business of public health is data intensive and the systems currently used have evolved one by one over time based on needs and funding availability.

State health department information systems are often dedicated to a particular disease or condition such as infectious disease, cancer, or injury. In Minnesota, for example, there are at least 21 such information systems that maintain individual level information and exchange information with hospitals, clinics and other health settings in the community (■ Table 18.2). The systems presented in the table are common but not representative of all states. For example, some states have integrated communicable disease surveillance systems, while others continue to operate separate systems for HIV/AIDS or TB surveillance, depending on state laws and funding. In addition, depending on the relationship between the state and its local (city/county/tribal) public health agencies, the systems may be the same, integrated, or separate. Finally, public health agencies have other systems as well (e.g., for **electronic health information exchange (HIE)**), so this list is not comprehensive, but rather illustrates the diversity of systems and the kinds of data that can be made available for national aggregation.

The systems listed in ■ Table 18.2 are categorized as monitoring, workflow management, or case/care management systems, based on their primary function and key features. Monitoring systems typically rely on clinical or laboratory data as their source of information and attempt to aggregate data across health systems. They are often dependent on providers to identify the records that need to be shared and on evolving health data and interoperability standards to efficiently and accurately share the information used to generate a population-level view. The events may differ (e.g., a birth, a ‘case’ of measles or COVID-19, a birth defect, any blood lead level result, a health claim, etc.) but the event detection, information summarization, and reporting processes are more similar than different. In contrast, the workflow management systems are internally-focused on scheduling and collecting information, but may require interactions with external systems to process requests or reports. While such systems are common in many industries, the health and personal data managed in public health impose additional security and privacy

requirements. Finally, the case and care management systems are similar in functionality to outpatient EHRs where persons (either effected by a condition or exposed to a health threat) must receive diagnostic testing, preventive services, treatment, and management to ensure ongoing monitoring and/or treatment to prevent further spread in the community.

Before planning to develop a new public health information system, one should first determine which of these three fundamental system categories is required as a prerequisite to deciding whether modifying an existing system or building/buying an entirely new one can most effectively address the need. Establishing the system type also enables the development team to more effectively seek out and learn from the experience of those who have previously built or managed similar systems.

The systems are often designed with special features for population-level analysis and context, with multiple variables indexed, to support sophisticated statistical and **Geographic Information System (GIS)** support capabilities. The system may be optimized for retrieval from very large (multi-million) record databases, and to quickly cross-tabulate data to study seasonal and secular trends and look for patterns by person, place, and time.

#### *National Public Health Practice*

There are numerous federal-level public health agencies that directly and indirectly support and fund public health activities at the local and state level, provide direct clinical services (e.g., through the Indian Health Service or other federal agencies), provide specific services in response to critical events (e.g., in response to bioterrorism threats or events that occur offshore), perform regulatory oversight, or aggregate information from across the U.S. to provide nationwide information and guidance for policy development. The agencies supporting the public health mission range from the CDC, Food and Drug Administration (FDA), Environmental Protection Agency (EPA), Department of Agriculture, Consumer Product Safety Commission, and Occupational Safety and Health Administration, among others. These

<sup>b</sup>Data collection occurs using a pre-planned sampling strategy

agencies may or may not have a regulatory role, but they illustrate the diversity and complexity of public health at the federal level. They all require some level of cross-state aggregation of information and typically do not gather person-specific data.

In the U.S., public health data is processed via distributed information systems with minimal aggregation at the federal level. In fact, it is only reportable conditions such as infectious diseases, births, and deaths that are uniformly and relatively completely reported on a national basis by the CDC. The U.S. lacks a unifying public health information infrastructure. Thus, the U.S. relies on state and local health departments to develop and use independent information systems to support their public health needs. This presents significant challenges, as described in the next section. In contrast, France, Great Britain, Denmark, Norway and Sweden have comprehensive systems in selected areas, such as occupational injuries, infectious diseases, and cancer. No country, however, has complete reporting for every problem, but many are often able to deliver timely answers to important public health questions by having information on the entire population.

**Informatics Challenges and Opportunities**

*U.S. Public Health Information Infrastructure*

The inadequate national infrastructure to detect and respond to public health threats and support the management of local, state and national prevention and control programs are amplified by the COVID-19 pandemic with its devastating morbidity and financial impact. The current infrastructure in the U.S. has a patchwork of diverse information systems due, in part, to siloed and short-term funding and the U.S. Constitution which is silent on the responsibility for protecting the public’s health, leaving state law to govern public health actions. Federal leadership can provide overarching structure and resources, consolidate information, and present the rationale for a unified approach. However, each state functions independently to deal with the multiplicity of response, management and recovery decisions presented by health threats.

The grand challenge for public health is to create and maintain a unified public health information infrastructure based on informatics principles that supports multi-jurisdictional (local, state, federal) and cross-jurisdictional needs, and seamlessly interacts

with other relevant information systems such as those containing clinical, laboratory or environmental data (see ► Chap. 15).

High level informatics characteristics and considerations for such a public health information infrastructure include the ability to:

- Support both routine and emergent public health functions using the same infrastructure, avoiding the development of systems that compete for resources in the context of an outbreak.
- Rapidly scale existing surveillance systems to make local, statewide, and national data actionable in a timely manner to meet demands at each level in a crisis.
- Provide data and information in sufficient granularity to meet the needs of local, state and national public health needs.
- Rapidly add new information system capability (e.g., contact tracing for COVID-19 control) in the context of an outbreak.
- Routinely onboard, validate, and use new electronic data sources
- Ensure high quality, timely, complete and accurate data.
- Incubate innovations in technology and foster workforce capacity
- Operate with leadership and governance that is independent from jurisdictional boundaries and with authority to define requirements and engage public and private partners.
- Educate leaders and the public regarding the purpose of the infrastructure and the essential role of science to inform public policy.

#### *Emerging Innovations and Opportunities*

Advances in informatics methods and tools, CDSS and health interoperability standards, and the increasing availability of clinical and other novel sources of data (e.g., individual genomic sequences, patient-generated health data from wearable devices), are all impacting the way business is done at public health agencies, leading to new opportunities. Public health data collection systems are a potential gold mine for applying novel analytic or visualization tools, and advances in health data standards are improving opportunities to exchange data and knowledge,

allowing for 2-way communication between public health and clinical systems. Closing the information loop with providers by enabling data aggregated by public health to be used for clinical decision making is a long-time goal that is becoming more achievable over time.

The development of sophisticated knowledge management and decision support methods represents a growing opportunity to more effectively use public health resources and EHR data. For example, there are an increasing number of public health guidelines that, if structured and encoded as standardized digital algorithms, can be widely distributed to provide CDS at the point of care through EHRs (e.g., laboratory testing criteria for coronavirus). Similarly, there are advances in harmonizing and standardizing case definitions, reporting logic, and patient summaries that are relevant for identifying conditions of interest to be reported from an EHR to a public health agency (i.e., to support electronic case reporting or death certificate records reporting). These knowledge resources are a necessary component for automating event detection and the generation of electronic case reports but are not sufficient. Ongoing efforts are focused on improving data and exchange standards, testing and evaluating various implementation strategies, and increasing collaboration between the multiple stakeholders involved (e.g., the vendor, clinical, and public health communities). Eventually, successful implementation requires 2-way communication with providers, which is particularly relevant for case reporting where it is important for providers to be promptly alerted about unusual disease or risk factors in their local area, such as disease clusters, environmental hazards, and antibiotic resistance patterns.

### **18.4.2 Immunization Information Systems: A Public Health Informatics Exemplar**

**Immunization Information Systems (IIS)**, also known as immunization registries, are confidential, computerized, population-based systems that collect and consolidate vaccination

data from vaccine providers and offer tools for designing and sustaining effective immunization strategies at the provider and program levels (CDC 2013). In the U.S., an IIS is operating in almost every state and can share data with other IIS using national standards. IIS are a critical resource for rapidly identifying and reporting gaps in immunization coverage, such as the precipitous decline in child vaccinations observed as the COVID-19 pandemic emerged in spring 2020 and well-child visits transitioned to telemedicine video conferences. Administration of immunizations require an in-person visit. Using IIS data from Michigan, public health authorities were able to report that “vaccination coverage declined in all milestone age cohorts, except for birth-dose hepatitis B coverage, which is typically administered in the hospital setting. Among children aged 5 months, up-to-date status for all recommended vaccines declined from approximately two thirds of children during 2016–2019 (66.6%, 67.4%, 67.3%, 67.9%, respectively) to fewer than half (49.7%) in May 2020” (Bramer et al. 2020).

The success of IIS in the U.S. is a compelling story that illustrates the principles of public health informatics and describes the multi-decade efforts that were needed to implement large-scale population-level IIS in each state and link them into a reliable national network. The story highlights how informatics capabilities in leadership, collaboration, and collective problem solving have been critical to overall success. In addition to their orientation to prevention, IIS can function properly only through continuing interaction with the health care system; in fact, they were designed to optimize connections for use in the clinical setting. Although IIS are among the largest and most complex public health information systems, the successful implementations and extensive interoperability in 49 states show conclusively that it has been possible over time to overcome the challenging informatics problems they present.

The major functions of IIS include (a) the ability to accept immunization records electronically using a variety of file formats

and messaging standards, with online secure access to patient immunization records 24/7, (b) providing vaccine forecasting/decision support based on a patient’s consolidated and **de-duplicated** immunization history, (c) supporting vaccine inventory management and vaccine ordering, producing official immunization records for school and other institutional enrollment, (d) generating immunization coverage reports for an individual provider, clinical practice or jurisdiction, and (e) supporting the national Vaccine Adverse Event Reporting System (VAERS).

#### ■ History, Context and Success of IIS

Childhood immunizations are among the most successful public health interventions, resulting in the near elimination of nine vaccine preventable diseases that historically extracted a major human toll in terms of both morbidity and mortality (IOM 2000). The need for IIS stems from the challenge of assuring complete immunization protection for the approximately 10,388 children born each day in the U.S. in the context of three complicating factors: the scattering of immunization records among multiple providers given that a complete history is essential to providing an accurate forecast of vaccines needed at a visit; new vaccines, vaccine combinations, and antigen formulations regularly made available leading to a schedule that is increasingly complex as the number of vaccines has increased to over 25 doses recommended by age 6; and the conundrum that the very success of mass immunization has reduced the incidence of disease, lulling parents and providers into a sense of complacency where potential vaccine side effects often get more attention than the diseases.

The IIS history from the 1990s is remarkable for a number of key success factors including the committed leadership and shared vision. It is a story of a long slow discovery of challenges and the successful collaboration of many stakeholders to overcome those challenges over several decades. Understanding the lessons learned is foundational to successful implementation of similar large-scale public health information systems in the future.

During 1989–91, a large-scale measles epidemic occurred in the U.S. that highlighted the dangers of inadequate vaccination coverage among preschool aged children and resulted in approximately 165 deaths and 60,000 cases of disease. In response, a scientific community was established in the early 1990s to focus on testing, building and sharing knowledge to advance the impact of IIS. The complex and challenging issues confronted included policy, organizational concerns, funding, and a rapidly changing technical landscape. The collaborative nature of the scientific learning community led to open sharing of successes and failures which led to consistent IIS advancement.

Leading the way towards IIS, the Robert Wood Johnson Foundation (RWJF) was a key funder of the pioneering All Kids Count (AKC) program established in the 1990s. Under this program, an IIS learning community was created and led by the Taskforce for Global Health based in Atlanta, Georgia. The AKC program provided critical national leadership early in the IIS movement by distributing and managing competitive grants to over a dozen cities, counties and states that funded IIS implementations. The AKC, CDC and others were also key disseminators of the rapidly growing body of IIS knowledge, including the sponsorship of multiple meetings of the IIS learning community. As private funding ended, the **American Immunization Registry Association (AIRA)** was founded and became a key national focal point for the IIS community for coordination, cooperation, collaboration and policy development and engagement with the stakeholders, vendors and others in the private sector and expanded the community of interest nationwide. These efforts were funded by CDC as well as states and local jurisdictions.

An example of successful collaboration came from the need for timely exchange of a high volume of immunization information accurately and consistently with health providers. This led to the first public health HL7 version 2 messaging standards and guides for immunization information (see ► Chap. 7), beginning in 1995.

As knowledge was gained from early implementation successes and failures, the

**Table 18.3** Essential IIS Infrastructure Functional Standards v4.0 2017 (CDC 2018)

1.0	The IIS contains complete and timely demographic and immunization data for children, adolescents, and adults residing or immunized within its jurisdiction.
2.0	The IIS identifies, prevents, and resolves duplicated and fragmented patient records using an automated process.
3.0	The IIS identifies, prevents, and resolves duplicate vaccination events using an automated process.
4.0	The IIS implements written and approved confidentiality policies that protect the privacy of individuals whose data are contained in the system.
5.0	The IIS implements comprehensive account management policies consistent with industry security standards.
6.0	The IIS is physically and digitally secured in accordance with industry standards for protected health information, security, encryption, uptime, and disaster recovery.
7.0	The IIS supports IIS users who access and use the IIS functions and submit or access IIS data.
8.0	The IIS exchanges data with health information systems in accordance with current interoperability standards endorsed by CDC for message content, format, and transport.

*Source.* Centers for Disease Control and Prevention. (2018). IIS functional standards, v4.0 Atlanta, GA. Retrieval 08/31/2018: ► <https://www.cdc.gov/vaccines/programs/iis/functional-standards/func-stds-v4-0.html>

IIS community also developed Essential Infrastructure Functional Standards, codifying years of experience in refining system requirements (► Table 18.3), (CDC 2018<sup>5</sup>). Version 4.0 of the standards identifies eight critical functions needed for IIS implementation that are supported by 44 detailed standard requirements, which has led to greater IIS functional uniformity nationwide.

5 Centers for Disease Control and Prevention. (2018). IIS functional standards, v4.0 Atlanta, GA. Retrieval 08/31/2018: ► <https://www.cdc.gov/vaccines/programs/iis/functional-standards/func-stds-v4-0.html>

■ **Key Informatics Issues in Immunization Information Systems**

The implementation, upgrading and management of IIS present challenging informatics issues in at least six areas: (1) Stakeholder collaboration and interdisciplinary communications; (2) Legislative and policy issues including privacy; (3) Funding, sustainability and governance; (4) Data quality and monitoring; (5) System design and interoperability; and (6) Limited prior experience with similar types of systems. While the specific manifestations of these issues are unique to IIS, these six areas represent the typical domains that must be addressed and overcome in most public health informatics projects. Over nearly three decades, many factors have contributed to the success of an individual IIS and also to the network of state IISs operating as a national system. ■ Table 18.4 shows key informatics factors that are important contributors to IIS success.

■ **Stakeholder Collaboration and Interdisciplinary Communications**

The organizational and collaborative issues involved in operating and upgrading an IIS are challenging because of the large number and wide variety of users, most of whom are outside the IIS organization. Each of the user groups has distinct needs, including clinicians (to ensure age-appropriate vaccination), clinic managers (for vaccine management and ordering), schools (to ensure student adherence to state school immunization laws), health plans (to measure immunization coverage among beneficiaries and perhaps by provider), local health departments (to assess immunization coverage in their jurisdiction and identify children who have fallen behind and require outreach), and CDC (for accountability for federally-funded vaccines and IIS funding). Ensuring these diverse needs are understood, balanced and effectively met can be daunting on the typically slim governmental budgets on which IIS have been developed and must operate.

Interdisciplinary communication is a key challenge in any biomedical informatics project—it is certainly not specific to public health informatics. To be useful, a public

■ **Table 18.4** Key Informatics factors contributing to the success of IIS Nationwide

Establish a shared vision and goals and ensure effective leadership that includes:
Understanding the complexity of establishing a population-based information system and that it operates within a multidimensional health information ecosystem.
Planning for change and reassess how to accomplish goals.
Developing an effective sustainability/business plan from the beginning.
Developing a robust communications plan and comprehensive communications strategy.
Focusing on immunization information as the primary asset; recognize that technology is a means to that end.
Implement with workforce, stakeholders, and end users in mind and include:
Supporting a learning community to create and share knowledge and address common problems collaboratively.
Involving stakeholders, particularly end users, from the beginning.
Designating key roles for informaticians.
Training all staff in informatics principles.
Create well-designed and effectively used information systems and include:
Defining the system requirements to support users' needs.
Developing and implementing according to standards (and create standards if none are available).
Using the registry information as early in the implementation process as possible (even if it's not perfect).
Establishing and using metrics to evaluate progress and quantify impact.

health information system must accurately represent and enable the complex concepts and processes that underlie the specific business functions required. Information systems represent a highly abstract and complex set of data, processes, and interactions. This complexity needs to be discussed, specified, and

understood in detail by a variety of personnel with little or no expertise in the terminology and concepts of information technology. Therefore, successful IIS implementation and enhancements require clear communication among public health specialists, immunization specialists, providers, IT specialists, and related disciplines, an effort complicated by gaps in a shared vocabulary and differences in the usage of common terms from the various domains.

To deal with the communications challenges, particularly between IT and public health specialists, it is essential to identify and engage a public health informatician who has familiarity with both information technology and public health, can perform system analyses, and understands business processes. The primary role of this informatician is to be able to effectively translate concepts between domains that use vocabularies that are unfamiliar to others (e.g., between IT specialists and clinicians). Also, the informatician should have a deep understanding of the information processing context of both the current and proposed systems. It is also important for individuals from all the user communities related to the project to have representation in the decision-making processes. A clear understanding and set of working definitions for common terms and terminology is essential for effective communication.

#### ■ **Legislative and Policy Issues Including Privacy**

Legislative and policy issues are important aspects of the informatics challenges of IIS. Federal laws including the **Health Insurance Portability and Accountability Act (HIPAA)** are important but State laws typically govern who has access to IIS data for what purposes, so system design must accommodate multiple levels of role-based access to functionality. A major issue is whether patient/parent consent is required before submission of immunization data to IIS, and, if so, how that consent is communicated and managed in the system. IIS must also be able to record that the patient has declined to receive vaccines for religious or other reasons as defined in state law and use that informa-

tion to suppress vaccine forecasting/decision support messages and reminder-recall notices. Some jurisdictions have enacted regulations requiring providers to submit immunization data to IIS. Such a regulatory approach to ensuring information completeness is less burdensome as automated electronic file submissions have largely replaced manual data entry. Negotiating and implementing policies for interstate access and data exchange with providers and other IIS is another example of a key issue that can be problematic.

#### ■ **Funding, Sustainability, and Governance**

Funding and sustainability are continuing challenges for all IIS. Naturally, an important tool for securing funding is development of a persuasive business case that shows the anticipated costs, benefits and value for the IIS investment. A substantial body of evidence now shows benefits, effectiveness and costs of IIS (Guide to Community Preventive Services 2015). However, many of the currently operational IIS had to develop and effectively justify their value before such information was readily available.

Specific benefits associated with IIS include preventing duplicate immunizations, eliminating the necessity to review vaccination records for school and day care admission, efficiencies in provider offices from the immediate availability of complete immunization history information, patient-specific vaccine schedule recommendations, and managing records during disasters (Boom et al. 2007). The careful review of the evidence on effectiveness, costs and benefits of specific immunization IIS functions may also be helpful in prioritizing system enhancement requirements.

Governance issues are also critical to success of implementation and enhancements to IIS. All the key stakeholders need to be represented in the ongoing, open and transparent decision-making processes, guided by a mutually acceptable governance mechanism. IIS require established rules for identifying needed enhancements, prioritizing them across the often-disparate needs of diverse user groups, and effectively managing and communicating the changes as they are developed and implemented. Governance can also

be used for establishing metrics for progress, such as number of provider sites enrolled and trained, setting other priorities, and for ongoing review of confidentiality policies.

### ■ Data Quality and Monitoring

Ensuring high quality data (including completeness, accuracy and timeliness) is vital to the success of an IIS. Provider use of an IIS increases with the confidence that they can trust that an IIS query will find the patient needing an immunization, the immunization history is complete and accurately consolidated, and the forecast of the immunizations that are due is reliable. High quality data is essential to support these core functionalities and thereby provide benefit to all the stakeholders. A variety of methods are used to maintain high quality data, including quality checks at the time of data acquisition and maintaining robust data feedback programs so all stakeholders can contribute to data quality and integrity.

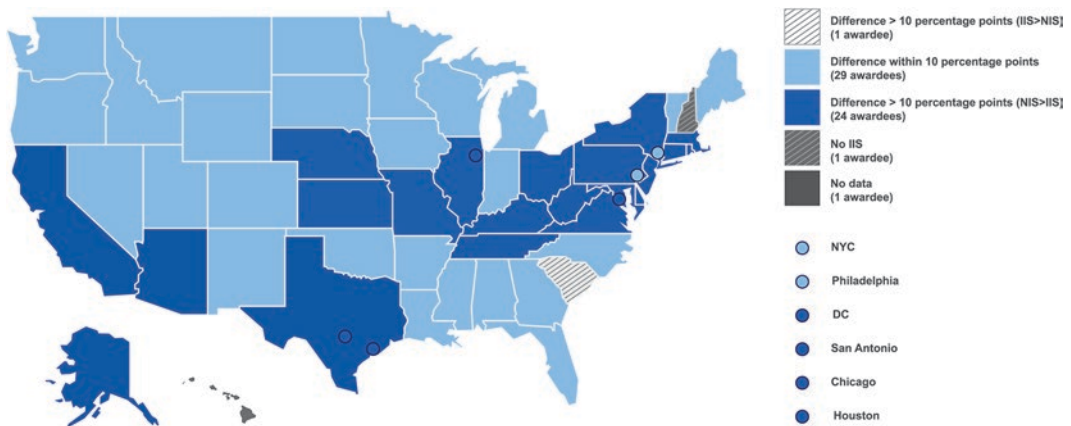

Monitoring levels of vaccine use also relies on high quality data. Examples include calculations of immunization rates across jurisdictions such as Medicaid, HEDIS, and supporting the National Immunization Survey (NIS). Quality data is also needed for outbreak support to provide rapid information on vulnerable populations and ongoing assessment of the response. In addition, local clinical community and small area analysis can help identify groups in need of commu-

nity outreach for assistance. Special studies on intervention trends in immunizations and effectiveness studies are other key uses of the data that require high quality data.

Examples of challenges for data quality include unmerged records on individuals, or wrongly combined records; unreported mobility where address, and other location information is not recorded or wrongly recorded; errors in data arriving from the providers or the birth records; duplicate records and inadequately de-duplicated records on individuals and on vaccines reported from several sources; and partial reporting of vaccines administered. Each of these data quality problems needs strong mitigation and monitoring strategies.

High data quality is the cornerstone of successfully reaching immunization program-related goals. IIS Functional Standards related to data quality are woven into the CDC AIRA IIS Essential Infrastructure Functional Standards (■ Table 18.3) and are reflected in multiple goals in that document (CDC 2018). This underscores the importance of planning for and ensuring data quality in all aspects of access and use of IIS data and functionality.

CDC and state IIS Directors have established a detailed monitoring and measurement system that uses about 100 measures for tracking progress to annually assess adherence to desired capabilities and standards. For example, ► Fig. 18.2 shows the percentage point differences between NIS and IIS for

■ Fig. 18.2 Percentage point differences between National Immunization Survey (NIS) and IIS for combined 7-vaccine series\* completion — IIS Annual Report, United States, 2017\* (Source: CDC 2018)

combined 7-vaccine series completion. This type of monitoring and analysis demonstrates that more universal use of IIS information has the potential to replace existing, expensive surveys and enable more timely data to support users and community needs. In addition, AIRA has facilitated the development of numerous best practice guidelines to help ensure ongoing quality improvement, efficiency and increased standardization.

#### ■ System Design and Information Architecture

System design and information architecture are important factors in the success of IIS. Difficult design issues include data acquisition methods, database organization, identification and matching of individuals, generating immunization recommendations, access to data, protocols for electronic exchange and interoperability, and reports related to clinical practice and community rates of immunization. Acquiring immunization data has been a challenging system design issue and an area of considerable IIS change as EHR use has become more common, new adolescent and adult immunizations are added to IIS, and information is submitted from a broader range of settings like pharmacies. Within the context of busy pediatric and primary care practices (where the majority of immunizations are given), the data acquisition strategy must by necessity be extremely efficient and result in minimal additional work for participating providers. Use of EHR systems can effectively support this strategy. Although most physician practices are using EHRs, only a minority have enabled bidirectional exchange with IIS.

Database design must support the desired IIS functions and allow efficient implementation of these capabilities. The design must consider operational needs for data access for an individual record and calculating individual forecasts of needed immunizations, and the requirements for population-based immunization assessment, management of vaccine inventory, and generating recall and reminder notices. One example of a particularly important database design decision for IIS is whether to represent immuniza-

tion information by vaccine or by antigen. Vaccine-based representations map each available preparation, including those with multiple antigens, into its own specific data element. Antigen-based representations translate multi-component vaccines into their individual antigens prior to storage. In some cases, it may be desirable to represent the immunization information both ways. Specific consideration of required response times for specific queries must also be factored into these key design decisions.

Identification and matching of individuals within IIS is another critical issue. Because it is very common for an individual to receive immunizations from multiple providers, any system must be able to match information from multiple sources to assemble a complete unduplicated record of immunizations and retain the sources of that information. In the absence of a national unique patient identifier, most IIS assign an arbitrary number to each individual and use a matching algorithm, which utilizes multiple items of demographic information to assess the probability that two records are really from the same person and can detect duplicate reports of an immunization. Development of such algorithms and optimization of their parameters has been the subject of extensive investigation in the context of IIS, particularly with respect to deduplication (PHII 2006<sup>6</sup>).

Another critical design issue is generating vaccine recommendations from an individual's prior immunization history, based on guidance from the CDC's Advisory Committee on Immunization Practices (ACIP). As more vaccines have become available, both individually and in various combinations, the immunization schedule has become increasingly complex, especially if any delays occur in receiving doses, an individual has a contraindication, or local issues require special consideration. The language used in the written guidelines can be

6 Public Health Informatics Institute. (2006). The Unique Records Portfolio. Decatur, GA: Public Health Informatics Institute. Retrieval 08/29/18: [▶ https://phii.org/resources/view/4380/unique-records-portfolio-guide-resolving-duplicate-records-health-information](https://phii.org/resources/view/4380/unique-records-portfolio-guide-resolving-duplicate-records-health-information)

ambiguous with respect to definitions, e.g., for ages and intervals, making implementation of CDSS problematic. Considering that the recommendations are updated relatively frequently, maintaining software that produces accurate immunization recommendations is a continuing challenge. Accordingly, the implementation, testing, and maintenance of decision support systems to produce vaccine recommendations has also been the subject of extensive study (Yasnoff 2014).

Finally, easy access to the information in IIS is essential. While independent web-based interfaces are common, the ideal is to provide a seamless query launched within the context of the provider's EHR workflow that returns IIS information and forecast to be incorporated into the EHR. Similarly, the design should support efficient access to summary reports on immunization rates for a clinic or community, reports on children who are behind schedule and support delivery of electronic reminder or recall notices to support prevention. Consumers' direct access to their own immunization record is desirable; however, there are design considerations regarding security, allowable data views and editing rights, so this is currently the subject of considerable experimentation and testing.

### 18.4.3 Global Health Perspective and Opportunities

---

Global health has been defined as “an area for study, research, and practice that places a priority on improving health and achieving equity in health for all people worldwide.” (Koplan et al. 2016) Improving health globally requires accurate and timely data that can be effectively applied to education, research, innovation and service. Thus, global health work provides a vision of a future of informatics closely integrated with public health practice.

#### ■ Current state

Today, we live in a globally interconnected world where no person is more than 36 hours

away from any other person (Friedman 2007). Almost every corner of the world has access to the Internet and in most countries, even the poorest, many segments of those societies have cellular and even smart phone access to the Internet. This rapid diffusion of these information technologies has sparked increased informatics activities to promote health progress.

For example, the U.S. Global AIDS Initiative, which became known as the President's Emergency Plan for AIDS Relief, or **PEPFAR**, which began in 2003, has relied heavily on informatics infrastructure. Today, PEPFAR is working in more than 120 countries and has resulted in massive investment in health system infrastructure: laboratories, primary care services, medical supplies, drug supply chains, and information systems. These same health systems have benefitted further from funding from the Bill and Melinda Gates Foundation (BMGF), which has sparked marked progress across vaccine preventable diseases, neglected tropical diseases and many other conditions that impact the poorest throughout the world. These social entrepreneurs also bring strong accountability to global health – they expect their funds to produce a specific health outcome. Tracking measured outcomes requires informatics.

Recognizing these trends, in 2013 the U.S. government funded the global health security agenda (GSHA), which promotes a range of health development activities across the lower income tier of countries. The agenda is designed to improve disease surveillance, laboratory and diagnostic capacity, workforce capacity, and basic health services. The GSHA has set the stage for widespread recognition that informatics is an essential tool towards health progress in these countries.

It is clear from these efforts that informatics will drive health improvement in low and middle income countries. Consequently, most countries now acknowledge, as does the World Health Organization, that their health efforts must be data informed and data driven.

### ■ Example of Informatics Innovation Leading to Health Impact: Global Trachoma Mapping

Trachoma is a bacterial disease that spreads through contact with the eyes or nose of an infected individual, shared towels or clothing, and vectors such as flies. Repeated infections cause eyelashes to turn inward, scratching and scarring the cornea, leading to blindness. About 1.9 million people in 42 countries are currently blind or visually impaired as a result. Treating the infection along with access to clean water and sanitation leads to elimination throughout entire populations.

In 2009, the International Trachoma Initiative (ITI), a program of the Task Force for Global Health (TFGH) and their partners recognized the need for better information about the prevalence of trachoma to inform decisions about where to implement specific intervention strategies such as eye surgery, antibiotic treatment, facial hygiene, and environmental sanitation (ITI 2012). In 2012, in partnership with ITI, the UK's Department for International Affairs announced the three-year Global Trachoma Mapping Project (GTMP) to complete *The Global Atlas of Trachoma* to map global trachoma prevalence.<sup>7</sup> Field teams used mobile devices to record findings of trachoma infection. Data management software converted the household-level findings to prevalence maps at the village and district levels. An electronic data capture and management tool called LINKS was adapted for GTMP. The interface was designed to be basic enough for field staff to understand and secure enough to prevent accidental data loss or breaches.

By 2016, more than 2.6 million people had been surveyed for trachoma to create prevalence maps of 29 countries, the largest infectious disease map ever created. The availability of high-quality data on trachoma

had widespread impact. The *Atlas* helped inform the scale-up of the global trachoma elimination program. With the availability of prevalence data, ITI was able to make better decisions about where to allocate antibiotic supplies and coordinate production. That same year, ITI reached scale when Pfizer donated 120 million antibiotic treatments to 32 countries, bringing the cumulative program total to 627 million treatments (Taskforce for Global Health 2018).

### ■ Emerging Opportunities and Directions

The African Union formed Africa CDC in 2017. Rather than being disease focused, it is built around the key disciplines that protect and promote the health of populations, i.e., informatics, surveillance, drug and medical supply chain, diagnostics/laboratory, and policy. As a result, a key goal is to educate a new cadre of informaticians throughout the African continent to assure that timely, accurate, and relevant data inform action across the spectrum of health needs.

Ubiquitous and reliable high-speed bandwidth also now readily enables worldwide collaborations. The notion of global to local shared learning is now a reality, with communities of practice forming that involve members from all continents. Learning is now multidirectional.

In the global health community, the lack of legacy institutions combined with very limited resources has created strong incentives for innovation. When combined with the insistence on specific, real-time quantitative results and outcomes from funding sources, the extensive use of informatics has been an inevitable consequence to ensure efficient and effective progress in health improvement.

## 18.5 Public and Population Health Informatics Conclusion

Public health informatics is the systematic application of informatics methods and tools to support public health goals and outcomes, regardless of the setting. Effective public health information systems and communi-

7 Taskforce for Global Health. (2018). The global trachoma mapping project: determining prevalence to help eliminate trachoma by 2020. Retrieval 10/20/18: <https://www.taskforce.org/case-study/global-trachoma-mapping-project-determining-prevalence-help-eliminate-trachoma-2020>

cation between clinical and other systems can help to assure prevention actions, timely monitoring of disease patterns, and rapid responses to epidemics, thereby saving lives and money.

Public health information and the development of **health information infrastructure** (HII) (see ► Chap. 15) are closely related. Public health informatics supports the population assessment, assurance and policy development roles of public health. In contrast, HIIs focus on medical care to individuals while also connecting providers and patients within a population. Ideally, these two areas work together supporting both community health assessment and individual care. In the past, public health and health care have not traditionally interacted as closely as they should. Both domains focus on the health of communities—public health does this directly, while the medical care system does it one patient at a time. However, it is now clear that medical care must also focus on the community to integrate the effective delivery of services across all care settings for all individuals (IOM 2011; Sittig and Singh 2020). An effective HII could allow many public health information needs currently met through independently operated and maintained systems to be more efficiently addressed via periodic HII queries (e.g., to assess relationships between various diseases, conditions, treatments, and possible risk factors) or through automatic real-time reporting of relevant information from the HII to public health (e.g., to support surveillance and control of COVID-19).

Successful public health and population health informatics requires an informatics-savvy organization that has a clear vision, strategy, and governance for information management and use; a workforce skilled in using information and information technologies; and well-designed and effectively used information systems (Baker et al. 2016). The information imperative is urgently driven by the increasing digitization of data coming into health departments from an increasing number of sources, the need for timely infor-

mation to inform increasingly complex public health decisions, and the growing costs of operating aging public health information systems (Brand et al. 2018a). Information innovation to address growing needs requires an agency-wide informatics-savvy organizational approach (LaVenture et al. 2014c, 2014d; 2017c, 2017d) and an appreciation that there are key stages of innovation to ensure the successful integration of research in the public health practice space (Xu et al. 2011).

Public health systems frequently involve non-health organizations such as law enforcement and parks and recreation departments. Thus, public health informaticians must adopt methodologies that bridge professional and organizational divides, such as the Public Health Informatics Institute's Collaborative Requirements Methodology (PHII 2011).

Despite the focus of many current public health informatics activities on population-based extensions of the medical care system (leading to the orientation of this chapter), applications beyond this scope are possible, desirable, and many innovative strategies and applications are under development or in use. Indeed, the phenomenal contributions to health made by the hygienic movement of the nineteenth and early twentieth centuries suggest the power of large-scale environmental, legislative, and social changes to promote human health (Rosen 1993). The effective application of informatics to populations through public health is a key challenge of the twenty-first century. It is a challenge we must accept, understand, and overcome if we want to create an efficient and effective health care system as well as truly healthy communities for all.

### ? Questions for Discussion

1. How might the trend of widespread adoption of electronic health records and interest in population health affect public health informatics?
2. Compare and contrast the types of data needed and functions required in an information system for clinical versus public health information systems. Explain it from non-technical and technical perspectives.
3. How can the successful model of immunization registries be used in other domains of public health (be specific about those domains)? How might it fail in others? Why?
4. A significant and increasing percentage of the U.S. GDP is spent on medical care. How could population and public health informatics help to use those monies more efficiently? Or lower the figure absolutely?
5. If public health informatics (PHI) involves the application of information technology in any manner that improves or promotes human health, does this necessarily involve a human “user” that interacts with the PHI application? For example, could the information technology underlying anti-lock braking systems be considered a public health informatics application? Provide other examples.
6. How might cloud computing (shared configurable computing resources including networks, servers, storage, applications, and services), and mobile technology transform public health informatics?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What is mobile health (mHealth), and how has it evolved over time?
- What are the current and potential values and benefits of mHealth for (a) patients and caregivers, (b) the general public, (c) clinicians, and (d) researchers?
- What are the key features of mHealth in supporting personal health management?
- What ethical considerations and issues do mHealth technologies raise regarding health disparities?

## 19.1 Introduction

The field of **mobile health (mHealth)** focuses on the uses of mobile technologies, such as mobile phones and **wearables**, to support both the delivery of healthcare services as well as individuals' efforts to manage their health in everyday lives. mHealth applications are highly varied, ranging from clinical tools for remote patient monitoring and shared decision making to patient-centered tools intended to help individuals better manage their health in daily life, such as increasing physical activity or controlling one's blood glucose levels. Although applications of mHealth overlap with other areas of informatics research and practice—such as personal health informatics (▶ Chap. 11) and telehealth (▶ Chap. 20), in the context of mHealth, these applications have a distinct flavor largely due to the omnipresence of mobile technology and the unique features that this omnipresence enables. In this chapter, we trace the history of mHealth, highlight key features of these technologies that make them uniquely suited for delivery of health interventions, and provide an overview of health services and health promotion for which they are used. We conclude with a brief

discussion of ethical issues raised by the rapid growth of mHealth.

### 19.1.1 The Omnipresence of Mobile

The rapid advancements and widespread adoption of mobile technologies have altered how healthcare providers practice medicine, how patients access healthcare and manage their health and well-being, and how researchers design and evaluate health interventions. Called mHealth, both industry and research sectors have been increasingly developing devices and applications that leverage mobile and wireless communication to deliver healthcare services or to support people managing their own health and well-being.

Mobile technologies are omnipresent. Since 1984 when the first handheld mobile phone called DynaTAC (see  Fig. 19.1) was introduced (Murphy 2013), mobile computing and communication devices have been significantly advanced and widely adopted. As of 2018, 95% of U.S. adults own a mobile phone of some kind, 77% own a **smartphone**, and 53% own a **tablet** computer.<sup>1</sup> Mobile phone ownership is widespread worldwide: 59% of people own a smartphone and a further 31% own other types of mobile devices such as flip phones.<sup>2</sup> mHealth devices include **smartwatches** and other wearables, technologies well-suited for monitoring activity and physiological data and for the delivery of lifestyle change interventions. As of 2018, the

■ **Fig. 19.1** A DynaTAC 8000X, a first commercially available mobile phone from 1984. By Redrum0486 - ► <http://en.wikipedia.org/wiki/File:DynaTAC8000X.jpg>, CC BY-SA 3.0, ► <https://commons.wikimedia.org/w/index.php?curid=6421950>

global market for wearable devices in the healthcare sector reached over 2 billion U.S. dollars, which is a 600% increase over the market size in 2016.<sup>3</sup>

Mobile devices have permeated every aspect of people's lives. In a 2011 study, Dey and colleagues (Dey et al. 2011) found that people keep their mobile device in close proximity (within the same room or closer) almost 90% of the time. With respect to usage time,

American adults spend about 5 hours/day on mobile devices.<sup>4</sup> The extensive use of mobile devices generates massive data from mobile sensors and usage behaviors, from which we can infer people's behavioral and psychological patterns, such as sleep, activity, mood (LiKamWa et al. 2013), and even psychological traits (Lee et al. 2014). The inference drawn from the data collected from mobile devices is meaningful and reliable as long as people keep using the device. Therefore, many mHealth technologies are designed to promote high engagement and long wear-time, so that people can "stick" with the technology. However, as smartphone overuse and addiction have become societal problems (Kwon et al. 2013), supporting healthy engagement with mHealth technology warrants careful consideration and future research.

## 19.1.2 Evolution of mHealth Technologies

mHealth technologies have evolved in parallel with the advancements in mobile communication technologies and portable computing devices. Although we cannot provide a detailed account of the history of mHealth technologies in this chapter, we hereby aim to provide key milestones and devices in the evolution of mHealth technologies to establish a broad context for later discussion. Specifically, we cover **personal digital assistants (PDAs)**, cellular phones and smartphones, and wearables, each of which sparked important innovations in mHealth applications. See ■ Table 19.1 for the summary of representative mHealth devices.

### 19.1.2.1 PDAs and Cellular Phones

Developed in 1993, the Apple Newton was marketed as the first PDA device (see ■ Fig. 19.2a). Early applications for Newton

**Table 19.1** Representative mHealth devices and their key technical specs and supported applications

Device Category	Example Device (Release year)	Key Technical Specs	Supported Applications
Personal Digital Assistant (PDA)	Palm Pilot Personal (1997)	Palm OS 2.0, 16 MHz CPU, 512 KB Memory, 160 × 160 pixel monochrome display, touchscreen LCD, speaker, serial hotsync port, desktop cradle	Note taking (patient progress notes), calculation, to-do list, calendar, reference materials (ePocrates, 5-Minute Clinical Consult)
Cellular Phone	Nokia 5500 Sport (2006)	Symbian OS 9.1, 235 MHz CPU, 8 MB Memory, 1.7" (208 × 208 pixel) display, camera, microphone, speaker, GSM network, Bluetooth connectivity, accelerometer,	Sports (stopwatch, steps, calories burn) tracking, multimedia messaging, email, text to speech
Smartphone	Samsung Galaxy S10 (2019)	Android OS 9.0, Octa-core CPU, 8GB Memory, 128GB Storage, 6.1" Quad HD+ (3040 × 1440 pixel) display, triple camera, GSM+CDMA/4G LTE network, Wi-Fi, Bluetooth connectivity, capacitive multi-touch, stereo speakers, microphone, accelerometer, barometer, gyro sensor, geomagnetic sensor, RGB light sensor, proximity sensor	Multiple health and fitness applications via Google Play Store
Tablet	Apple iPad 7th Generation (2019)	10.2" Retina display, LED-backlit with Multi-Touch and IPS technology, 2160 × 1620 pixel display, compatible with Apple Pencil and Keyboard, Cellular data network, Wi-Fi, Bluetooth connectivity, cameras, two speaker audio, fringerprint identity sensor, gyro sensor, accelerometer, ambient light sensor, barometer	Multiple health and fitness applications via App Store
Smartwatch	Fitbit Versa 2 (2019)	1.34" OLED display, Wi-Fi, Bluetooth connectivity, microphone, Accelerometer, optical heart rate monitor, altimeter, vibration motor, SpO2 sensor, NFC, ambient light sensor	Floors climbed, activity (e.g., walk, run, swim) tracking, sleep tracking with light, deep, and REM, personalized reminders, guided breathing, 24/7 heart rate tracking, resting heart rate, calories burn

were designed to assist everyday tasks such as note-taking, calculation, and to-do list management. The Newton was one of the first devices to feature pen-based handwriting recognition, which eventually became popular in other handheld devices. Due to the technical limitations, however, the Newton was not widely adopted and was eventually discontin-

ued in 1998. The Pilot 1000, introduced in 1996 by Palm Computing, was the first widely accepted PDA; it offered a 160 × 160 pixels monochrome touch-sensitive display, a separate area for pen text input (using a special script called Graffiti), and sufficient memory to store reference materials. Over the next decade, the Pilot 1000 was followed by a large

■ **Fig. 19.2** a The Apple Newton MessagePad 2100, running Newton OS, alongside the original iPhone running iOS. number of more advanced Palm devices (e.g., the PalmPilot Personal, ■ Fig. 19.2b), as well as Windows Mobile devices (e.g., the Pocket PC), which incorporated color displays, higher resolution screens, and eventually, cellular connectivity. Many medical apps and mHealth research prototypes were designed for these devices.

The new modes of data entry using pen-based gestures, paging navigation, and menu palettes were shown to be effective in capturing structured data in healthcare settings. These interface characteristics were effective in overcoming some of the limitations of paper-based data capture, such as high capture burden and low compliance (Lane et al. 2006). As a means to ease the data capture burden, PDA applications were designed for doctors to write patient progress notes (Poon et al. 1996), for patients to capture symptoms (Stratton et al. 1998), and for researchers to collect sensitive health data in resource-poor field sites (e.g., Jaspan et al. 2007).

PDAs also served as medical reference tools for medical students and doctors (e.g., with applications such as ePocrates Rx, 5-Minute Clinical Consult, MedMath, MedCalc). In a 2006 review paper on PDAs

and medical education, the authors reported that 60–70% of medical students and residents used PDAs for educational purposes or patient care (e.g., patient tracking and documentation) (Kho et al. 2006).

For researchers, PDAs were a good prototyping platform to test mHealth applications. Intille, Kukla, Farzanfar, and Bakr (2003) used a standard PDA with a barcode scanner plug-in to create an application that helps people compare food items at the time of making food purchasing decisions. The application delivered tailored, motivational information with an aim to help people make “just-in-time” incremental changes to their diet (Intille et al. 2003). Siek et al. (2006) leveraged PDAs’ voice recording feature, as well as a barcode scanner, to create a food monitoring tool for patients with chronic kidney disease.

Traditionally, PDAs did not support phone services. However, cellular phones, which became popular around the same time as the early PDAs, did by connecting to a wireless communications network through radio waves or satellite transmissions. Early cellular phones were equipped with voice and text communication capabilities, allowing

researchers to design health interventions that deliver health messages (e.g., a text messaging smoking cessation program) (Free et al. 2011). As with PDAs, cellular phones became more powerful over time, adding more advanced features, such as multimedia messaging (e.g., sending and receiving images), text to speech, and motion sensors. These features were promptly incorporated into health applications. For example, the Nokia 5500 Sport was the first mobile phone that had a built-in 3D accelerometer, and it came with an application that automatically detected running and walking. The phone also included a diary for planning and tracking workouts, as well as enabling users to add workouts that the phone did not detect automatically.

### 19.1.2.2 Smartphones and Tablets

IBM and BellSouth's Simon is largely considered the first "smartphone" because it featured a phone with a touchscreen, email and many other capabilities that became available to the public in 1994.<sup>5</sup> Simon did not last long, but it presaged other smartphones, such as the BlackBerry and Windows Mobile.<sup>6</sup> Smartphones gained popularity in 2007 when Apple announced the first generation of the iPhone, which featured a large capacitive touchscreen, multi-touch interactions (e.g., pinching for zooming), and thin slate-like form factor. In the following year, Apple opened the App Store, a marketplace to distribute applications, which became popularly known as "apps," for the iPhone (and subsequently other iOS devices). Soon after the iPhone was launched, in 2008, Google released a new mobile OS platform, Android. The choice of the OS determines which phone to choose and which apps the user can run. Google's Android

runs on a wide range of devices manufactured by a variety of companies, whereas Apple's iOS runs on Apple's iPhone devices only.

Due to the broad user base and convenient marketplaces (platforms) to distribute apps, the iPhone and Android smartphones have led to a rapid growth in digital health in the past few years. As of 2017, more than 325,000 health and fitness apps were available in the major mobile app stores, with 3.6 billion downloads.<sup>7</sup> As platforms evolve, so do the mHealth apps. For example, Epocrates, a medical reference app, has changed over time from its earlier version for Palm OS devices to its recent versions for iOS/Android devices.

Although 73% of mHealth apps in 2015 were designed for supporting general wellness—for example, apps for tracking exercise and diet, and for managing stress, the mHealth market is shifting toward the support for managing specific health conditions. Such applications constituted 40% of mHealth apps in 2017.<sup>8</sup> Some of the key categories of mHealth apps include: symptom checkers, healthcare professional finders, managing clinical and financial records, health-condition education and management, self-monitoring, remote patient monitoring, rehabilitation programs, and prescription filling and compliance (or adherence). Based on a review of commercial mHealth apps, the most prevalent conditions that mHealth apps are targeting are diabetes, depression, migraine, asthma, low vision, and hearing loss (Martínez-Pérez et al. 2013). In addition, apps for women's health and pregnancy, and medication reminders are now common.

### 19.1.2.3 Wearable Devices

Wearable devices include activity trackers (e.g., wrist-worn devices, rings, chest bands, belt-type, and earpieces), smartwatches (see ■ Fig. 19.3), and smart clothing (e.g., shirts, bras, socks, and pants). They track a variety of activities, such as walks, runs, workouts, smoking, and eating, as well as physiological processes, such as sleep, heart rate, breathing, and sun exposure. Activity trackers and smartwatches in particular have become increasingly popular (Choe et al. 2014; Fritz et al. 2014; Lupton 2014; Rooksby et al. 2014). These devices employ low-burden self-monitoring by leveraging wearable and mobile sensing to capture data; they commonly provide behavioral feedback with coaching, goal-setting, and reminders. Such devices are available from a variety of commercial companies (Apple, Fitbit, Garmin, Fossil, Polar, etc.) and come in a number of form factors, from thin bands that resemble a bracelet (e.g., Fitbit Alta) to devices that aim to look like traditional watches (e.g., Garmin Fenix, and watches from Skagen).

Although the adoption rate for activity trackers and smart watches in the US is 17.6%, they have not been taken up equally by all age groups, with older generation showing a significantly lower adoption rate (4.6% for age 65 and up) than younger generations (30.8%

among 25 to 34-year-olds).<sup>9</sup> In addition, the abandonment of wearable device is high; about one third of people who own a wearable device abandon the device after six months.<sup>10</sup> Researchers have identified a variety of reasons why people abandon these devices. For instance, common reasons for abandoning wearable devices include difficulty in deciding what to do with the data and disappointment with the level of information the devices provide (Lazar et al. 2015). Given that a key way that these devices try to help people maintain and change behavior is by making the monitored activities more salient, the abandonment of wearable device means that the benefits of wearable devices might fade away soon after the abandonment (Klasnja et al. 2011). To help enhance the device wear time and sustain the benefits of self-monitoring, these devices should be better integrated in people's everyday life, fostering user engagement.

Contrary to other computing equipment, wearable devices could serve as a fashion item. In this regard, companies attend to the device's form factor, providing diverse customization options. Customizability can enhance a person's sense of identity, which in turn is associated with more favorable attitude, higher exercise intention, and a greater sense of attachment towards the track (Kang et al. 2017).

Although many personalized options are available on the hardware side, designing effective and personalized behavioral feedback on the software side warrants future research. There are growing bodies of litera-

\* depending on number of data items (we tested 7, 12, & 24)

ture in the ubiquitous computing (Amini et al. 2017; Gouveia et al. 2016) and visualization (Blascheck et al. 2019 (see ■ Fig. 19.4); Brehmer et al. 2018) communities that have begun to examine ways to create effective feedback on a small screen. More cross-disciplinary collaboration on this front is needed to design and build effective intervention components for wearable devices (Lee et al. 2018).

Wearables have been popular subjects of research in healthcare domains due to their potential to serve as an intervention in a variety of contexts. See a systematic mapping study of how “Internet of Things,” including wearables have been deployed and evaluated in the medical field (Sadoughi et al. 2020).

### 19.1.3 Current Platforms

The smartphone user base is sharply divided between Google’s Android platform and Apple’s iOS. As of June 2018, 54.1% percent of U.S. smartphone users were using a Google

Android device, and 44.5% were using an Apple device.<sup>11</sup> The divide in the market share and the idiosyncratic characteristics of individual phones pose problems for developers and researchers. To create a native app (i.e., an app that has been developed for use on a particular platform), developers must redouble their efforts to create and maintain versions for each platform. Researchers, who often lack skills and resources to build native mobile apps for multiple mobile platforms, must pick either of the two platforms instead of supporting both, which can introduce a selection bias in recruitment.<sup>12</sup> To address such concerns, efforts have been devoted to developing frameworks and

11 Statista. 2019. Subscriber share held by smartphone operating systems in the United States from 2012 to 2019 [Data file]. Retrieval June 13, 2019: ► <https://www.statista.com/statistics/266572/market-share-held-by-smartphone-platforms-in-the-united-states/>

12 The U.S. Mobile App Report. 2014. Retrieval January 15, 2020: ► [https://www.comscore.com/Insights/Infographics/iPhone-Users-Earn-Higher-Income-Engage-More-on-Apps-than-Android-Users?cs\\_edgescape\\_cc=US](https://www.comscore.com/Insights/Infographics/iPhone-Users-Earn-Higher-Income-Engage-More-on-Apps-than-Android-Users?cs_edgescape_cc=US)

platforms to handle device and operating system compatibility. For example, Apache Cordova<sup>13</sup> enables developers to build cross-platform mobile apps with HTML5, CSS, and JavaScript, with extensions that provide access to some hardware features such as camera, **GPS**, and Bluetooth. Titanium<sup>14</sup> is a mobile development environment that allows the creation of native apps across different mobile devices and operating systems, while reusing a large part of the codes across apps. Such cross-platform support enables developers of mHealth technologies to reach potential users of either Android or Apple devices.

#### 19.1.4 Data Access & Data Standards

Accessing mHealth data could be valuable for many stakeholders, including self-trackers who want to learn insights about themselves (Choe et al. 2014), researchers who want to incorporate mHealth data in their research (e.g., Althoff et al. 2016; Jakicic et al. 2016; Fitabase<sup>15</sup>), and app developers who want to integrate multiple data sources in a new service (e.g., Exist.io,<sup>16</sup> Gyroscope,<sup>17</sup> and Instant<sup>18</sup>). For some patients, accessing their personal health data is a matter of life and death, as in the case of Type 1 diabetes patients, who have been struggling for a long time to have direct access to their **continuous glucose monitor (CGM)** data (Kaziunas et al. 2018). In clinical contexts, doctors can use the patients' data collected outside the hospital to diagnose patients accurately and monitor

them closely (Chung et al. 2015; Kim et al. 2017; West et al. 2016; Zhu et al. 2016).

People can access their data collected from mHealth apps through downloading a file (e.g., CSV, FIT, GPX, KML, and TCX) from an app, website, or a health platform (e.g., Apple Health), and using application programming interfaces (APIs). However, it is typically difficult for lay people to download and repurpose the data, even if they are the ones who contributed to collecting them (Kim et al. 2019). Although recent regulations—such as the European General Data Protection Regulation (GDPR)<sup>19</sup>—have the potential to enhance personal data accessibility, the industry lags behind the reforms.

Data standards are defined as “documented agreements on representations, formats, and definitions of common data” (Fenton et al. 2013).<sup>20</sup> They support interoperability among heterogeneous systems, and are critical in leveraging patient-generated data in the current mHealth ecosystem. Among a few existing health platforms in the market (e.g., Apple Health, Google Fit, and Samsung Health), Apple Health and its frameworks (HealthKit and ResearchKit) are widely being adopted, and have become the standard interface to fitness and medical devices.<sup>21</sup> Apple's HealthKit supports data integration from iOS apps by allowing third party apps to transfer data to and from the HealthKit. However, data loss could happen during the transfer, and HealthKit is not compatible with Android apps, failing to accommodate more than half of the smartphone users. As in the case of the Open mHealth ini-

tiative<sup>22</sup> and Human API,<sup>23</sup> some efforts have been made in creating standard for personal health data schema. However, the uptake of the Open mHealth initiative and Human API has been slow, and no incentives encourage companies to follow the standardization just yet. Health platform companies and health app developers need to make a concerted effort to establish standards for personal data schemas to support interoperability and to prevent data loss.

On the clinical informatics side, app developers have been building 3rd party clinical apps—some of which are mHealth apps—that can access patients data directly from EHR by leveraging **SMART on FHIR**,<sup>24</sup> an open, standards-based platform for medical apps. Through SMART on FHIR, healthcare organizations can plug third-party medical apps into their EHR that use those standard data types, which poses immense opportunities for clinicians and patients to use EHR data for diverse purposes (e.g., patient engagement, disease management, and research) on mobile devices.

## 19.2 Key Features of mHealth Technologies

A great deal of utility of mobile technology for health applications comes from the ways in which these tools can collect data about individuals' health status, behavior, and context. Unique to mobile technology is its ability to collect data *passively* via various types of sensors embedded in mobile phones and wearable devices. With the number of mobile sensors and the quality of the inference increasing at a rapid rate, mobile health tools are able to detect a broad range of behaviors and states continuously and in the background, with minimal user interaction,

enabling collection of rich, longitudinal data that can be used for assessment and treatment. When self-report is needed, mobile tools offer ways to collect self-report data in context and with low burden, greatly increasing the ecological validity of user-provided information.

### 19.2.1 Sensing to Collect Data

A key feature of many mHealth applications is that they make use of information generated via sensors contained in mobile phones or worn on the body. Modern mobile phones contain a large number of sensors, including GPS, accelerometers, gyroscopes, cameras, and microphones. In recent years, the use of on-body sensors that continuously monitor individuals' activities and states has exploded. Examples include wrist-worn fitness trackers as well as a large variety of specialty sensors such as those that detect galvanic skin response, oxygen saturation, blood glucose, heart rate variability, core body temperature, and blood pressure.

The data from such on-body sensors are typically transmitted to a mobile phone, where, along with data collected on the phone itself, it is used to provide feedback to users or is made available to third-party applications. Sensor data are used for three basic purposes: (1) for assessing physiological processes, such as resting heart rate or blood glucose; (2) for inferring individual's activities, such as physical activity, eating, and sleep; and (3) for inferring context, such as location and social environment.

#### 19.2.1.1 Assessing Physiological Processes

An important use of sensing in mHealth technologies is to assess physiological processes and states that are important for supporting health management. Such sensing is usually done through devices that users wear on their bodies (e.g., bands worn on the wrist, or instrumented adhesive patches worn on the torso) or even through their phone. Regardless of the sensor form factor, physiological data obtained through mobile sensing are typically

22 Open mHealth. 2015. The Tides Center. Retrieval June 13, 2019: ► <http://www.openmhealth.org/>

24 SMART Health IT. Retrieval January 15, 2020: ► <https://smarthealthit.org/>

transmitted to a mobile phone via a low-power radio (e.g., Bluetooth), where it can be used to drive intervention delivery through an mHealth app or uploaded to remote servers for monitoring by the healthcare team.

The most common type of sensors used to monitor physiological processes are wrist-worn wearables. The exact set of sensors—and, thus, what they are able to detect—varies by device, but the main physiological sensor found in such devices is the optical heart-rate sensor, which uses green and orange light emitting diodes (LEDs) and a photodetector to detect the pulse waveform (Alexander et al. 1989). Recently, heart rate sensors have begun to add pulse oximetry functionality as well, by incorporating a red LED, and, as of 2018, these more advanced heart rate sensors are beginning to show up even in devices in the \$150 range, such as Fitbit Charge 3 and Garmin Vivosmart 4, which represent a large segment of the wearables market.

The chief physiological metrics sensed by heart rate sensors are momentary heart rate and resting heart rate. Combining momentary heart rate data with physical activity data (sensed via an accelerometer), wrist-worn devices also try to estimate energy expenditure, although the quality of these calculations is variable (see Consolvo et al. 2014 for examples of design implications of this variability in inference). Certain wristbands—notably, recent devices made by Garmin—attempt to characterize users' stress levels, which can be estimated from the inter-beat interval data obtained from optical heart rate sensors (Hovsepian et al. 2015). Finally, wrist-based devices with pulse oximeters are able to detect blood oxygen saturation, although the current generation of devices do not provide continuous monitoring of this metric.

Although wristbands are currently the most common form factor for commercial wearable sensors, the range of physiological data that can be sensed unobtrusively at the wrist is limited. As such, several other form factors exist, including smart rings (e.g., Moodmetric and Motiv), instrumented clothing (e.g., Hexoskin, OMSignal, and Skiin), and adhesive tags that can be attached to clothing (Spire). Such devices are able to detect other physiological

metrics beyond heart rate—including respiration, body temperature, and electrodermal activity—enabling, among other things, more robust assessment of stress (e.g., Moodmetric and Spire).

In addition to consumer-oriented commercial devices, physiological sensing using wearable sensors is a thriving research area. The current crop of commercial devices described above are based on decades of sensing research, with the research on optical pulse oximetry dating back to the 1980s (see Alexander et al. 1989 for a brief review), and stress detection drawing on ten years of work on multimodal sensing (Ertin et al. 2011; Hovsepian et al. 2015). More recently, two key topics in mobile physiological sensing research have been cuff-less, continuous measurement of blood pressure and noninvasive measurement of blood glucose.

Over the last few years, there has been a quickly growing body of research aimed at developing unobtrusive methods for blood pressure (BP) measurement. Much of this work attempts to repurpose optical heart rate sensors already present in the wrist-based activity trackers to estimate blood pressure from photoplethysmography (PPG) measurements. Recent work (Zhang and Feng 2017; Patil et al. 2017) has shown that machine learning techniques can be used to estimate both systolic and diastolic BP from PPG signals with around 90% accuracy. Similarly, Carek et al. (2017) have used the accelerometer and optical heart rate sensor in a smart watch to estimate BP from the pulse transit time, with similar accuracy. Although these accuracy rates are still too low for widespread clinical applications, this line of work is quickly developing, and accurate continuous BP monitoring is likely not too distant.

The other key target for physiological sensing in the context of mHealth has been blood glucose measurement. Traditionally, blood glucose could only be measured from blood samples, typically obtained from a finger prick or, in the case of continuous glucose monitors, from a needle semi-permanently inserted into the subcutaneous tissue. In recent years, both the finger prick-based glucose monitors and CMGs have started to incorpo-

rate Bluetooth connectivity, enabling glucose readings to be automatically uploaded to and logged in a smartphone app, greatly facilitating keeping of accurate logs and provision of data-driven self-management coaching. For instance, BlueStar (► [www.welldoc.com](http://www.welldoc.com)), an FDA-approved app for diabetes self-management, uses patients' glucose readings uploaded from a connected glucometer to provide just-in-time advice for specific actions patients can take to keep their glucose levels in the prescribed range. An early randomized clinical trial of BlueStar showed a 2% HbA1c improvement in the BlueStar arm compared to the .68% improvement in the control condition (Quinn et al. 2008). As with BP measurement, recent research has focused on making blood glucose measurement more convenient and less invasive. Researchers have explored multiple approaches to detecting glucose levels non-invasively, including optical, by shining light into the skin to detect changes in glucose concentration in the blood, chemical, to detect glucose levels in the saliva, and electrochemical, to detect glucose via a smart contact lens (see Eadie and Steele 2017 for a review). A number of systems that are using these approaches are currently undergoing clinical trials.

Finally, many research projects aim to use sensors found in mobile phones to enable detection of physiological processes that have traditionally required expensive, medical-grade equipment. Among other metrics, projects in this category used cell phone sensors to detect lung function via the phone microphone (Larson et al. 2012), hemoglobin concentration in the blood using the phone camera (Wang et al. 2016), intraocular pressure from the video captured on a smartphone (Mariakakis et al. 2016), and blood alcohol level from interaction patterns with app user interfaces (Mariakakis et al. 2018). The purpose of projects such as those listed above is to make expensive medical tests that require specialized equipment cheaper and more accessible to decrease health disparities and increase access to care.

### 19.2.1.2 Inferring Activities

A key role of sensing in the context of mobile health is detection of individuals' activities and states. The most common application of sensing in this domain has been detection of physical activity. Accelerometers and gyroscopes are found not only in wearable fitness trackers but also in smartphones, as well in a growing segment of "hybrid" watches—standard quartz or mechanical timepieces which contain a small number of sensors and ability to receive phone notifications. Accelerometers in all these devices are continuously assessing users' movements to determine how active they are. The chief metric derived from this data is the number of steps that an individual has taken, but many devices and mobile apps also combine accelerometer data with heart rate data to estimate the number of active minutes, usually calculated to correspond to minutes of moderate to vigorous physical activity (MVPA), a metric that is commonly used in physical activity guidelines (e.g., Piercy et al. 2018). Additionally, more advanced wearables are increasingly attempting to detect exactly which physical activity a user is performing (e.g., biking, swimming, elliptical, etc.) to help users keep more accurate exercise logs and improve calorie expenditure estimation. As with many other areas of mobile health, detection of specific physical activities was pioneered in the research setting (Choudhury et al. 2008), but its accuracy has only recently become sufficiently high to make it feasible for broad inclusion in commercial devices.

Another common activity detected via mobile devices is sleep. Most wrist-based activity trackers (from Fitbit, Garmin, etc.) track sleep using accelerometry, and many of them try to categorize different stages of sleep as well, providing users with summaries of the amounts of time spent in deep, light, and REM sleep. A recent systematic review of reliability and validity of consumer activity trackers found that these devices typically overestimate total sleep time and sleep efficiency when compared to polysomnography but underestimate wake-after-sleep onset (Everson et al. 2015). Given that these devices

estimate sleep duration using wrist-worn accelerometers, part of the problem appears to be that evening activities that involve little movement (reading, watching a movie, etc.) can be confused for sleep, leading to the over-estimation of total sleep time.

An important focus of recent work has been automated detection of eating. Diet tracking has been consistently shown to be one of the most effective self-management strategies for weight loss (Michie et al. 2009; Webb et al. 2010), and it is of great importance to a range of epidemiological research. Yet, consistent manual diet tracking is notoriously difficult to achieve over extended periods of time. For this reason, a great deal of recent research has focused on trying to automate diet tracking in various ways. mHealth researchers have taken a number of approaches to address this problem. One approach has been to simplify tracking by enabling users to take pictures of their meals using the phone's camera. To extract information about what was eaten, the photo-based approach relies either on computer vision (e.g., Kitamura et al. 2010), or on crowdsourcing, where the food images are analyzed through a sequence of tasks assigned to workers on **Amazon Mechanical Turk** (Noronha et al. 2011). The photo-based approach still requires active user engagement, but the user burden is reduced compared to manual logging, albeit at a higher financial cost (for crowdsourcing) or at the cost of lower data accuracy (for computer vision-based approaches).

As an alternative to photo-logging of food intake, recent research has attempted to facilitate diet tracking by automating detection of eating episodes. To do so, researchers have used a number of sensing approaches, including using microphones to detect the sound of chewing and swallowing (Alshurafa et al. 2014; Makeyev et al. 2012), using wrist-based accelerometers to detect hand movements indicative of eating or drinking (Amft et al. 2005; Kyritsis et al. 2017), and using a small neck-worn camera to detect when food is brought to the mouth (Sun et al. 2014; Chen et al. 2013). Unlike photo-logging, which aims to produce the same kind of data as traditional manual diet tracking (a log of the foods eaten with corresponding micro and macronu-

trient information), these approaches focus on detecting the *activity* of eating, rather than detecting *what* is eaten. As such, detection of eating currently does not result in accurate nutrient information, although it can provide some information about the types of food eaten (fresh fruit and vegetables are crunchier and require more chewing than, say, a hamburger), as well as the amount (by virtue of detecting the total number of eating episodes and their duration). Even with this limitation, automatic eating detection can be very useful for a range of mobile health applications, from supporting independent living of the elderly by verifying they are eating regularly, to interventions for weight management that attempt to decrease snacking and mindless eating.

mHealth systems have used sensor data to detect a range of other activities, including medication adherence via instrumented pill bottles (Hayes et al. 2006; Abbey et al. 2012), falls (Dai et al. 2010; Fang et al. 2012) smoking (Ali et al. 2012; Parate et al. 2014), and activities of daily living, such as washing and cooking. The latter category is particularly relevant for supporting independent living, but detecting such activities with a high level of precision often involves combining mobile devices with instrumenting the environment, such as adding RFID tags to common objects like pots (Buettner et al. 2009), or using cameras (Liu et al. 2014).

### 19.2.1.3 Inferring Context

In addition to detecting physiological processes and user activities, mobile devices are commonly used to detect user's context to tailor intervention delivery to the user's current situation. The key contextual variable used by mHealth apps is location. Both iOS and Android contain robust location capabilities that leverage GPS, Wi-Fi, and cell tower information to determine user's location in a battery-efficient way and enable third-party applications to obtain location information even while the application is in the background (i.e., the phone screen is off or the user is interacting with another application). These capabilities enable mHealth apps to identify nearby resources (e.g., healthy restaurants or

emergency rooms), and to provide intervention content that is appropriate to the user's current context. For instance, HeartSteps, an mHealth physical activity intervention, sends user's activity suggestions that are tailored to their location, weather, time of day, and day of the week (Klasnja et al. 2018).

Similarly, MyBehavior (Rabbi et al. 2015), another physical activity intervention, tracks users' daily movements and then, based on the current location, provides recommendations for walking routes a user can take to increase their steps, balancing the user's step goal with the suggested activity's feasibility (e.g., how much time it would take). In the addiction space, location is often used to determine high-risk situations (e.g., proximity to a bar) to provide just-in-time support, such as coping strategies (e.g., see Gustafson et al. 2014). Such **just-in-time adaptive interventions (JITAI)s**, enabled by knowledge of the individual's current context and activity, hold great promise for achieving goals of precision behavioral health by providing support only when it's most likely to be effective and when individuals are receptive to it (Nahum-Shani et al. 2015; Spruijt-Metz and Nilsen 2014).

Other contextual variables that can be passively sensed by current smartphones include weather (by lookup via the user's location), the user's calendar (e.g., free/busy blocks), ambient noise levels, and proximity to other people. A number of research efforts (Kanhere 2011; Devarakonda et al. 2013) have examined incorporation of chemical sensors into the phone that would allow sensing of pollution levels. Although such pollution levels can currently be approximated by looking up pollution data based on the user's location, sensing on the phone could enable more timely and potentially more effective just-in-time support for individuals with asthma and other respiratory problems.

## 19.2.2 Collecting Self-Reported Data

Across physiological processes, user activities, and context, mobile devices are increasingly able to detect information about a person that

can be used to characterize that person's health-related needs and provide timely support to address those needs. However, not everything can be sensed, and a range of important metrics needed to monitor patients' health (e.g., pain levels and medication side effects) and support self-management require self-report data. For these cases, mobile devices enable self-report that is precise, timely, and minimally burdensome. Collecting and leveraging in-situ self-report data using mobile devices has recently gained tremendous interest among researchers in multiple fields, such as ubiquitous computing, behavioral sciences, psychology, public health, and machine learning.

### 19.2.2.1 In-Situ Data Collection Methods

Research methods such as diary study and **ecological momentary assessment (EMA)** (Shiffman et al. 2008; Stone et al. 2007) help researchers understand details about a person's context, intentions, and actions that traditional research methods (e.g., interview, survey, and system log analysis) cannot reveal. Diary study and EMA share the same purpose of collecting data in people's natural environment to maximize ecological validity. In diary study, people capture self-report data—usually once a day—using either pen and paper, mobile diary apps, or online survey. Some diaries are structured (e.g., sleep diary for Cognitive Behavioral Therapy for Insomnia) whereas others are less structured (e.g., free-form note). Although diary study helps researchers collect in-situ data relatively easily, it is subject to low adherence (if participants forget to fill it out) and recall bias (if there is a large time interval between when an event happened and when the event was captured). More recently, researchers increasingly use EMA, which refers to frequent, brief collection of self-report data about the person's current situation and experiences. As a data collection method, EMA is intended to decrease recall biases and memory limitations inherent in retrospective self-report, while—by collecting self-report frequently (often 5 to 8 times a day)—enabling researchers to understand how behavior, psychological processes,

and individuals' experiences change over time and are influenced by time-varying factors such as the person's physical environment.

### 19.2.2.2 Mobile Research Platforms for In-Situ Data Collection

Mobile devices are particularly well suited for supporting diary and EMA studies in multiple ways. Researchers and commercial companies have developed a number of software platforms for collecting in-situ data that enable researchers to create data-collection schedules with no or minimal programming. These tools typically support the collection of self-report data, passive logging of smartphone sensors (e.g., GPS, bluetooth, device status, and activity), or some combination of both (semi-automated tracking) (Choe et al. 2017).

One of the early projects of this kind, MyExperience (Froehlich et al. 2007) ran on Windows Mobile device, and it enabled researchers to construct sophisticated EMA surveys and schedules by writing a single configuration file in XML. MyExperience surveys could collect traditional questionnaire-style data (i.e., multiple-choice questions, text responses, etc.), as well as use the phone's camera and microphone to collect rich multimedia data. They also allowed complex survey schedules where different questionnaires were delivered to participants at different times and based on different triggering conditions.

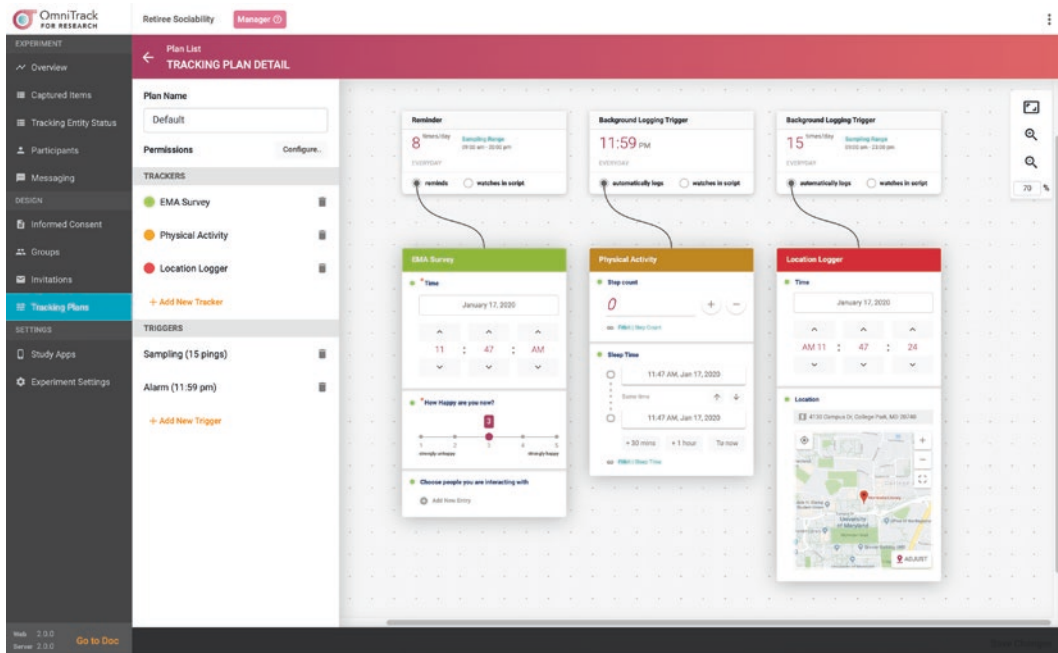

Many similar systems have since been developed for different mobile platforms, and researchers can now choose among both commercial solutions where survey configuration is done by a commercial company that has developed a proprietary EMA platform (e.g., Life Data Corp and Ilumivu) and open-source platforms that researchers can configure and deploy themselves (e.g., Memento (Carter et al. 2007), MyExperience (Froehlich et al. 2007), AWARE (Ferreira et al. 2015), Jeeves (Rough and Quigley 2015), PACO (Evans 2016), Sensus (Xiong et al. 2016), Extrasensory App (Vaizman et al. 2018), OmniTrack (Kim et al. 2017), and TEMPEST (Batalas et al. 2018)). Among the latter group, the most mature

current offering is PACO,<sup>25</sup> a cross-platform (Android and iOS) system built by the Google engineer Bob Evans and his colleagues. Like MyExperience, PACO supports construction of multiple surveys and schedules, a broad range of question types, and sophisticated questionnaire triggering. All configuration of PACO questionnaires can be done through a web interface without any programming, and its website provides study management functionality, including enrolling participants, monitoring their adherence, and downloading response data in standard formats for statistical analyses. To further extend people's data capture capability, OmniTrack enables people to create an Android native tracking app without programming (Kim et al. 2017). By combining various data fields and integrating external data services (e.g., Fitbit) into a single tracking app, people can create a customized tracking app and configure the app to be used as a general diary app or an EMA tool. Researchers can design and deploy an OmniTrack app using OmniTrack for Research (see ■ Fig. 19.5), which handles app deployment, updates, and participant monitoring.<sup>26</sup> The ability to construct data capture instruments and conduct studies from the web with no programming greatly increases opportunities for researchers outside of technical disciplines to integrate rich in-situ data into their research projects.

Many of the EMA platforms support not just traditional time-based prompting where questionnaires are triggered based on time, but also event-based prompting, where questionnaires are triggered when the phone detects that a particular kind of event has occurred. To do so, EMA systems use sensors in the phone and connected devices to monitor users' state and behavior, and then trigger a questionnaire when a particular set of conditions are met. The sensors and types of

25 PACO: The Personal Analytics Companion. Retrieval June 13, 2019: ► <https://pacoapp.com/>

26 Kim YH, Lee B, Choe EK, Seo J. 2019. OmniTrack for Research. GitHub. Retrieval June 13, 2019: ► <https://omnitrack.github.io/research/>

**Fig. 19.5** OmniTrack for Research. Researchers can use the graphical user interfaces to create mobile data collection apps equipped with both manual and automated data collection functionalities

events that can be used for triggering vary from platform to platform, but it is common to be able to define events based on location (e.g., a questionnaire can trigger when the person gets home or stops moving), phone activity (a questionnaire can trigger after the person finishes a phone call), or data from accelerometers (a questionnaire can trigger when the person finishes a physical activity). Event-based prompting allows researchers to collect data at precise times when an event of interest (e.g., physical activity) occurs, maximizing their ability to get timely information about the person's experience and surrounding events and minimizing recall biases and the risk of forgetting.

Finally, some EMA platforms enable not just collection of EMA data but also the use of the provided answers to trigger interventions. Such ecological momentary interventions (EMIs; Heron and Smyth 2010) are particularly useful in the substance use arena (e.g., Gustafson et al. 2014; Dennis et al. 2015), where a person's answers to EMA questions can be used to calculate risk of relapse, which, if it reaches a predefined threshold, can trigger coping interventions or facilitate

contact with a recovery coach. The ability of EMA systems to trigger a request for self-report at times of high risk (e.g., when a person recovering from alcoholism is near a bar) and immediately respond to provided answers enables the kind of tailored, just-in-time support that was impossible prior to the development of modern mobile technology.

### 19.2.2.3 Incorporating Self-Reporting Into User Interactions

In addition to diary and EMA studies, mobile technology can facilitate collection of self-report by incorporating self-reporting into interactions that users already perform on their mobile devices. Particularly interesting attempts to do this involved appropriating the unlock gesture on Android phones to enable a user to provide a single piece of self-report data as part of the process of unlocking the phone. The first project that took route, Slide to X (Truong et al. 2014), found that individuals unlocked their phones between 20 and 100 times per day on average. To take advantage of this frequent interaction, Truong et al. built three applications that turned the

phone's standard unlocking interface into a data-collection tool. One of them, Slide To QuantifySelf, enabled users to answer a single question (e.g., "how happy are you right now?") on a Likert scale in place of using performing a standard unlock gesture. Users could specify multiple questions with which to be prompted, as well as when during the day each question should be asked (e.g., asking about whether they ate breakfast mid-morning), providing a low-burden way to collect a rich self-report dataset that can help an individual better manage her health. A recent project called LogIn (Zhang et al. 2016) expanded on this idea by developing gesture-based unlock interactions to track pleasure and accomplishment, sleepiness, and mood. Unlike Slide to QuantifySelf, which used a single Likert scale item to record self-report, LogIt used more sophisticated gesture-based interactions, such as measuring mood on Russell's affect grid (Russell et al. 1989).

Self-report can be incorporated into applications as well. Here too the underlying idea is to decrease the burden of providing self-report by tying it to an action the user is already performing. In HeartSteps (Klasnja et al. 2018), an mHealth physical activity intervention, users can receive prompts to go for a brief walk or move to disrupt prolonged sitting. Like many mHealth interventions, these prompts are provided as push notifications to the user's phone. Other than dismissing them through a simple OK button, however, HeartSteps provides users with three different buttons to dismiss the notification, each intended to indicate how the user perceived that particular prompt. Users can press a thumbs-up icon to indicate that they liked the activity suggestion and that it came at a good time, a thumbs-down icon to indicate that the suggestion was not helpful or came at a bad time, and a button to turn off future prompts for a certain period of time, indicating that they will be busy or unavailable for the intervention. The data from a study of HeartSteps showed that participants were significantly more active after the prompts they marked thumbs-up than those to which they responded in either of the two other ways, suggesting that the self-report obtained in this

manner is a useful indicator of individuals' receptivity to intervention.<sup>27</sup> In the new version of HeartSteps, these data are being used by a learning algorithm that personalizes intervention provision for each HeartSteps user. Adding a single question to an application dashboard, or triggering a question by observing the use of other applications (e.g., when a user quits a social media app) are other ways when interactions already taking place on the phone can be leveraged to collect self-report data without the need for additional disruptive prompting of the user.

#### 19.2.2.4 Easing Data Entry

Finally, mobile devices offer a number of ways to ease data entry during self-report. As we mentioned, most EMA platforms enable users to take pictures and use the phone's microphone to speak their answers to the questions. Such multimedia responses enable collection of rich qualitative data that would be too burdensome or even impossible to collect by requiring users to type their responses into a text form. Multimedia capture enables additional types of data analyses that cannot be done on traditional questionnaire data. For instance, PlateMate (Noronha et al. 2011) lets users track what they are eating by taking pictures of meals. The system then uploads these images to Mechanical Turk, where they are processed through a number of steps that extract detailed nutritional information from the images, enabling logging of calories and micro-nutrients with much lower self-report burden than is involved in traditional database-based nutritional logging. Similarly, machine learning algorithms can be used to process audio recordings of data individuals enter by speaking into the phone not only to extract content of those recordings, but also to detect user's mood or features such as latency or pitch that can be indicative of changes in the individual's mental health, such as an onset of a manic episode (e.g., Gideon et al. 2016).

27 Predrag Klasnja, personal communication, 8/31/2019.

Self-report can be made more convenient by placing self-reporting interfaces into easily accessible locations and minimizing how much user interaction is required. Choe et al. (2015) enabled low-burden self-monitoring of sleep by placing a self-tracking widget on the phone's lock screen, making it visible every time a person reached for her phone, and by recording sleep quality via a single tap. Similarly, Fitabase Engage, a new platform from Fitabase, enables simple questions to show up on individuals' Fitbit smartwatches, and the questions to be answered with a single tap. The speed of this interaction, and not needing to reach for the phone, greatly decreases the perceived burden on answering questions delivered via Fitabase Engage.

### 19.2.3 Providing Interventions in Individuals' Daily Lives

By facilitating passive data collection via sensors embedded in the phone and wearable devices, and by providing ways to collect brief self-report data at the right time and in the right context, mobile technology has greatly enhanced collection of data that are needed to understand health behaviors, to monitor patients' health, and to provide interventions. We now turn to how this information can be used by mHealth systems to provide interventions at times when those interventions are most needed and when individuals are most receptive to them.

Given the immense number of mHealth apps, their content can be categorized in a number of different ways (e.g., see Klasnja & Pratt, 2012 for one classification). For simplicity, many mHealth apps can be seen as falling into one or more of the following five categories:

1. **Reminders.** One of the simplest functions of mHealth interventions is to provide reminders. Reminders exist for many different health behaviors, including attending scheduled clinic visits, taking medications, and applying sunscreen on sunny days. Sometimes reminders are a stand-alone intervention (e.g., a text messaging intervention to increase adherence

to clinic visits (Koshy et al. 2008; Leong et al. 2006)), while other times they are embedded into more complex interventions, such as those for chronic disease management.

2. **Support for behavior change.** A large number of mHealth interventions are intended to help individuals make health-promoting changes in their behavior. mHealth interventions exist for improving medication adherence, increasing wellness behaviors like physical activity and healthy diet, helping with cessation of addictive behaviors like smoking and substance use, preventing relapse, and adhering to health management practices like monitoring of glucose or blood pressure. Some of the applications for the management of mental health (e.g., depression and bipolar disorder) fall into this category as well, as they often focus on helping individuals enact therapeutic practices like behavioral activation, or increase the regularity of sleep, social contact, and other behaviors that support mental well-being.
3. **Discovery of patterns.** A related category is mHealth interventions that support individuals in discovering patterns in their behavioral or physiological responses. For instance, TummyTrials (Karkar et al. 2017) is a recent mHealth intervention intended to help individuals detect food triggers that aggravate irritable bowel syndrome. Other interventions, like Health Mashups, (Bentley et al. 2013), try to help individuals understand what factors influence their physical activity, sleep, and other wellness behaviors. Although interventions in this category do not have explicit behavior-change features, such as goal-setting or planning, the **self-experimentation** they support is usually in service of making health-promoting changes in one's behavior, making this category a close relative of the behavior-change interventions.
4. **Detection or prediction of critical health events.** An important use of sensors and self-report data in the mHealth context is to enable interventions that detect and/or predict critical health events that may

require prompt medical attention. mHealth solutions exist to detect a broad range of acute health events, including falls, alarming levels of chemotherapy toxicity, imminent risk of a heart attack, onset of a manic episode, and decompensation in chronic heart failure. Depending on the severity of the detected event, such interventions either provide guidance to the individual on how to manage the event or automatically contact the emergency services to get the individual medical help as quickly as possible.

5. Communication with the healthcare system. A growing number of mHealth interventions are intended to facilitate communication with the health system through the support of remote patient monitoring, secure messaging, prescription refills, accessing labs and imaging, and scheduling appointments. Unlike the categories reviewed above, mHealth apps in this category are almost always provided by and tied to a particular health system, pharmacy, or a clinic. To make such mHealth interventions work, clinical workflows often have to be restructured to accommodate the use of mHealth tools by patients and the data that are generated as part of that use.

Although the above categories are not intended to be exhaustive, they do cover many of the common types of mHealth applications. Thus, they demonstrate the range of the intervention work that has been done in the field of mHealth.

#### 19.2.4 Providing Just-in-Time Adaptive Interventions

From the earliest days of mHealth, a major promise of mobile technology, given its constant proximity to the person, has been its ability to provide support for health management when that support is most needed (Intille 2004; Patrick et al. 2008; Nilsen et al. 2012): at times when a person is at risk (e.g., of a substance use relapse) and needs help with coping, when there is an opportunity to engage in

health-promoting behaviors, or when the sensors detect that there is a critical change in the person's health (e.g., high likelihood of a heart attack) and she needs to receive immediate medical attention. The development of such just-in-time interventions is made possible by continuous, low-burden data collection, always-on Internet connectivity, powerful phone-based information processing, and the ability to prompt the person via a push notification or a text message to deliver an intervention. A great deal of recent work on mHealth interventions has aimed to realize this promise of smart, timely intervention delivery.

Although the promise of timely, in-context information has been acknowledged for many years, it is only recently that the technical, algorithmic, and methodological developments have enabled the development of interventions that realize this goal. In recent literature, such mHealth interventions have been referred to as just-in-time adaptive interventions (JITAI; Nahum-Shani et al. 2015; Nahum-Shani et al. 2016; Spruijt-Metz and Nilsen 2014). JITAI refer to mHealth systems that use *decision rules*—if-then rules or algorithms that specify when, where, and how interventions are delivered to individuals—to attempt to provide the right type of support at the right times and in the right contexts. JITAI use sensors and low-burden self-report to continuously monitor individuals' state, behavior, and the environment, and when they detect that an individual is in a state of high risk or has an opportunity to engage in a health-promoting behavior, they make a decision about whether to intervene. How these decisions are made varies. Simple JITAI use deterministic if-then rules that determine what the system should do when a situation of risk or opportunity is detected. For instance, a JITAI might send a person recovering from alcohol use disorder a push notification with a coping strategy every time that person is within a certain distance of a bar (Gustafson et al. 2014). Or the decision rules may be stochastic, where intervention is not provided every time a situation of risk or opportunity is encountered but only with certain probability—usually to reduce user burden (e.g., Klasnja et al. 2018). Finally, the system

may incorporate algorithms that evolve the decision rules over time to maximize their effectiveness for each individual (we will return to this point shortly).

What form the decision rules take depends on the nature of a JITAI's intervention components, as well as the situations it is trying to target. For situations that occur frequently—such as getting stressed or high likelihood of lighting up a cigarette—interventions have to be spaced out to manage user burden and reduce the risk of system abandonment. Stochastic rules are well suited for meeting these criteria, as they can reduce the overall number of interventions while creating a sense of unpredictability, which may increase the effectiveness of the interventions by reducing habituation. On the other hand, for risk states that occur rarely—or for which the consequences of not intervening are severe (the risk of suicide being an extreme example)—simple deterministic decision rules may be both appropriate and adequate.

As we mentioned above, decision rules can also evolve over time. Although standard deterministic and stochastic decision rules do not change over the course of system use and are typically the same for all users of a system, mHealth systems with evolving rules aim to personalize delivery of interventions for each system user. The idea is that the system learns patterns in user behavior and intervention response over time, and it can then adjust how it provides interventions to maximize their effectiveness for each individual user and to minimize user burden.

Two approaches to intervention personalization are currently being investigated: reinforcement learning and control systems engineering. JITAIs based on reinforcement learning (RL) use algorithms to continually adjust the probability of intervening based on observations of the outcome of previously delivered interventions (Sutton and Barto 1998). Observations of successful outcomes lead the algorithm to increase the probability of intervening in the similar context in the future; unsuccessful outcomes decrease that probability. RL algorithms can focus either on short-term outcomes—the most immediate outcomes of individual intervention provi-

sions (e.g., the number of steps a person walks on a day when the system sent a motivational message in the morning)—or long-term outcomes that prioritize how the system performs over time (e.g., the user's average daily step count over the course of a month). Much of the foundational research in RL has been done in areas like robotics where both the definition of success and the relevant state variables are relatively unambiguous. As human behavior is inherently more messy and the system's knowledge of the person's state and environment is far more noisy, it's an open research question whether mHealth systems would work better by employing algorithms that focus on clearer but shorter-term outcomes, or if the more sophisticated algorithms that focus on the long-term can be made to work in this setting.

The other approach to personalized JITAIs draws on control systems engineering (Hekler et al. 2018; Phatak et al. 2018). Control systems engineering focuses on the development of systems that are capable of controlling complex processes, such as the flight of an airplane or blood glucose metabolism. At the heart of this approach is the development of mathematical models—called **dynamical systems models**—that encode what is known about the influences on the process or behavior that needs to be controlled. Those models are then used by control systems such as the plane autopilot or the artificial pancreas to make decisions about how the system should intervene to maximize the likelihood that the process will behave in a desired way (the flight will get to the destination city, the blood glucose will be in the healthy range, etc.). In the context of mHealth, the approach is being used to form dynamical models of health behaviors (e.g., an individual's daily steps), and the models are then used by an mHealth system's “controller” to decide when and how to intervene to move the behavior in the desired direction (e.g., to increase the daily step count). What is notable about this approach is that the controller is constantly updating its model based on continual observation of the person's behavior and response to interventions, so that subsequent intervention decisions are always based on the updated model, one that

progressively better describes the idiosyncrasies of each user's behavior. Although control systems engineering has been used successfully to manage complex processes for decades, its application to mobile health is still in its infancy (see Hekler et al. 2018 for the state of the field).

### 19.2.5 Supporting Self-Experimentation

---

We see a growing interest in supporting patients and laypeople to design and conduct self-experimentation in personalized health. Although traditional clinical studies (e.g., epidemiological surveys, longitudinal studies, and randomized controlled trial) provide relevant knowledge at the population level, they do not provide the necessary knowledge for any given individual. On the other hand, in self-experimentation (or n-of-1 trials), an individual serves as their own control, allowing them to systematically explore a specific hypothesis (e.g., Does caffeine impact my sleep?) of their interest. To support laypeople in designing and conducting scientifically rigorous self-experimentations, researchers designed self-experimentation platforms leveraging mobile devices' continuous monitoring and capture capabilities. PACO and IFTTT<sup>28</sup> can be used as a general-purpose self-experimentation platform due to their random notification and tracking features (Evans 2016). Domain-specific self-experimentation platforms can provide customized support. For example, TummyTrials (Karkar et al. 2017) helps people identify food triggers, and SleepCoacher (Daskalova et al. 2016) helps identify connections between potential sleep disruptors and sleep quality. Despite some underlying limitations of self-experimentations—such as carryover effects and blinding—self-experimentation augmented with mHealth technologies has great potential to leverage personal knowledge and advance personalized medicine (Lillie et al. 2011).

## 19.3 Broad Considerations and Challenges

---

All health technologies have associated pragmatic challenges and ethical issues regarding privacy and security, impact on people's work, the potential to increase health disparities, and regulatory issues. In this section, we focus on aspects of those issues that are unique to or particularly problematic for mHealth applications.

### 19.3.1 Privacy and Security

---

For mHealth technologies, the key privacy and security concerns center around the personal data that can be obtained from a device that is always or nearly always with you. Information that could be collected from one's mobile device includes a great deal that people often want to keep private, such as their location, time spent with the device on, other apps used (including the duration and frequency of use), websites visited, search terms used, etc. Often those data are stored "in the cloud," making it vulnerable to hackers, and allowing the applications to sell or use the data for other purposes. An alternative to such cloud-based systems would be to store all the information only on one's mobile device, so that no other system has access to it. However, then the user is vulnerable to the loss of such important data if the mobile device is lost or damaged. Although many applications claim to use or sell only aggregate, anonymized data, the amount and kind of data collected from one's mobile device make it particularly vulnerable to reidentification. In addition, people tend to agree to terms of service without reading them, and thus, likely have little knowledge about what data are available to others.

An additional challenge for mHealth applications comes from its ubiquitous nature—others could easily observe notifications or reminders on someone's mobile screen because the screen is often visible to many others throughout the day. Much harm can come from the disclosure of such private information, whether it is from observing the

---

28 IFTTT. Retrieval June 13, 2019: ► <https://ifttt.com/>

information on the screen or from gathering stored data. For example, location logs could be used to disclose businesses or locations a person has visited when and or for how long, or to predict where a person will be when, which could endanger someone who needs to conceal their whereabouts for safety reasons. Although most mobile operating systems now attempt to make such location tracking optional, many mHealth apps need such data to function fully. For example, fitness trackers need location data to accurately record users' activity. Thus, users often must choose between using an mHealth application and keeping their data private.

### 19.3.2 Changes in Clinician Work

---

The proliferation of these mHealth apps brings the potential for substantive changes in clinician work as well as for clinician-patient interactions. Because many people are now using mHealth apps to generate huge amounts of detailed health data, people could expect clinicians to use those data to gain new insights into a person's health and positively influence their care. However, the volume and variety of data as well as applications that generated the data make it challenging for clinicians to incorporate the new data into their workflow. A literature review of empirical studies of self-tracking tools identified many clinician work-related concerns about information quality and the lack of standards for representing or viewing that data (West et al. 2016, 2017). Yet, recent research points to the value of human-centered design approaches to addressing these concerns. For example, one study of DataMD showed that such an approach could help clinicians develop a new workflow that would allow them incorporate this kind of data and improve their counseling skills and support more in-depth conversations (Kim et al. 2017).

Yet, irrespective of good design, the real-time sensing nature of the data creates other workflow concerns, particularly ethical and legal expectations that clinicians respond to the sensed data promptly. For example, mental health providers could be expected to

intervene immediately when a mobile sensor indicates a high likelihood that their client could harm themselves or others. Although such responsiveness could improve outcomes, these expectations could lead to further problems with clinician burnout and challenges with patient autonomy and confidentiality. Physicians are already experiencing a greater increase in burnout and reduction in satisfaction with work-life balance than peer adults in the U.S. (Shanafelt et al. 2015). However, a scoping review of physician well-being in the mHealth context showed that these technologies are playing important roles in the improvement of physicians' well-being too (Chen et al. 2018). Such advances are additionally changing both the nature and amount of patient-clinician interactions. We have much to learn about how clinicians' use of these new mHealth technologies and their response to patients' use of the technologies will affect clinicians' work.

### 19.3.3 Changes in Patient Work

---

This increasing prevalence of mHealth apps are changing the work and personal lives of the people who use these tools to assist in their everyday health and well-being. With constant sensing of our health comes the potential for unhealthy disruptions to daily life. Even simple apps that count steps for physical fitness typically interrupt people when they have reached their step goal or remind people to get up and move during the day. Although these rewards and reminders can help people meet their health goals, such disruptions can come at inopportune times or places and negatively impact people's overall well-being. Many apps allow people to disable those disruptive features, but then they risk missing important information or reminders that could be key to its successful use. Frequent tracking and constant reminders of one's health can also lead to detrimental obsessions. For example, one study examined the effect of tracking technology on college students and found that those students who used fitness trackers had higher levels of eating concerns and symptoms of eating disorders (Simpson

and Mazzeo 2017). Other studies have shown that such tracking can make healthy activities that people used to enjoy feel more like work and lead to a decrease in those activities and subjective well-being (Etkin 2016). Furthermore, people could become overly reliant on the objectively sensed but not necessarily accurate data and discount their own or others' subjective experiences.<sup>29</sup>

Nonetheless, such widespread availability of mobile health apps also brings unprecedented power to everyday people in their ability to collect new forms of data about their own health and to interpret that data independently from clinicians. For example, HemaApp allows people with anemia or pulmonary illnesses to detect and monitor total hemoglobin in their blood using a smartphone's camera and flash, rather than requiring a visit to a clinician's office for a blood draw and follow up visit about their results (Wang et al. 2016). Many other apps, such as BiliScreen for jaundice detection and pancreatic cancer screening (Mariakakis et al. 2017) and SpiroSmart for assessing lung function (Larson et al. 2012), allow people to detect health problems or monitor existing problems that previously required a clinician visit.

### 19.3.4 Health Disparities

Despite the increasing uptake of mobile phones by people—regardless of race, age, or socioeconomic status—and the high prevalence of smartphone usage (81% of all U.S. adults),<sup>30</sup> concerns still remain about whether increased reliance upon such mobile technologies will exacerbate existing health disparities. A recent systematic review examined the research literature to investigate mHealth interventions for vulnerable populations

(Stowell et al. 2018). They identified familiarity with the technology, use of engaging multimedia content, frequent delivery of content, and personalization as facilitators in successful interventions. However, costs and concerns about confidentiality and privacy (particularly for those who hadn't completed their immigration paperwork) were substantial barriers. Although a slight majority of the reviewed studies showed significant improvements in the evaluated health measures, their meta-analysis failed to show that the mHealth interventions successfully impacted health outcomes in vulnerable populations. Researchers are beginning to work together to identify opportunities for socio-technical interventions to reduce health disparities (Siek et al. 2019), but much work remains.

### 19.3.5 Regulatory Issues

The staggering number of mHealth apps that are available in the marketplace makes it challenging for clinicians, patients, and the general public to discern which apps are effective and safe to adopt. Many worry about the proliferation of these mHealth apps, particularly the wide variation in quality, potential misleading or unsubstantiated claims, and the vulnerability of disclosure of personal health information. The US Food and Drug Administration (FDA) is the regulatory body that could provide such safety and effectiveness oversight of mHealth apps, but its role and influence has been changing. In 2013, 2015, and 2019, the FDA revised its guidance about what it will regulate in the mHealth space and is now focusing only on apps that pose a great risk if they do not work as intended.<sup>31</sup> The regulations pertain to apps that diagnose, treat, or prevent a health condition. To help developers determine what laws and

regulations apply to their mHealth apps, the FDA created an interactive tool that poses questions and summarizes the applicability of the laws based on the answers.<sup>32</sup> In the private sector, Xcertia serves as an mHealth app collaborative effort of the American Medical Association (AMA), the American Heart Association (AHA), DHX Group and the Healthcare Information and Management Systems Society (HIMSS) “to foster safe, effective, and reputable health technologies.”<sup>33</sup> They have developed a set of guidelines for assessing operability, privacy, security, content, and usability. Clearly, the safety and regulation of mHealth apps will remain a key issue for the future.

## 19.4 Future Directions

The rapidly changing nature of technology makes writing a book chapter on any aspect of it challenging, but anticipating future directions is even more daunting. All aspects of this book face that challenge, but the field of mHealth and the applications that characterize it are especially dynamic. Exact statistics are hard to find and rapidly out of date, but nonetheless paint a picture of mHealth’s growing influence. A 2017 report from IQIA reports that over 318,000 mHealth apps were available worldwide and that more than 200 health apps are added each day.<sup>34</sup> According to App Annie’s State of Mobile 2019 Report, the global download of mHealth apps exceeded 400 million in 2018 with the growth

coming from many different countries.<sup>35</sup> Grand View Research predicts that the global market for mHealth apps will reach 236 billion in US dollars by 2026 with fitness as the largest type of mHealth app.<sup>36</sup>

Some see the future of mHealth through the eyes of science fiction. In particular, many have envisioned Star Trek’s® tricorder-like technology of a small, hand-held device that could quickly diagnose a variety of medical conditions. Qualcomm incentivized this vision with its \$10 million XPRIZE competition to develop a mHealth device that could accurately diagnose 13 medical conditions, capture 5 real-time health vital signs, and provide a compelling consumer experience, without input from a healthcare professional or facility.<sup>37</sup> Although no one was able to meet all their criteria, Final Frontier Medical Devices (now Basil Leaf Technologies<sup>38</sup>) received the top prize of \$2.5 million with their DxtER device that employed non-invasive sensors to collect vital signs, body chemistry, and biological functions.<sup>39</sup> Many others have alternative, grand views of the future of mHealth apps. One point is clear: mHealth applications will continue to influence all aspects of healthcare—from wellness and prevention through

### Questions for Discussion

- What challenges does the rapid evolution of mobile technologies and platforms (OS) pose to the people who develop mHealth interventions?
- What are some of the ways in which mHealth technologies are designed for health professionals? In designing such tools, what are some key design considerations?
- How can lay individuals access their own data collected from mHealth technologies? In what cases such data access might be useful for individuals?
- In addition to creating new ways to deliver health interventions, mHealth has been seen as having the potential to greatly advance health research, including fields such as epidemiology. How can mHealth tools advance our understanding of factors that shape individuals' health?
- What are just-in-time adaptive interventions and how do mHealth tools enable this type of health intervention?
- Most patient-centered mHealth tools are discretionary use technologies, in the sense that individuals can choose whether, how much, and for how long to use these devices and applications. Yet, for these tools to have a hope of being effective, they have to be used. Given what learned in this chapter, what aspects of mHealth tools can facilitate and hinder engagement? How can mHealth designers make these tools more engaging so individuals can benefit from them?

  - 20.3.8 The Emergence of Telehealth during a Global Pandemic – 684
- 20.4 Challenges and Future Directions – 684**
  - 20.4.1 Challenges to Using the Internet for Telehealth Applications – 684
  - 20.4.2 Licensure and Economics in Telehealth – 685
  - 20.4.3 Logistical Requirements for Implementation of Telehealth Systems – 687
  - 20.4.4 Telehealth in Low Resource Environments – 687
  - 20.4.5 Future Directions – 688
- References – 690**

## Learning Objectives

After reading this chapter you should know the answers to these questions:

- What are the key informatics requirements for successful implementation of telehealth systems?
- What are some key benefits from and barriers to implementation of telehealth systems?
- What are the most promising emerging application domains for telehealth?

## 20.1 Introduction

Complexity and collaboration characterize health care in the early twenty-first century. Complexity arises from increasing sophistication in the understanding of health and disease, wherein etiological models must acknowledge both molecular processes and physical environments. Collaboration reflects not only inter-professional collaboration, but also a realization that successful attainment of optimal well-being and effective management of disease processes necessitate active engagement of clinicians, lay persons, family members, communities, and society as a whole. This chapter introduces the concepts of **telemedicine** and **telehealth**, and illustrates how advanced networks make possible the collaborations necessary to achieve the full benefits of our growing understanding of health promotion, disease management and rehabilitation. Consider the following situation:

Samuel is a 76-year-old man with coronary artery disease, poorly-controlled Type II diabetes, and high blood pressure. He lives alone in a rural area and does not drive. His daughter lives further away but visits occasionally. One of his neighbors visits regularly to check on him and assist with various errands. In the past, Samuel has been unable to keep medical appointments consistently because of difficulty arranging transportation. He had a recent acute hyperglycemic episode that required hospitalization. After 4 days he is medically stable and ready for discharge. He is able to measure his blood glucose and can safely administer the appropriate dose of

insulin. The nurse notes that Samuel sometimes has trouble calibrating his insulin dose to the blood glucose reading.

### 20.1.1 Telemedicine and Telehealth to Reduce the Distance Between the Consumer and the Health Care System

Historically, health care has usually involved travel. Either the health care provider traveled to visit the patient, or more recently, the patient traveled to visit the provider. Patients with diabetes, like Samuel whom we will be discussing later and throughout the chapter, typically meet with their physician every 2–6 months to review data and plan therapy changes. Travel has costs, both directly, in terms of gasoline or transportation tickets, and indirectly, in terms of travel time, delayed treatment, and lost productivity. In fact, travel has accounted for a significant proportion of the total cost of health care (Starr 1982). Because of this, both patients and providers have been quick to recognize that rapid electronic communications have the potential to improve care by reducing the costs and delays associated with travel. This has involved both access to information resources, as well as communication among various participants, including patients, family members, primary care providers and specialists whether it is synchronous communication (where all stakeholders interact at the same time) or asynchronous (where information is exchanged with a time lag).

As is the case with informatics, the formal definitions of telemedicine and telehealth tend to be very broad. **Telemedicine** involves the use of modern information technology, especially two-way interactive audio/video communications, computers and telemetry to deliver health services to remote patients and to facilitate information exchange between primary care physicians and specialists at some distance from each other (Bashshur et al. 2009). **Telehealth** is a somewhat newer and broader term referring to remote health care that includes clinical and social services provided

using telemedicine, as well as interactions with automated systems or information resources. Because of its broader scope, we are using the term telehealth in this chapter.

As is the case with biomedical informatics, there are many different sub-domains within telehealth. For nearly every clinical domain, there is a “tele-X” or “X telehealth”, where X is the clinical domain. Examples include: **Teleradiology** (see ▶ Sect. 20.3.4); **Teleophthalmology** (see ▶ Sect. 20.3.4); **Telepsychiatry** (see ▶ Sect. 20.3.5); and, **home telehealth** (see ▶ Sect. 20.3.5). Some sub-domains do not fit neatly into this naming paradigm. **Correctional Telehealth** (see ▶ Sect. 20.3.5) refers to the location of the patient in a prison. It is discussed separately because of the unique business model, and the fact that it represents an early and sustained success. **Remote Intensive Care** (see ▶ Sect. 20.3.5) is the term used to describe the use of telehealth technologies in an ICU setting. **Teleconsultation** is a general term describing the use of telehealth technologies to support discussions between clinicians, or between a clinician and a patient. The archetypal teleconsultation occurs when the patient and the generalist clinician are in a rural or remote location and a specialist is at a distant tertiary referral facility. **Telepresence** (see ▶ Sect. 20.3.6) refers to high-speed, multi-modality telehealth interactions, such as **Telesurgery**, that gives the feeling of “being there”. In this chapter we will review how some of these sub-domains may play a role in supporting Samuel manage their health care needs more effectively.

It is clear from the definition above that there is considerable overlap between telehealth and biomedical informatics. In fact, one will frequently find papers on telehealth systems presented at biomedical informatics conferences and presentations on informatics at telehealth and telemedicine meetings. Some groups, especially in Europe, have adopted the rubric **health information and communication technology** (HICT). The major distinction is one of emphasis. Telehealth and telemedicine emphasize the notion of distance, especially

the provision of care to remote or isolated patients and communities. In contrast, biomedical informatics emphasizes methods for handling the information moving between the participants, irrespective of the distance between patient and provider.

**Consumer health informatics** (CHI), also called **personal health informatics** (PHI), is a related domain that bridges the distance between patients and health care resources, and that typically emphasizes interactions with computer-based information such as websites or information resources. Collectively, CHI and telehealth deliver health care knowledge and expertise to where they are needed, and are ways to involve the patient as an active partner in care. Despite their similarities, CHI and telehealth come from very different historical foundations. Telehealth derived from traditional patient care, while CHI derived from the self-help movements of the 1970’s. Largely owing to this historical separation, practitioners and researchers in the two fields tend to come from different backgrounds. For these reasons, we are presenting CHI and telehealth as two distinct, but closely related domains (see ▶ Chap. 11 for more information on personal health informatics).

## 20.2 Historical Perspectives

The use of communication technology to convey health-related information at a distance is nothing new. The earliest known example may be the use of so-called “leper bells” carried by individuals during Roman times. Sailing ships would fly a yellow flag to indicate a ship was under quarantine and awaiting clearance by a doctor, or a yellow and black “plague flag” to indicate that infected individuals were on board. By some accounts, when Alexander Graham Bell said “Mr. Watson. Come here. I need you” in 1876, it was because he had spilled acid on his hand and needed medical assistance. In 1879, only 3 years later, the first description of telephone use for clinical diagnosis appeared in a medical journal (Practice by Telephone 1879).

### 20.2.1 Early Experiences

One of the earliest and most long-lived telehealth projects is the Australian Royal Flying Doctor Service (RFDS), founded in 1928 and continuing to this day. In addition to providing air ambulance services, the RFDS provides telehealth consultations. These consultations first used Morse Code, and later voice, leveraging radio communications to the remote sheep stations in the Australian outback. Lay people played a significant role here, clearly communicating their concerns and clinical findings to the RFDS and carefully carrying out instructions while awaiting, if necessary, the arrival of the physician. The RFDS is most famous for its standardized medical supply chest, introduced in 1942. The chest contains diagnostic charts and medications, identified only by number. This allowed the consulting clinician to localize symptoms by number and then prescribe care, such as “take one number five and two number fours.”

Modern telehealth can be traced to 1948 when the first transmission of a radiograph over a phone line was reported. Video-based telehealth can be traced to 1955 when the Nebraska Psychiatric Institute began experimenting with a closed-circuit video network on its campus. In 1964 this was extended to a remote state mental health facility to support education and **teleconsultation**. In 1967, Massachusetts General Hospital (MGH) was linked to Logan International Airport via a microwave audio-video link (Bird 1972; Murphy et al. 1973). In 1971 the National Library of Medicine began the Alaska Satellite Biomedical Demonstration project linking 26 remote Alaskan villages utilizing NASA satellites (Hudson and Parker 1973).

The period from the mid 1970’s to the late 1980’s was a time of much experimentation, but few fundamental changes in telehealth. A variety of pilot projects demonstrated the feasibility and utility of video-based telehealth. The military funded a number of research projects aimed at developing tools for providing telehealth care on the battlefield. The early 1990’s saw several important advances.

Military applications developed during the previous decades began to be deployed. Military **telerradiology** was first deployed in 1991 during Operation Desert Storm. Telehealth in military field hospitals was first deployed in 1993 in Bosnia. Several states, including Georgia, Kansas, North Carolina and Iowa implemented statewide telehealth networks. Some of these were pure video networks, based on broadcast television technology. Others were built using evolving Internet technology. During this same period, correctional telehealth (see ► Sect. 20.3.5) became much more common. For example, in 1992 East Carolina University contracted with the largest maximum-security prison in North Carolina to provide telehealth consultation.

Telehealth projects in the early 1990s continued to be plagued by two problems that had hampered telehealth since its inception: high cost and poor image quality. Both hardware and **high-bandwidth** connections were prohibitively expensive. A single telehealth station typically cost over \$50,000 and connectivity could cost thousands of dollars per month. Most programs were dependent on external grant funding for survival. Even with this, image resolution was frequently poor and **motion artifacts** were severe.

The Internet revolution that began in the late 1990s drove fundamental change in telehealth. Advances in computing power both improved image quality and reduced hardware costs to the point that, by 2000, comparable systems cost less than a tenth of what they had a decade earlier. Improvements in **image compression** made it possible to transmit low-resolution, full-motion video over standard telephone lines, enabling the growth of telehome care. With the increasing popularity of the World Wide Web, high-bandwidth connections became both more available and less expensive. Many telehealth applications that had relied on expensive, dedicated, point-to-point connections were converted to utilize commodity Internet connections. The availability of affordable hardware and connectivity also made access to health-related electronic resources from the home, school

or work place possible and fueled the growth of consumer health information. In 2020, the COVID-19 pandemic highlighted the potential of telehealth in facilitating essential health care services and led to an expedited adoption of telehealth services across many health systems worldwide (Jain et al. 2020).

### 20.2.2 Recent Advances in Medical-Grade Broadband Technology

---

As telemedicine applications are being increasingly used in critical medical situations such as emergency care and remote surgery applications, quality of service (QOS) becomes extremely important. It is important to note that optimally provisioning a network for medical-grade QOS does not simply imply that the network will provide “quality” in the sense of reliability, consistency and bandwidth performance, although these characteristics are certainly important requirements. Any network, no matter the bandwidth available, can become congested – overwhelmed with the volume of traffic to the extent that sessions are interrupted and data lost. Bandwidth availability limitations are particularly prevalent in rural locations where high-capacity circuits may be unavailable or prohibitively expensive.

Newer network routing technologies such as **multiprotocol label switching (MPLS)** can, in addition to providing superior network throughput performance, permit explicit prioritization of clinical traffic while simultaneously providing access to lower priority administrative and other non-clinical traffic. The individual data packets of high priority traffic (e.g., telehealth or patient monitoring sessions) are “tagged” with a numerical priority flag. As the QOS-tagged packets traverse the network, each routing/switching device recognizes the priority tag and preferentially processes and forwards the packets. This explicit QOS combined with advanced security and privacy features within a broadband network has been characterized as “Medical Grade” broadband.

## 20.3 Bridging Distance with Informatics: Real-World Systems

---

There are many ways to categorize telehealth resources, including classifications based on participants, bandwidth, information transmitted, medical specialty, immediacy, health care condition, and financial reimbursement. The categorization in [Table 20.1](#) is based loosely on bandwidth and overall complexity. This categorization was chosen because each category presents different challenges for informatics researchers and practitioners.

A second categorization of telehealth systems that overlaps the previous one is the separation into synchronous (or real-time) and asynchronous (or **store-and-forward** systems). Video conferencing is the archetypal synchronous telehealth application. Synchronous telehealth encounters are analogous to conventional office visits. Telephony, chat-groups, and **telepresence** (see [▶ Sect. 20.3.6](#)) are also examples of synchronous telehealth. A major challenge in all synchronous telehealth is scheduling. All participants must be at the necessary equipment at the same time.

Store-and-forward, as the name implies, involves the preparation of a dataset at one site that is sent asynchronously to a remote recipient. Remote interpretation, especially teleradiology, is the archetypal example of store-and-forward telehealth. Images are obtained at one site and then sent, sometimes over very low bandwidth connections, to another site where the domain expert interprets them. Other examples of store-and-forward include access to Web sites, e-mail and text messaging. Some store-and-forward systems support the creation of multimedia “cases” that contain multiple clinical data types, including text, scanned images, wave forms and videos.

### 20.3.1 The Forgotten Telephone

---

Until recently, the telephone was a forgotten component in telehealth. The field of telemedicine and telehealth focused on video

**Table 20.1** Categories of telehealth and consumer health informatics

Telehealth category	Bandwidth	Applications
Information resources	Low to moderate	Web-based information resources, patient access to electronic medical records
Messaging	Low	E-mail, chat groups, consumer health networks, personal clinical electronic communications (PCEC)
Telephone	Low	Scheduling, triage
Remote monitoring	Low to moderate	Remote monitoring of pacemakers, diabetes, asthma, hypertension, Congestive Heart Failure (CHF).
Remote interpretation	Moderate	PACS, remote interpretation of radiographic studies and other images, such as dermatologic and retinal photographs.
Videoconferencing	Low to high	Wide range of applications, from telehome care to telerobotics and telepsychiatry
Telepresence	High	Remote surgery, telerobotics

and largely ignored the audio-only telehealth. This is paradoxical given that up to 25% of all primary care encounters occur via the telephone. These include triage, case management, results review, consultation, medication adjustment and logistical issues, like scheduling. In part, this can be traced to the fact that telephone consultations are not reimbursed by most insurance carriers.

More recently, increased interest in cost control through case management has driven renewed interest in use of audio-only communication between patients and providers. Multiple articles have appeared on the value of telephone follow-up for chronic conditions (Downes et al. 2017; Jayakody et al. 2016). Several managed care companies have set up large telephone triage centers. The National Health Service in the UK is investing £123 million per year in NHS Direct, a nation-wide telephone information and triage system that handles 27,000 calls per day.

### 20.3.2 Electronic Messaging

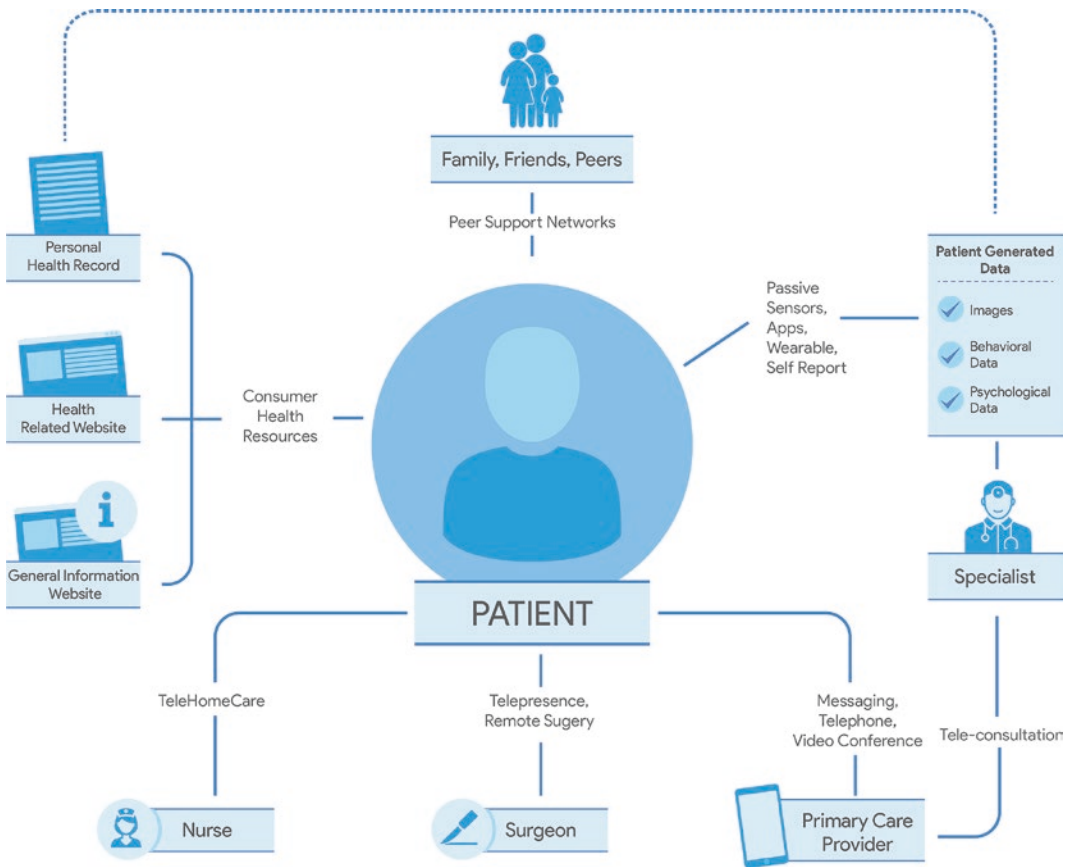

Electronic text-based messaging has emerged as a popular mode of communication between patients and providers. It began with patients sending conventional e-mails to physicians. The popularity of this grew so rapidly that

national guidelines were developed (Kane and Sands 1998). However, e-mail has a number of disadvantages for health-related messaging: delivery is not guaranteed; privacy and security are problematic; e-mail is transient (there was no automatic logging or audit trail); and the messages are completely unstructured.

To address these limitations, a variety of Web-based messaging solutions, called **personal clinical electronic communications**, have been developed (Sarkar and Starren 2002). Because the messages never leave the Web site, many of the problems associated with conventional e-mail are avoided. Web-based messaging is a standard feature of **patient portals** see ► Chap. 11) associated with many EHRs. The inclusion of messaging as a Meaningful Use requirement for Certified EHRs significantly increased the use of web-based messaging to provide telehealth (■ Fig. 20.1).

### 20.3.3 Remote Monitoring

**Remote monitoring** is a subset of telehealth focusing on the capture of clinically relevant data in the patients' homes or other locations outside of conventional hospitals, clinics or health care provider offices, and the subsequent transmission of the data to central locations for review. The conceptual model

**Fig. 20.1** Connections. The figure shows different ways that electronic communications can be used to link patients with various health resources. Only connections directly involving the patient are shown (e.g., use of the EHR by the clinician is not shown). Patient generated data are created via passive monitoring (such as home-

based sensors) or active monitoring (such as wearables or other active monitoring devices) in the patient's home or other community settings. Other resources, such as remote surgery or imaging, would require the patient to go to a telehealth-equipped clinical facility

underlying nearly all remote monitoring is that clinically significant changes in patient condition occur between regularly scheduled visits and that these changes can be detected by measuring physiologic parameters.

The care model presumes that, if these changes are detected and treated sooner, the overall condition of the patient will be improved. An important distinction between remote monitoring and many conventional forms of telemedicine is that remote monitoring focuses on management, rather than on diagnosis. Typically, remote monitoring involves patients who have already been diagnosed with a chronic disease or condition. Remote monitoring is used to track param-

eters that guide management. Any measurable parameter is a candidate for remote monitoring. The collected data may include continuous data streams or, more commonly, discrete measurements.

Another important feature of most remote monitoring is that the measurement of the parameter and the transmission of the data are typically separate events. The measurement devices have a memory that can store multiple measurements. The patient will send the data to the caregiver in one of several ways. For many studies, the patient will log onto a server at the central site (either over the Web or by direct dial-up) and then type in the data. Alternately, the patient may connect the

measurement device to a personal computer or specialized modem and transfer the readings electronically.

More recently, a variety of monitoring devices have been developed that either connect directly to mobile telephones or transmit the data to the mobile phone using Bluetooth wireless. The mobile phone then transmits the data to a provider for review. A major advantage of direct electronic transfer is that it eliminates problems stemming from manual entry, including falsification, number preference and transcription errors. The role of mobile telephones in providing health services has grown so rapidly that the term **mobile health** (or “mHealth”) has been coined. The term appeared first, one time, in 2004 in PubMed. See ► Chap. 19 for more on mHealth systems. Additionally, the emergence of interconnected sensors and devices referred to as **Internet of Things (IoT)** described later in the chapter, have the potential to contribute to remote monitoring systems.

Any condition that is evaluated by measuring a physiologic parameter is a candidate for remote monitoring. The parameter most measured in the remote setting is blood glucose for monitoring diabetes. A wide variety of research projects and commercial systems have been developed to monitor patients with diabetes. Patients with asthma can be monitored with peak-flow or full-loop **spirometers**. Patients with hypertension can be monitored with automated blood pressure cuffs. Patients with congestive heart failure (CHF) are monitored by measuring daily weights to detect fluid gain. Remote monitoring of pacemaker function has been available for a number of years and has recently been approved for reimbursement. Home coagulation meters have been developed that allows the monitoring of patients on chronic anticoagulation therapy. See a discussion on remote intensive care later in the chapter and also ► Chap. 21 for more on patient monitoring systems.

Several factors limit the widespread use of remote monitoring. First is the question of efficacy. While these systems have proven acceptable to patients and beneficial in small studies, few large-scale controlled trials have been done. Second is the basic question of

who will review the data. Research studies have utilized specially trained nurses at centralized offices, but it is not clear that this will scale up. Third is money—for most conditions, remote monitoring is still not a reimbursed activity.

### 20.3.4 Remote Interpretation

Although Samuel was diagnosed with Type II diabetes over 20 years ago and realizes that visual loss can be a serious complication, he has only rarely received dilated eye exams for retinopathy screening. There is no eye doctor conveniently located near his home, and he feels that the appointments are always too long and that he has no problems such as blurred vision. However, his primary care doctor has recently implemented a new retinal screening machine in the office. During a routine medical examination, Samuel receives a retinal photograph from an office technician that is then interpreted by a remote ophthalmologist. Samuel is told that he has high-risk diabetic retinopathy that requires treatment to prevent visual loss. He is emergently referred to an ophthalmologist, who performs a successful laser procedure to treat the diabetic retinopathy.

**Remote interpretation** is a category of store-and-forward telehealth that involves the capture of images, or other data, at one site and their transmission to another site for interpretation. This may include radiographs (*teleradiology*), photographs (*teledermatology*, *teleophthalmology*, *telepathology*), wave forms such as ECGs (e.g. *telecardiology*), and text-based medical data.

The store-and-forward telehealth modalities have benefited most from the development of the **commodity Internet** and the increasing availability of affordable high bandwidth connections that it provides. The shared commodity Internet provides relatively high bandwidth, but the available bandwidth is continuously varying. This makes it much better suited for the transfer of text-based data and image files, rather than for streaming data or video connections. Although image files are often tens or hundreds of megabytes

in size, the files are typically transferred to the interpretation site and cached there for later interpretation. From a logistical perspective, multiple remote interpretations may be batched and performed together, thereby providing important workflow and convenience advantages over traditional medical examinations or real-time video telehealth paradigms.

#### ■ Teleradiology

By far, teleradiology is the largest category of remote interpretation, and probably the largest category of telehealth. Teleradiology (along with telepathology) represents the most mature clinical domain in telehealth. With the deployment of **picture archiving and communications systems** (PACS) that capture, store, transmit and displays digital radiology images, the line between teleradiology and conventional radiology is blurring. In fact, routine medical care in radiology and pathology is increasingly being delivered primarily through “telehealth” strategies (Radiology image management is discussed in more detail in ► Chap. 22).

Many factors have contributed to the more rapid adoption of telehealth in domains such as radiology and pathology. One important factor is the relationship between these specialists and their patients. In both domains, the professional role is often limited to the interpretation of images, and the specialist rarely interacts directly with the patient. To patients, there is therefore little perceived difference between a radiologist in the next building and one in the next state.

An important factor driving the growth of teleradiology is that it is reimbursable by insurance payers. Because image interpretation does not involve direct patient contact, few payers make any distinction about where the interpretation occurred. Rapid dissemination of teleradiology systems has also been supported by widespread adoption of vendor-neutral image storage and transmission standards such as **Digital Imaging and Communication in Medicine** (DICOM; discussed in more detail in ► Chaps. 7 and 22). Finally, numerous evaluation studies have demonstrated that digital image interpretation by through teleradiology has compara-

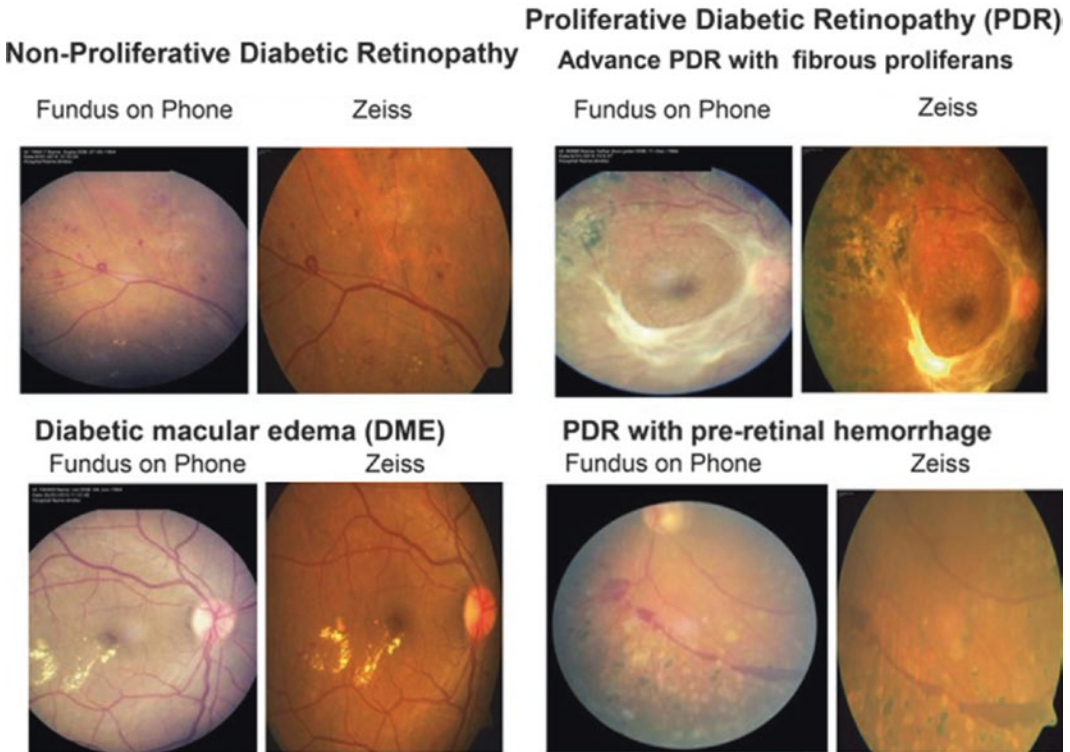

ble, or potentially even better, accuracy and efficiency compared to traditional film-based radiological examination (Franken et al. 1992; Mackinnon et al. 2008; Reiner et al. 2002).

#### ■ Teleophthalmology

Another area of remote interpretation that is growing rapidly is teleophthalmology, particularly for retinal disease screening. As one example, diabetic retinopathy (retinal disease) is a leading cause of blindness that can be treated if detected early. However, it has been found that nearly 50% of diabetics are non-compliant with guidelines recommending annual screening eye examinations (Brechnner et al. 1993). Systems have been developed that allow nurses or technicians in primary care offices to obtain high quality digital retinal photographs. These images are sent to regional centers for interpretation. If diabetic retinopathy is identified or suspected, the patient is referred for full ophthalmologic examination.

Large-scale operational systems have been implemented by the Veterans Health Administration and by other institutions, particularly in areas with limited accessibility to eye care specialists (Cavalleranno et al. 2005; Cuadros and Bresnick 2009). In fact, remote interpretation of retinal images by certified reading centers, when taken after dilation of the eyes using standard photographic protocols originally developed for clinical research trials, has been demonstrated to classify diabetic retinopathy more accurately than traditional dilated eye examination. This is likely because retinal abnormalities found on photographs may be reviewed in more detail than what is generally feasible during traditional eye examinations.

Another application of teleophthalmology is in retinopathy of prematurity (ROP), a leading cause of blindness in premature infants, whereby hospitalized infants are examined regularly to identify treatment-requiring disease. However, these examinations are logistically difficult and time consuming, and the number of ophthalmologists willing to perform them has decreased. As a result, systems have been developed in which trained nurses capture retinal photographs and transmit

■ **Fig. 20.2** Retinal images of diabetic retinopathy obtained via a fundus on phone (FOP) smartphone system compared to a professional Zeiss camera tradition-

ally used by optometrists. (Source: Rajalakshmi et al. 2015) Creative Common Attribution

them to experts for remote interpretation (Richter et al. 2009). The proliferation of smartphones has introduced additional ways to promote teleophthamology, using a “fundus on phone” (FOP) camera to facilitate a smartphone-based cost-effective retinal imaging system (■ Fig. 20.2).

### 20.3.5 Video-Based Telehealth

To many people telehealth is videoconferencing. Whenever the words “telehealth” or “telemedicine” are mentioned, most people have a mental image of a patient talking to a doctor over some type of synchronous video connection. Indeed, most early telehealth research did focus on synchronous video connections. For many of the early studies, the goal was to provide access to specialists in remote or rural areas. Nearly all of the early systems utilized a hub-and-spoke topology where one hub,

usually an academic medical center, was connected to many spokes, usually rural clinics.

Many of the early telehealth consults involved the patient and the primary care provider at one site conferring with a specialist at another site. Most of the state-wide telehealth networks operated on this model. This was so engrained in the telehealth culture, that the first legislation allowing Medicare reimbursement of telehealth consults required a “presenter” at the remote site.

This requirement for a “presenter” exacerbated the scheduling problem. Because synchronous video telehealth often uses specialized videoconferencing rooms, the televisits need to be scheduled at a specific time. Getting the patient and both clinicians (expert and presenter) at the right places at the right time has forced many telehealth programs to hire a full-time scheduler. The scheduling problem, combined with the advent of more user-friendly equipment, ultimately led

Medicare to drop the presenter requirement. Even so, scheduling is often the single biggest obstacle to greater use of synchronous video consultations.

A second obstacle has been the availability of relevant clinical information. Because of the inability to interface between various EHRs, it was not unusual for staff to print out results from the EHR at one site and then to fax those to the other site prior to a synchronous video consultation.

Unlike store-and-forward telehealth, synchronous video requires a stable data stream. Although video connection can use conventional phone lines (commonly referred to as **plain old telephone service**, or POTS) that provide 64 bits-per-second (64 kbs) transmission speed, diagnostic quality video typically requires at least 128 Kbs and more commonly 384 Kbs. In order to guarantee stable data rates, synchronous video in clinically critical situations still relies heavily on dedicated circuits, either **Integrated Service Digital Network** (ISDN) connections or leased lines. Within single organizations, or in consultative or educational settings, Internet Protocol (IP) based video conferencing has become the dominant modality. While POTS-based telehealth systems were common in 1990s and even early 2000s, the diffusion of high-speed Internet has led to a much wider adoption of IP based videoconferencing. The anticipated growth of **5G (fifth generation wireless systems)** facilitating far higher speeds and connections with massive capacity and low latency for consumer devices, is expected to accelerate the use of telehealth for a broad spectrum of applications and target populations.

Synchronous video telehealth has been used in almost every conceivable situation. In addition to traditional consultations, the systems have been used to transmit grand rounds and other educational presentations. Video cameras have been placed in operating rooms at hub sites to transmit images of surgeries for educational purposes. Video cameras have been placed in emergency departments and operating rooms at spoke sites to allow experts to “telementor” less experienced physicians in the remote location. Video cameras

have also been placed in ambulances to provide remote triage.

More recently, the growing popularity of mobile devices is creating potential for new strategies involving real-time video communication between patients and health care providers. This is especially promising because mobile networks are low-cost and widely-available for consumers, and because they are increasingly accessible even in developing countries. However, health information exchange using mobile networks raises concerns about privacy, security, and compliance with **Health Insurance Portability and Accountability Act** (HIPAA). With appropriate encryption settings, wireless video communication using mobile device applications may be HIPAA-compliant (e.g. FaceTime; Apple Computer, Cupertino, CA). There are already various commercially available solutions that allow patients to download smartphone apps to access clinicians. Some of these apps use chatbot technology to screen symptoms before matching patients with clinicians who can communicate with text, images and videos and can e-prescribe to local pharmacies. In the future, these mobile technologies may provide additional opportunities for increased communication between patients and providers.

Prior to the adoption of IP-based videoconferencing, programs that begun with grant funding ended soon after the grant funding ended. Even after the advent of IP-based conferencing, many programs continued to struggle. This was in spite of the fact that Medicare had begun reimbursing for synchronous video under limited circumstances. The COVID-19 pandemic introduced short-term policy changes and led to an accelerated growth of telehealth as we discuss later (see ► Sect. 20.3.8).

Some rural health care providers, such as the Marshfield Clinic in Wisconsin, have integrated synchronous telehealth into their standard care model to provide routine specialist services to outlying location. Some categories of synchronous video telehealth have developed sustainable models: telepsychiatry, correctional telehealth; home telehealth, emergency telehealth, and remote intensive care.

### ■ Telepsychiatry

In many ways, psychiatry is the ideal clinical domain for synchronous video consultation. Diagnosis is based primarily on observing and talking to the patient. The interactive nature of the dialog means that store-and-forward video is rarely adequate. Physical examination is relatively unimportant, so that the lack of physical contact is not limiting. There are very few diagnostic studies or procedures, so that interfacing to other clinical systems is less important. In addition, state offices of mental health deliver a significant fraction of psychiatric services, minimizing reimbursement issues. This is illustrated by two projects. In 1995, the South Carolina Department of Mental Health established a telepsychiatry network to allow a single clinician to provide psychiatric services to deaf patients throughout the state (Afrin and Critchfield 1997). The system allowed clinicians, who had previously driven all over the state, to spend more time in patient care and less time traveling.

The system was so successful that it was expanded to multiple providers and roughly 20 sites. The second example comes from the New York State Psychiatric Institute (NYSPI), which is responsible for providing expert consultation to mental health facilities and prisons throughout the state. As in South Carolina, travel time was a significant factor in providing this service. To address the problem, the NYSPI created a videoconference network among the various state mental health centers. The system allows specialists at NYSPI in New York City to provide consultations in a timelier manner, improving care and increasing satisfaction at the remote sites.

### ■ Correctional Telehealth

Prisons tend to be located far from major metropolitan centers. Consequently, they are also located far from the specialists in major medical centers. Transporting prisoners to medical centers is an expensive proposition, typically requiring two officers and a vehicle. Depending on the prisoner and the distance, costs for a single transfer range from hundreds to thousands of dollars. Because of the high cost of transportation, correctional tele-

health was economically viable even before the advent of newer low cost systems.

Correctional telehealth also improves patient satisfaction. A fact surprising to many is that inmates typically do not want to leave a correctional institution to seek medical care. Many perceive it as stigmatizing to navigate a medical facility in prison garb. In addition, the social structure of prisons is such that any prisoner who leaves for more than a day risks losing privileges and social standing. Correctional telehealth follows the conventional model of providing specialist consultation to supplement to on-site primary care physicians. This has become increasingly important with the rising prevalence of AIDS in the prison population.

### ■ Home Telehealth

After Samuel misses two scheduled visits, the Diabetes Educator calls see what the matter is. Samuel explains that it is a 1-h drive from his home to the diabetes center, that his daughter had trouble taking time off from work to drive him, and that he would have difficulty leaving his wife home alone because she has been ill recently. The Diabetes Educator notes that Samuel lives in a rural area and is eligible to receive educational services via telehealth. She signs Samuel up to receive a Home Telehealth Unit and schedules delivery. The unit is initially difficult for him to use because he is not familiar with computer systems. However, after this initial learning process, Samuel rarely misses a video education session. At one visit, Samuel complains that his daughter who lives further away, is always “on his case” about his injections. The nurse schedules the next video visit during an evening when Samuel’s daughter can join the video-call. She also schedules Samuel to have a video visit with the dietician.

Somewhat paradoxically, one of the most active areas of telehealth growth is at the lowest end of the bandwidth spectrum—telehealth activities into patients’ homes. In the late 1990s, many believed that home broadband access would soon become ubiquitous and a number of vendors abandoned POTS-based systems in favor of IP-based video

solutions. The broadband revolution was slower than expected, especially in rural and economically depressed areas most in need of home telehealth services. A few research projects paid to have broadband or ISDN installed in patients' homes. In response to this, the American Telemedicine Association released new guidelines for Home Telehealth in 2002 in which synchronous video was provided over POTS connections. However, more recently high speed Internet and wireless networks have significantly expanded coverage in the US and abroad leading to a growth of high speed Internet based video delivery products. In addition to video, home telehealth systems typically have data ports for connection of various peripheral devices, such as a digital stethoscope, glucose meter, blood pressure meter, or spirometer or allow for Bluetooth connection.

Home telehealth can be divided into two major categories. The first category, often called **telehome care**, is the telehealth equivalent of home nursing care. It involves frequent video visits between nurses and, often homebound, patients. With the advent of prospective payment for home nursing care, telehome care is viewed as a way for home care agencies to provide care at reduced costs and potentially lead to a reduction of rehospitalization for home care patients with complex care needs. As with home nursing care, telehome care tends to have a finite duration, often focused on recovery from a specific disease or incident. Several studies have shown that telehome care can be especially valuable in the management of patients recently discharged from the hospital and can significantly reduce readmission rates.

The second category of home telehealth centers on the **management of chronic diseases**. Compared with telehome care, this type of home telehealth frequently involves a longer duration of care and less frequent interactions. Video interactions tend to focus on patient education, more than on evaluation of acute conditions. An important distinction between telehome care and disease management telehealth is that interactions in the former are initiated and managed by the nurse. Measurements, such as blood pressure, are

typically collected during the video visit and uploaded as part of the video connection. For disease management, the system also needs to support remote monitoring, patient-initiated data uploads and, possibly, Web-based access to educational or disease management resources.

One of the earliest, and the first large-scale project to examine the value of telemedicine systematically in the home setting, was the Informatics for Diabetes Education and Telemedicine (IDEATel) project (Starren et al. 2002). Started in 2000, the IDEATel project was an 8-year, \$60 million demonstration project funded by the Center for Medicare and Medicaid Services (CMS) involving 1665 diabetic Medicare patients in urban and rural New York State. In this randomized clinical trial, half of the patients received Home Telemedicine Units (HTU), and half continued to receive standard care. In addition to video, the HTU allowed patients to interact in multiple ways with their online charts. When patients measured blood pressure or fingerstick glucose, the encrypted results were transmitted to the Columbia University Web-based Clinical Information System (WebCIS; Hripacsak et al. 1999) at New York Presbyterian Hospital (NYPH). Nurse case managers monitored patients by reviewing the generated data and potential alerts, and providing consultation to patients.

In 2012 Steveton et al. (2012) published findings from one of the largest home telehealth randomized clinical trials to date. The trial was conducted in the UK and involved 179 general practices and 3230 people with diabetes, chronic obstructive pulmonary disease or heart failure who were randomly assigned to either usual care or the telehealth group that also received a set top box connected to their television capturing symptom questions and educational messages and various peripheral devices such as pulse oximeters, glucometers and digital weight scale for capturing and transmitting vital signs. The study demonstrated that home telehealth was associated with lower mortality and emergency department (ED) admission rates. That same year findings from another clinical trial (Takahashi et al. 2012) in the US revealed

different trends. In this study, 205 participants were randomly assigned to a telemonitoring group (including video, peripheral devices for vital signs and symptom reporting) or to usual care. No significant differences in hospitalizations and ED visits were found between the two groups; mortality however was higher in the telemonitoring group. This study did focus on frail older adults (with an average age over 80 years) and followed a different design and analytic approach.

The advancement of sensor technologies has led to the concept of “smart homes”, namely residential settings with embedded passive monitoring technologies to facilitate monitoring of residents with the goal to maximize their well-being and safety (Demiris and Hensel 2008). Passive monitoring tools utilize sensors to facilitate functional, safety or physiological monitoring or cognitive support or sensory aids, to monitor security or address social isolation. Examples include a bed sensor that detects restlessness at night or sleep interruptions, motion sensors that capture overall activity levels in the home, sedentary behaviors or bathroom visits, door sensors that measure time spent inside or number of visitors, gait sensors to assess gait characteristics and changes over time as well as fall risk (Liu et al. 2016; Reeder et al. 2013). Insight into behavioral health and activity levels along with more traditional home telehealth data sets such as vital signs and symptom reporting provide a more comprehensive assessment of one’s well-being (including not only the physiological but also the physical, social, mental and cognitive aspects of wellness (Dawadi et al. 2016)) introducing a new era for home telehealth. The rise of the Internet of Things (IoT), namely the diffusion of networks of devices, appliances and sensors that are interconnected and enable different passive monitoring components to exchange data and be remotely controlled (Lhotska et al. 2018), allows not only for monitoring of behavioral data but also for providing tailored responses to these observations (for example, adjusting lighting if unstable gait is detected or allowing a clinician to remotely adjust environmental parameters). These concepts are still emerging and technical, clinical and ethical impli-

cations have not been fully examined but it is certain that the future of home telehealth will encompass new data sets and tools, and expanded roles and responsibilities for clinicians, patients and families.

#### ■ Emergency Telemedicine

Samuel develops slurred speech and weakness on the right side of his body. His daughter, who happens to be with him at the time, calls 911. The ambulance crew notifies the emergency room that they are in route with a possible stroke victim. On arrival, the rural emergency department (ED) physician does a quick evaluation and connects via telemedicine with a stroke neurologist at an academic health center. The neurologist talks with the Samuel and his daughter, and participates in the examination with the ED physician. Following laboratory work and a CT negative for hemorrhage, the ED physician again consults with the neurologist who confirms the diagnosis of ischemic stroke and institutes thrombolytic therapy via pre-arranged protocol. Samuel is transferred to the intensive care unit for close monitoring of his diabetes, hypertension, and evolving stroke.

“Just in time” consultation in the emergency setting potentially represents one of the most beneficial uses of telehealth. Emergency telemedicine has been used in a variety of ways and has demonstrated significant benefits, including in such area as tele-trauma care, burn care, and critical care pediatric specialists consulting on critically ill or injured children (Heath et al. 2009; Ricci et al. 2003; Saffle et al. 2009). Telehealth in the emergency setting is likely to have the greatest benefit when time-limited critical decision making by a specialist physician regarding a specific intervention is necessary.

An important and increasingly frequently used application demonstrating this is in the evaluation and treatment of the stroke patient. Best practice management of ischemic stroke in appropriate patients now includes the use of thrombolytic therapy such as tissue plasminogen activator (tPA), which has been shown to have statistically significant clinical and financial benefits. Recommendations and drug labeling limit the use of intravenous tPA

to within 3 h of when the patient was last seen as well or had witnessed onset of symptoms.

This therapy, however, has significant complications, particularly in patients with hemorrhagic rather than ischemic events – requiring urgent specialty consultation, along with rapid expert interpretation of imaging and laboratory work. Many settings lack the specialty expertise to have on-site “stroke teams” to accomplish best practice. Telemedicine can bring specialty expertise to a remote location for emergency evaluation of the patient directly, while transmit images and laboratory work for immediate interpretation.

This model of care, first called “telectroke” care by Levine and Gorman, has been increasingly used throughout the country (Levine 1999). The efficacy of this model, compared to traditional telephone consultation, was evaluated by Meyer et al. (2008). These investigators found that telestroke care resulted in more accurate decision making than did telephone consultation. Based on a comprehensive review of evidence, the American Heart Association and American Stroke Association concluded that “evidence supporting the equivalence of telestroke to in-person care is accumulating (Wechsler et al. 2017)”. In their report, they review models of telestroke and provide suggestions for standardizing and adopting quality measures (highlighting among others the responsibility for collecting quality data as a core component of the agreement between telestroke sites and a coordinating stroke center or distributed partner), and recommendations for licensing, credentialing, training and documentation.

#### ■ Remote Intensive Care

Samuel was admitted to the intensive care unit (ICU) in his local hospital with the diagnosis of stroke, diabetes and hypertension. He is being treated with thrombolytic therapy. During the night, Samuel’s blood pressure begins to rise significantly above the recommended level for patients under treatment with thrombolytic therapy. This is quickly recognized by a remote tele-ICU team that provides coverage for all of the ICU beds in Samuel’s rural hospital. This remote intensive care team has complete access to Samuel’s

electronic health record and bedside monitors and they also have video and audio connectivity into the room. The remote critical care team is able to quickly connect to Samuel’s room and do a neurological exam with the assistance of the on-site nursing team. They determine that the exam is unchanged from the emergency room. They are able to order appropriate medications, recommend more frequent neurological checks, and directly follow his blood pressure response.

Consultation models in the in-patient setting using telemedicine in a variety of specialties have been reported. Including intensive care where timely consults are often essential (Assimacopoulos et al. 2008; Marcin et al. 2004). Although, these consultation models in critical care have shown benefit, a comprehensive multi-modality model has become more common. This is often referred to as tele-ICU, and is defined as care provided to critically ill patients with at least some of the managing physicians and nurses in a remote location.

Some of the initial work in this area, done by Rosenfeld and Bresslow in the Sentara Health System, demonstrated improved mortality, reduced lengths of stay and decreased costs (Rosenfeld et al. 2000). Remote intensive care has grown significantly over time with an estimated 10% of all ICU beds in the U.S. covered under this model of care, in large part due to a shortage of critical care physicians. Typically, a single “Command Center” can cover multiple intensive care units over a large geographic region creating significant efficiencies and economies of scale.

This model of care integrates several of the technologies discussed in this book and is primarily enabled using electronic health records, evidenced based decision support tools, connections to bedside monitoring systems and audio/video based telemedicine into patient rooms. Most commonly, critical care health professionals co-manage care from a Command Center led by board-certified critical care physicians. Protocols and treatments reviews for patient management are incorporated into the care process using data from the monitoring and alert systems that indicate when changes in care should take place. The goal is to assure adherence to best practice,

achieve shorter response times to alarms, abnormal laboratory values and more rapid initiation of life saving interventions (Lilly et al. 2011).

Published studies have shown mixed results in terms of the benefits of tele-ICU. Lilly et al. reported that in a single academic medical center, implementation of tele-ICU was associated with reduced mortality and LOS, as well as lower rates of preventable complications (Lilly et al. 2011). A recent study compared inter-hospital transfer rates in hospitals with a tele-ICU with transfer rates of facilities with no telemedicine program in the Veterans Health Administration system (examining 52 ICUs in 23 acute care facilities) and found that ICU telemedicine was associated with a decrease in inter-hospital ICU transfers (Fortis et al. 2018). Another successful demonstration of the concept of the tele-ICU is the eICU at Emory University. In 2012, Emory launched an innovative plan to develop a collaborative network supporting intensive care units remotely throughout Georgia and more recently even partnered with clinicians in Australia to ensure 24/7 monitoring by experts. In the eICU experts can monitor the patient and speak directly to a care provider at the patient's bedside in Atlanta, while also talking with the patient and family caregivers. The use of specialized cameras, video monitors, microphones and speakers installed in Emory's ICU rooms, at four of its hospitals and one non-Emory hospital connect providers throughout the state of Georgia and more recently also to care teams in Australia. The eICU was found to reduce length of patient stay, resulted in fewer readmissions, reduced costs while addressing the shortage of intensivists (Buchman et al. 2017). In a systematic review and meta-analysis of studies examining outcomes of tele-ICUs, the authors concluded that the tele-ICU may reduce the ICU and hospital mortality and shorten the ICU length of stay but have no significant effect in hospital length of stay (Chen et al. 2018). This analysis also highlighted that further examination of the cost-effectiveness of a tele-ICU is needed.

### 20.3.6 Telepresence

Telepresence involves systems that allow clinicians to not only view remote situations, but also to act on them. The archetypal telepresence application is telesurgery. The most basic surgical telepresence systems simply permit two-way audio-video communications, by which remote surgeons can observe, teach, and collaborate with local surgeons while they operate on patients.

More advanced surgical telepresence systems allow procedures to actually be performed remotely. Although largely still experimental, a trans-Atlantic gall bladder operation was demonstrated in 2001 (Kent 2001). The military has funded considerable research in this area in the hope that surgical capabilities could be extended to the battlefield. Telepresence requires high bandwidth, low **latency** connections. Optimal telesurgery requires not only teleoperation of robotic surgical instruments, but also accurate **force feedback** (or **haptic feedback**) that requires extremely low network latencies. Accurate millisecond force feedback has been historically limited to distances under 100 miles. The endoscopic gall bladder surgery mentioned above is an exception to this general principle because that specific procedure relied almost exclusively on visual information. It used a dedicated and custom configured 10 Mb/s fiberoptic network with a 155 ms latency.

Providing tactile feedback over large distances actually requires providing the surgeon with simulated feedback while awaiting transmission of the actual feedback data. Such simulation requires massive computing power and is an area of active research. Telesurgery also require extremely high-reliability connections. Loss of a connection is an annoyance during a consultation; it can be fatal during a surgical procedure.

Robotic surgery systems have been commercially available since the early 2000s. In these systems, surgical instruments and a camera are introduced into the patient through small incisions. The surgeon controls these instruments remotely, while he or she is

viewing a magnified three-dimensional camera image of the patient's anatomical structures. These systems are currently being used in some medical centers for small-incision surgery, typically performed by surgeons seated adjacent to their patients. The increasing availability and use of these robotic surgery systems creates possibilities for an increasing number of telesurgery applications.

To date, robotically-assisted surgery has been most common in fields such as cardiothoracic surgery, gynecology, and urology. Potential advantages of remote robotically-assisted surgery may include smaller incisions, improved anatomic visualization, and finer control of surgical instrumentation. Several clinical studies comparing robotically-assisted surgery with traditional surgery have suggested that the outcomes are similar (Ficarra et al. 2009). However, additional research is required to determine the optimal role of robot-assisted surgery and its applications to telesurgery.

A novel form of telepresence gives clinicians the ability not only to see, but also to walk around. Since the early 2000s, a commercially-available system has combined conventional video telehealth with a remotely controlled robot (■ Fig. 20.3). It allows clini-

cians literally to make remote video rounds. A frequent problem with telehealth systems is having the equipment where it is needed. With this system, the telehealth equipment is able to take itself to wherever it is needed. Remote monitoring may also be performed by interfacing digital devices such as stethoscopes or imaging systems to the remote-controlled robot. These remote-controlled systems are most often used by physicians and nurses to examine patients in nursing homes or other long-term facilities, to improve health care access in rural areas, and eaperform post-operative examinations. Croghan et al. (2018) designed and tested a remotely controlled mobile audiovisual drone to access inpatients in surgical wards based on a lightweight device that is freely mobile and “emulates human interaction by swiveling and adjusting height to patients’ eye-level.” As technological advancements in robotics introduce new innovative models of telepresence, identification of relevant outcome measures and rigorous evaluation studies are needed to assess both the effectiveness and unintended consequences of such solutions.

### 20.3.7 Delivering Specialty Knowledge to a Network of Clinical Peers

Telemedicine is used not only to provide direct services to patients but also to facilitate continuing education and peer support for clinicians with the goal to ultimately improve health care outcomes. The Project ECHO (Extension for Community Healthcare Outcomes) was originally established by the University of New Mexico as a partnership of academic medicine, public health offices and community clinics to use videoconferencing in order to promote knowledge networks and connect clinicians in rural areas with specialists in order to study cases of patients with unique needs (Arora et al. 2007). The first program focused on Hepatitis C but has since been adopted in numerous settings in the United States and worldwide, for various chronic conditions and populations including among

■ **Fig. 20.3** Telehealth robot. This is controlled by a remote clinician, and includes videoconferencing and remote monitoring capabilities. In this example, a specialist is connecting with a nurse during a patient transfer. Image courtesy of InTouch Health, reproduced with permission

others, care of children with autism (Mazurek et al. 2017), geriatric mental health (Fisher et al. 2017) and diabetes (Swigert et al. 2014). The wide adoption of ECHO aims to utilize telehealth to strengthen workforce capacity in underserved areas and address health disparities. As of 2018 Project ECHO operated more than 220 hubs for more than 100 conditions or diseases in 31 countries. In a recent study, a program informed by the original ECHO model called SCAN-ECHO (Specialty Care Access Network-Extension for Community Healthcare Outcomes) was introduced by the Veterans Health Administration (VHA) to improve care for patients with liver disease in rural and underserved areas where care to specialized care can be challenging. The study collected 5 years of clinical data from 62,237 veterans with liver disease in the region. Only 513 of these veterans had a primary care physician who participated in SCAN-ECHO where they could discuss their patient cases with specialists but they had a 54% higher survival rate compared to the rest of their cohort even when adjusted for other variables (Su et al. 2018).

### 20.3.8 The Emergence of Telehealth during a Global Pandemic

---

As telehealth bridges geographic distance, it enables continuity in delivery of services even at times when populations may not have access to travel or even be restricted by physical distancing and quarantine. The COVID-19 pandemic in 2020 highlighted this potential and led to rapidly accelerated growth of telehealth. Worldwide health systems quickly adopted telehealth solutions. In the US, insurers expanded coverage to include all telemedicine and telehealth visit types including home visits, and licensure requirements were relaxed (Centers for Medicare and Medicaid Services 2020). The US Department of Health and Human Services (2020) waived enforcement of HIPAA regulations to allow the use of video-conferencing for telemedicine visits including the use of widely available video-conferencing solutions. In one large health system (NYU Langone Health) which was

at the COVID-19 outbreak epicenter at that time, telemedicine visits increased by 135% in urgent care and by 4345% increase in non-urgent care between March 2 and April 14, 2020 (Mann et al. 2020). In addition to using telehealth for the delivery of traditional health care services, this platform also played a role for decision making and self-triage in the context of the pandemic. One such example is a telehealth patient portal for self-triage and scheduling that was created at the University of California San Francisco to enable asymptomatic patients to report exposure history and for symptomatic patients to be triaged and paired with appropriate levels of care (Judson et al. 2020). The rapid expansion of telehealth in times of this pandemic highlights the significance of investing in infrastructure and training to better prepare health systems in times of public health emergencies.

## 20.4 Challenges and Future Directions

---

As telehealth evolves from research novelty to being a standard way that health care is delivered, many challenges must be overcome. Some of these challenges arise because the one patient, one doctor model no longer applies. Basic questions of identity and trust become paramount. At the same time, the shifting focus from treating illness to managing health and wellness requires that clinicians know not only the history of the individuals they treat but also information about the social and environmental context within which those individuals reside. In the diabetes example, knowledge of the family history of risk factors, diseases, and the appropriate diagnostic and interventional protocols, aid the clinical staff in providing timely and appropriate treatment.

### 20.4.1 Challenges to Using the Internet for Telehealth Applications

---

Because of the public, shared nature of the Internet, its resources are widely accessible by citizens and health care organizations.

This public nature also presents challenges to the security of data transmitted along the Internet. The openness of the Internet leaves the transmitted data vulnerable to interception and inappropriate access. In spite of significant improvements in the security of Web browsing several areas, including protection against viruses, authentication of individuals and the security of email, remain problematic.

Ensuring every citizen access to the Internet represents a second important challenge to the ability to use it for public health purposes. Access to the Internet presently requires computer equipment that may be out of reach for persons with marginal income levels. Majority-language literacy and the physical capability to type and read present additional requirements for effective use of the Internet. Preventing inequalities in access to health care resources delivered via the Internet will require that health care agencies work with other social service and educational groups to make available the technology necessary to capitalize on this electronic environment for health care. A 2019 Report by the U.S. Federal Communications Commission indicated that more than 20 million Americans lack advanced broadband Internet access (defined as download speeds of at least 25 megabits per second with upload speeds of 3 Mbps) highlighting that many rural settings depend on satellite Internet for access at a higher cost. The COVID-19 pandemic intensified the disparities that emerge from this digital divide and strengthened ongoing efforts to disseminate higher bandwidth to rural settings.

As health care becomes increasingly reliant on Internet-based telecommunications technology, the industry faces challenges in insuring the quality and integrity of many devices and network pathways. These challenges differ from previous medical device concerns, because the diversity and reliability of household equipment is under the control of the household, not the health care providers. There is an increased interdependency between the providers of health services, those who manage telecommunication infrastructure and the manufacturers of commercial electronics. Insuring effective use of telehealth

for home and community-based care requires that clinical services be supported by appropriate technical resources. The challenge of the digital divide that highlights varying degrees of access for patients to infrastructure and tools necessary for telehealth, must be addressed when designing and implementing such systems. This consideration is necessary to ensure that telehealth systems, meant to bridge geographic distance and increase access, do not end up further exacerbating inequities and raising additional barriers to high quality care. Additionally, consumer education is necessary so that patients and families fully understand risks and benefits of using telehealth software and hardware integrated into the care they receive. Educational initiatives need to address a wide spectrum of consumers' literacy and health literacy but also data literacy, namely consumers' ability to process, extract meaning and communicate knowledge generated by data.

#### 20.4.2 Licensure and Economics in Telehealth

---

Licensure is frequently cited as the single biggest problem facing telemedicine involving direct patient-provider interactions. This is because medical licensure in the United States is state-based, while telemedicine frequently crosses state or national boundaries. The debate revolves around the questions of whether the patient “travels” through the wire to the clinician, or the clinician “travels” through the wire to the patient. Several states have passed legislation regulating the manner in which clinicians may deliver care remotely or across state lines. Some states have enacted “full licensure models” that require practitioners to hold a full, unrestricted license in each state where a patient resides. Many of these laws have been enacted specifically to restrict the out-of-state practice of telemedicine. To limit Web-based prescribing and other types of asynchronous interactions, several states have enacted or are considering regulations that would require a face-to-face encounter before any electronically delivered care

would be allowed. In contrast, some states are adopting regulations to facilitate telehealth by exempting out-of-state physicians from in-state licensure requirements provided that electronic care is provided on an irregular or episodic basis. Still other models would include states agreeing to either a mutual exchange of privileges, or some type of “registration” system whereby clinicians from out of state would register their intent to practice via electronic medium.

At the same time, national organizations representing a variety of health care professions (including nurses, physicians and physical therapists) have proposed a variety of approaches to these issues. While the existing system is built around individual state licensure, groups that favor telemedicine have proposed various interstate or national licensure schemes. The Federated State Board of Medical Examiners has proposed that physicians holding a full, unrestricted license in any state should be able to obtain a limited telemedicine consultation license using a streamlined application process. The American Medical Association is fighting to maintain the current state-based licensure model while encouraging some reciprocity. The American Telemedicine Association supports the position that—since patients are “transported” via telemedicine to the clinician—the practitioner need only be licensed in his or her home state. The National Council of State Boards of Nursing has promoted an Interstate Nurse Licensure Compact (NLC) whereby licensed nurses in a given state are granted multi-state licensure privileges and are authorized to practice in any other state that has adopted the compact. By 2015, 25 states had adopted the NLC; in 2017 the eNLC went into effect as an enhanced compact that addressed the challenge of uniform criminal background checks. As of early 2020, 34 states had enacted the eNLC.

The second factor limiting the growth of telehealth is reimbursement. Prior to the mid-1990s there was virtually no reimbursement for telehealth outside of teleradiology. For many years Medicare routinely reimbursed for synchronous video only for rural patients. In January 2015, the Centers for Medicare

and Medicaid Services (CMS) created a new chronic care management (CCM) code that provides for non-face-to-face consultation which introduces options for reimbursement for asynchronous remote monitoring. Furthermore, starting in 2018 CMS allowed providers to get reimbursed separately for time spent on the collection and interpretation of health-related data that were generated remotely. As technologies advance and play a pervasive role in our health care system, we anticipate the incremental changes in telehealth legislation to accelerate. In 2017, 210 telehealth related bills were active across thirty states and as new technological capabilities are introduced, we anticipate further legislative efforts. Over 25 states have laws mandating private insurers to reimburse for telehealth services (with at least another 10 additional states have pending or proposed laws to do so). Numerous insurers provide reimbursement for electronic messaging and online consultations. The Medicare Telehealth Parity Act of 2015 has led to advancements in reimbursement for teleradiology and teler dermatology including payments for store-and-forward telehealth; however, restrictions still apply to types of technologies used, services provided and populations covered. Few groups have even considered reimbursement for telehealth services that do not involve patient-provider interaction. An expert system could provide triage services; tailored on-line educational material, or customized dosage calculations. Such systems are expensive to build and maintain, but only services provided directly by humans are currently reimbursed by insurance.

Historically, patients have been perceived as reluctant to pay directly for telehealth services, especially when face-to-face visits were covered by insurance. This trend is changing as consumers are more familiar with the use of various technologies to bridge geographic distance and embrace various innovative tools to bridge geographic distance. In a 2017 study (Chang et al. 2017) estimating US households’ willingness to pay for telehealth, the representative household was willing to pay \$4.39 per month for telehealth. This valuation increased for household with higher opportu-

nity costs and even more for households living more than 20 miles away from their nearest medical facility (to \$6.22 per month).

Finally, home telehealth monitoring may reduce the health care costs associated with unreimbursed hospital readmissions. For example, some insurance payers do not reimburse for hospital readmissions that occur within 30 days of discharge, and there are anecdotal reports of health systems paying for 32 days of home monitoring post-discharge. Determining whether, and how much, to pay for telehealth services will likely be a topic of debate for years to come. Starting in 2020 Accountable Care Organizations (ACOs) with Medicare fee-for-service beneficiaries will have the option to expand telehealth services to include the home as an eligible originating site (without being subject to the current Medicare geographic requirements for the telehealth originating site). Public health developments affect the legal landscape as the recent COVID-19 pandemic highlighted where several of the regulatory and licensing barriers were temporarily lifted. The regulatory landscape will evolve over time as both technology and medical knowledge advance and societal needs change.

### **20.4.3 Logistical Requirements for Implementation of Telehealth Systems**

---

Telehealth systems must be carefully evaluated before implementation for routine use in individual disease situations, to ensure that they have sufficient diagnostic accuracy and reproducibility for clinical application. Appropriate training and credentialing standards must be developed for personnel who capture clinical data and images from patients locally, as well as for physicians and nurses who perform remote interpretation and consultation. Clear rules and responsibilities must be developed for remote patient management, including the appropriate response for situations in which data are felt to be of insufficient quality for telehealth. Guidelines for medicolegal liability must be established.

Software that displays clinical information required for remote management, and that integrates into existing workflow patterns and maximizes efficiency through good usability principles will be required. More specifically in the context of usability, when patients are asked to utilize telehealth equipment, several factors should be taken into consideration such as patients' previous experience with and comfort in using technology, potential functional or cognitive limitations, and the availability of family members or informal caregivers who may be able to assist. Consider our example of Samuel who lives alone and has some visual limitations. The decision to use software and/or hardware for home-based monitoring should address Samuel's living arrangements and residential infrastructure, as well as his ability and willingness to operate the telehealth system (and the potential role his neighbor may play who is involved in Samuel's care). Methods for providing added value from technology toward telehealth diagnostic systems through strategies such as links to consumer health resources or computer-based diagnosis may be explored (Koreen et al. 2007). Finally, studies have suggested that patient satisfaction with telehealth systems is high (Lee et al. 2010). However, the practitioner-patient relationship is fundamental to health care delivery, and mechanisms must be developed that this bond is not lost from telehealth.

### **20.4.4 Telehealth in Low Resource Environments**

---

In many parts of the developing world, the density of both health care providers and of technology is quite low. Thus, the demand for telehealth is high, but the ability to deliver it is challenged. Many of these regions have largely skipped traditional land-line telephony and moved directly to cellular infrastructure (Foster 2010). This, combined with advances in low-cost laptop computers that do not depend on stable power-grids, has allowed the development of a wide variety of telehealth and tele-education applications. The majority

of these are based on an asynchronous model. Transport media range from standard broadband in the urban areas, to satellite connections, to cellular data, to **SMS messaging**. The largest group of applications focuses on the provision of remote consultations for difficult cases using computer-based systems, while general health education and remote data collection have been the primary applications using cellular telephony applications. However, the development of smart mobile telephones with high-resolution cameras is rapidly blurring this distinction. Successful implementation of telehealth in various low resource settings is demonstrated in a series of projects captured by an e-book by Wootton and Bonnardot (2015).

### 20.4.5 Future Directions

Telehealth validation studies across a range of clinical domains have demonstrated good diagnostic accuracy, reliability, and patient satisfaction. Based on these results, numerous real-world telehealth programs have been implemented throughout the world. In the long term, successful large-scale expansion of these programs will require addressing the above challenges.

Beyond these practical factors, traditional medical care uses a workflow model based on synchronous interactions between clinicians and individual patients. The workflow model is also a sequential one in that the clinician may deal with multiple clinical problems or data trends but only within the context of treating a single patient at a time. Medical records, both paper and electronic, as well as billing and administrative systems all rely on this sequential paradigm, in which the fundamental unit is the “visit.” Advances in telehealth are disrupting this paradigm. Devices have been developed that allow remote electronic monitoring of diabetes, hypertension, asthma, congestive heart failure (CHF), and chronic anticoagulation. As a result, clinicians may become inundated by large volumes of electronic results. This may mean that clinicians will no longer function in an assembly-line fashion, but will become more like dispatchers or air-traffic controllers, elec-

tronically monitoring many processes simultaneously. Clinicians will no longer ask simply, “How is Mrs. X today?” They will also ask the computer “Among my 2,000 patients, which ones need my attention today?” Neither clinicians, nor EHRs, are prepared for this change.

Many service industries such as the travel and transportation sectors have more recently experienced dramatic changes due to the concept of “shared economy” that promotes a shift from strictly regulated frameworks for transactions to decentralized approaches where community networks promote identifying and optimizing resources based on needs identified by the community members. This paradigm shift has started to also permeate the health care field introducing an expanded perspective of telehealth whereby consumers use an app to arrange for on-demand home visits or “virtual visits” enabled by videoconferencing. One example is the Pager app that helps consumers find a doctor who will contact and visit within a guaranteed two-hour window. Similarly, various apps like Mend or HealApp arrange for on-demand videoconsultations or visits. Other examples of sharing economy apps utilize crowd sourcing to support diagnosis processes. These trends introduce opportunities and challenges as we consider the extent to which regulatory and quality safeguards may be necessary to maximize benefits and reduce unintended consequences. Furthermore, the use of wearables and smart home technologies expands the traditional models of telehealth so that in the near future comprehensive telehealth systems may integrate physiological, behavioral, social, cognitive, environmental and genomic data sources to deliver “precision medicine” in a continuum of care. Artificial intelligence and predictive analytics will play a key role in this expansion of the telehealth paradigm.

Perhaps the greatest long-term effect of the information and communication revolution will be the breaking down of role, geographic, and social barriers. Medicine is already benefiting from this effect. Traditional “doctors and nurses” are collaborating with public health professionals, and anyone with computer access can potentially communicate with patients or experts around the world. The

challenge will be to facilitate productive collaborations among patients, their caregivers, biomedical scientists, and information technology experts to promote patient engagement and shared decision making.

### Suggested Readings

Bashshur, R. L., Shannon, G. W., Krupinski, E. A., Grigsby, J., Kvedar, J. C., Weinstein, R. S., et al. (2009). National telemedicine initiatives: Essential to healthcare reform. *Telemedicine and e-Health*, 15, 600–610. This paper discusses cost-benefit tradeoffs associated with telemedicine within the context of large-scale efforts promoting health care reform in the United States.

Chi, N. C., & Demiris, G. (2015). A systematic review of telehealth tools and interventions to support family caregivers. *Journal of Telemedicine and Telecare*, 21, 37–44. This review focuses on telehealth applications targeting either solely the family caregiver of a patient or the dyad (caregiver and patient) examining the impact of telehealth on caregiver outcomes. Six categories of telehealth interventions for caregivers were identified: education, consultation (including decision support), psychosocial/cognitive behavioral therapy, social support, data collection and monitoring, and clinical care delivery. Studies demonstrate caregiver satisfaction as well as reduction of caregiver anxiety and burden.

Reed, M. E., Parikh, R., Huang, J., Ballard, D. W., Barr, I., & Wargon, C. (2018). Real-time patient-provider video telemedicine integrated with clinical care. *New England Journal of Medicine*, 379, 1478–1479. Kaiser Permanente Northern California began offering telemedicine visits enabling patients to use videoconferencing on a mobile phone, computer or tablet to communicate with their physicians. In this study 210,383 video visits conducted over three years (involving 2796 primary care providers and 152,809 patients) were examined. The telemedicine visits extended established patient–physician relationships and led to high levels of patient satisfaction (93% of surveyed patients responded that the video visit met their needs).

Wechsler, L. R., Demaerschalk, B. M., Schwamm, L. H., Adeoye, O. M., Audebert, H. J., Fanale,

C. V., Hess, D. C., Majersik, J. J., Nystrom, K. V., Reeves, M. J., Rosamond, W. D., Switzer, J. A., & American Heart Association Stroke Council; Council on Epidemiology and Prevention; Council on Quality of Care and Outcomes Research. (2017). Telemedicine quality and outcomes in stroke: A scientific statement for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke*, 48, e3–e25. This is an updated systematic evidence-based review of scientific data examining the use of telemedicine for stroke care delivery. Published studies are categorized according to their level of certainty and class of evidence.

### Questions for Discussion

1. Telehealth has evolved from systems designed primarily to support consultations between clinicians to systems that provide direct patient care. This has required changes in hardware, user interfaces, software, and processes. Discuss some of the changes that must be made when a system designed for use by health care professionals is modified to be used directly by patients.
2. There are still some challenges regarding reimbursement for telemedicine services. Imagine that you are negotiating with an insurance carrier to obtain reimbursement for a store-and-forward telemedicine service that you have developed. The medical director of the second insurance payer states: “Telemedicine seems like ‘screening’ rather than a mechanism for delivering health care. This is because you are simply using technology to identify patients who need to be referred to a real doctor, rather than providing true medical care. Therefore, we should only reimburse a very small amount for these screening services.” In your opinion, is this a legitimate argument? Explain.
3. Using telehealth systems, patients can now interact with multiple health care stakeholders and monitor multiple aspects of their health generating large data sets. In order to inform timely and

tailored interventions based on data generated both during clinical encounters and outside the clinical setting, many propose for telehealth enabled patient generated health data to be directly integrated into the Electronic Health Record. Discuss both challenges and opportunities for such an approach.

4. A significant barrier to widespread telehealth adoption has been limited validation studies demonstrating that its diagnostic accuracy is comparable to that of traditional in-person medical care. Do you feel this is a realistic goal, given the extremely large number of potential disease states and clinical scenarios that may require validation studies? Are there alternate scenarios that could lead to telehealth becoming accepted as standard medical practice? Explain.
5. Home telehealth often requires interpretation of data collected directly by patients, which may create challenges because of concerns about accuracy, as well as challenges from a data management perspective because of the large volume of incoming data. Describe possible approaches toward addressing these challenges involving accuracy and data management.

## Learning Objectives

After reading this chapter, you should be able to answer these questions:

1. What is patient monitoring and why is it used?
2. What patient parameters do bedside physiological monitors track?
3. What are the major problems with acquisition and presentation of monitoring parameters?
4. In addition to bedside physiologic parameters, what other information is fundamental to the care of acutely ill patients?
5. Why is real-time computerized decision support potentially more beneficial than monthly or quarterly quality-of-care reporting?
6. What technical and social factors must be considered when implementing real-time data acquisition and decision support systems?

## 21.1 What is Patient Monitoring?

---

Life, from the physiologic standpoint requires supplying oxygen to tissues to address the metabolic needs for the purpose of fueling mitochondrial respiration in cells. When this cycle is broken humans become critically ill. That physiologic cycle could be controlled through oxygenation and perfusion monitoring but there are no direct methods existing to measure mitochondrial respiration. All modern monitoring methods are proxy methods for such processes. In hospitals, and especially in the intensive care unit (ICU), patient monitoring becomes critical for control and optimization of hemodynamic, ventilation, temperature, nutrition, and metabolism of the human body.

Measurement of patient physiologic parameters such as heart rate (HR), heart rhythm, arterial blood pressure (ABP), respiratory rate, and blood-oxygen saturation, have become common during the care of the hospitalized and, especially, critically ill patients. When accurate and prompt decision making is crucial for effective patient care, bedside monitors are used to collect, display, and store

physiologic data. Increasingly, such data are collected by noninvasive sensors connected to patients in ICUs, neonatal ICUs, operating rooms (ORs), labor and delivery suites, emergency departments, and other hospital care units where patient acuity is increased.

We often think of a patient monitor as something that watches for, and warns about, serious or life-threatening events in patients, and provides guidance for care of the critically ill. Such systems must include continuous observations of a patient's physiologic measurements and the assessment of the function of attached life support equipment. Such monitoring is important in detecting life-threatening conditions and guiding management decision making, including when to make therapeutic interventions and to assess the effect of those interventions.

In this chapter, we discuss the use of computers in collecting, displaying, storing, and interpreting clinical data, making therapeutic recommendations, and alarming and alerting. In the past, most monitoring data (called vital signs) were in the form of HR and respiratory rate, blood pressure (BP), and body temperature. However, today's ICU monitoring systems are able integrate data from bedside monitors and devices, as well as data from many sources outside the ICU. Although the material presented here deals primarily with patients who are in ICUs, the general principles and techniques are also applicable to other hospitalized patients and electronic medical records (EMRs). Patient monitoring is performed extensively for diagnostic purposes in the emergency department or for therapeutic purposes in the OR. Techniques that initially were only used in the ICU such as bedside monitors are now used routinely on general hospital wards and in some situations even by patients in their homes.

### 21.1.1 Case Report

---

This case report provides a perspective on the problems faced by the team caring for a critically ill patient.

A 27-year-old man is injured in an automobile accident and has multiple chest and

head injuries. His condition was stabilized at the scene of the accident by skilled paramedics using a portable computer-based electrocardiogram (ECG) and pulse oximeter, and he is quickly transported to a trauma center. Once in the trauma center, he is connected via noninvasive sensors to a computer-based bedside monitor that displays physiologic signals, including his HR and rhythm, arterial oxygen saturation, and BP. Radiographic and magnetic resonance imaging provide further information for care.

Because of the severe chest injury, the patient has difficulty breathing, so he is connected to a computer-controlled ventilator that has both therapeutic and monitoring functions and he is transferred to the ICU. Because of the head injury a bolt is placed in a hole drilled through his skull and a fiber optic sensor is inserted to continuously measure intracranial pressure with another computer-controlled monitor. Blood is drawn and clinical chemistry and blood gas tests are promptly performed by the hospital laboratory. Results of those tests are displayed to the ICU team as soon as they are available. With intensive treatment, the patient survives the initial threats to his life and he now begins the long recovery process. ■ Figure 21.1 shows a nurse at the patient's bedside surrounded by a bedside monitor, infusion pumps, a ventilator, and other devices.

■ **Fig. 21.1** Overall view of an ICU patient's room. Shown is a nurse standing at the bedside computer screen (*left*), a ventilator (*center*), and a respiratory therapist suctioning the patient (*right*). The patient is connected to the ventilator, bedside monitor (*upper right*), and to three IV pumps (*lower right*). ICU indicates intensive care unit, IV intravenous

Unfortunately, a few days later, the patient is beset with a problem common to multiple trauma victims—he develops a major **nosocomial hospital-acquired infection**, sepsis, and acute respiratory distress syndrome (ARDS). Multiple organ failure follows. As a result, antibiotics and electrolytes are required for treatment and are dispensed via intravenous (IV) pumps. The quantity of information required to care for the patient has increased dramatically; with monitor data excluded, critically ill patients produce in average 10 times more clinical data than patients on the typical general hospital unit (■ Fig. 21.2) (Herasevich et al. 2012).

Decision-making for patients with complex rapidly changing acute conditions requires much data in addition to monitoring data (■ Fig. 21.3) (Bradshaw et al. 1984).

Increased data flow, rapid changes in the patient's state, and a multidisciplinary approach involving different care providers required the next generation of data management clinical systems outside of distributed, often not connected, multiple patient monitors and data from hospital EMRs.

In ▶ Sect. 21.6 (“Monitoring and Advanced Information Management in ICUs”) we describe two integrated patient monitoring systems: the HELP system used by Intermountain Healthcare's Hospitals and the AWARE system developed at Mayo Clinic Hospitals. Both of these systems integrate diverse clinical data for complex decision making.

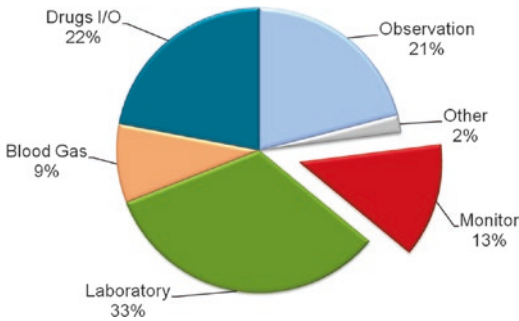

## 21.1.2 Patient Monitoring

Careful monitoring and alerting care team about changes in a patient's physiologic status is a vital part of diagnostic and therapeutic processes. There are at least three categories of patients who need physiologic monitoring:

1. Patients with compromised physiologic regulatory systems; eg, a patient whose respiratory system is suppressed by a drug overdose or during anesthesia
2. Patients who are currently stable but with a condition that could suddenly change to become life threatening; eg, a patient who

**Fig. 21.2** Average number of total clinical data points per patient hour, excluding vitals, before and after admission to the ICU (time zero). Bars in red indicate first hours in ICU. Y-axis indicated number of data points

**Fig. 21.3** Six main data categories and their relative distribution used in clinical decision making in trauma shock intensive care unit. I/O indicates Intake and Output

capable of capturing multiwaveform/multiparameter information with advanced alerting functionality.

In general, patient monitoring could be divided to five groups (Fig. 21.4):

1. Hemodynamic monitoring
2. Respiratory monitoring
3. Neuromonitoring
4. Metabolic monitoring
5. Specialty monitoring

Not all monitoring techniques needed for every patient or are widely available. Also, using invasive methods should take into account the risk of complications.

In terms of technologic classification, monitoring could be divided by three general parts:

1. Vital signs monitoring
2. Diagnostic monitoring
3. Specialized or disease-specific monitoring

has findings indicating an acute myocardial infarction (heart attack) or immediately after open-heart surgery, or a fetus during labor and delivery

3. Patients in a critical physiologic state; eg, patients with multiple trauma or septic shock like in our case study

Clinical monitoring has evolved over the time and has a tendency to change from intermittent to continuous and from invasive to non-invasive methods. Also, there is a trend for monitoring systems to become multipurpose and integrate multiple parameters, including nonmonitoring data. Current stand-alone bedside monitors have data storage and are

## 21.2 Historical Perspective and the Measurement of Vital Signs

The earliest foundations for acquiring physiologic data occurred at the end of the Renaissance period. In 1625, Santorio

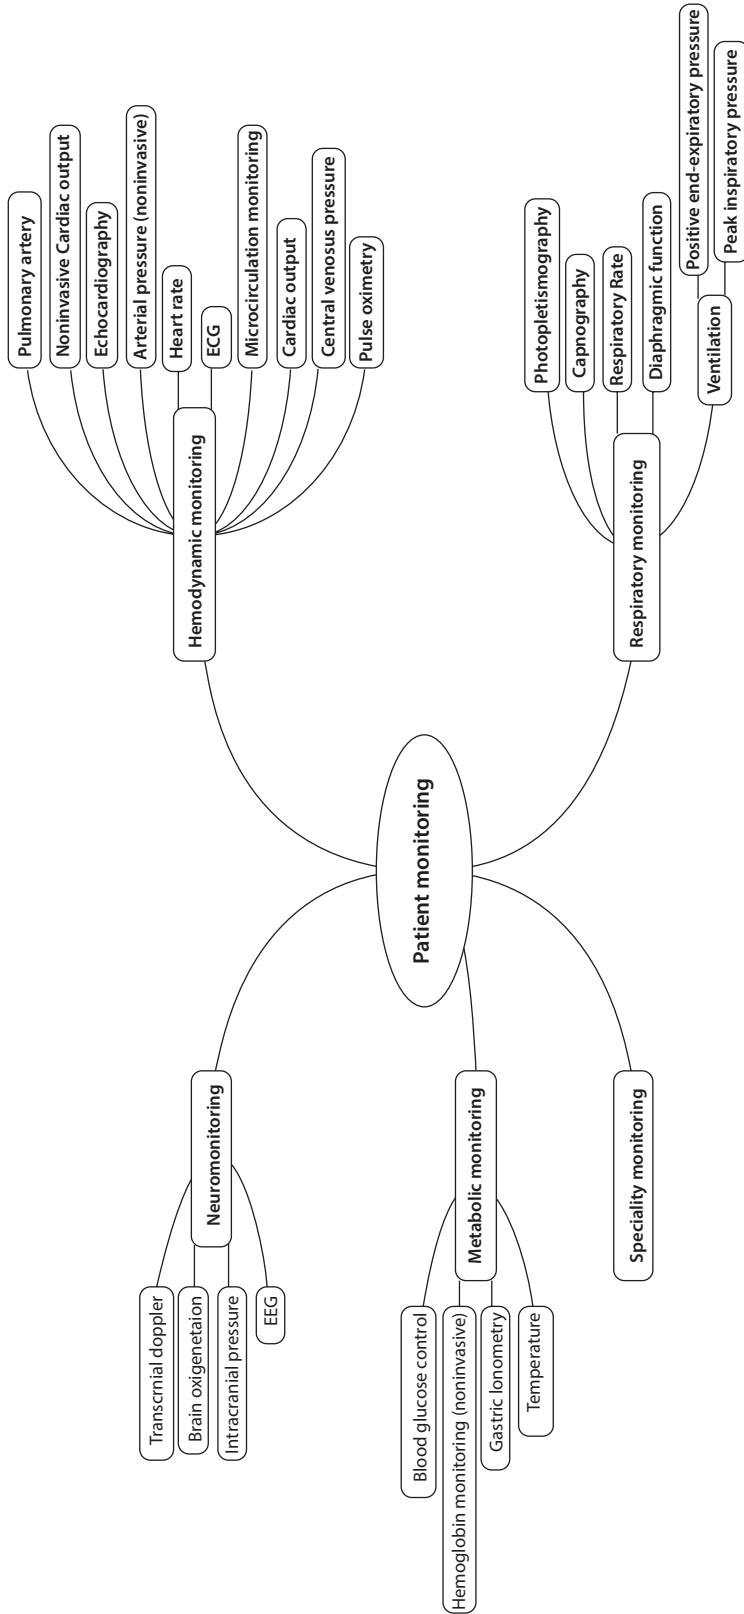

Fig. 21.4 Different types of patient physiologic monitoring. ECG indicates electrocardiogram, EEG electroencephalogram

■ Fig. 21.5 Pulsilogium at center to measure HR and thermoscope (right) to measure body temperature. HR indicates heart rate. (From Sanctorius (1626))

Santori, who lived in Venice, Italy, published his methods for measuring body temperature with the spirit thermometer and for timing the pulse (HR) with a pendulum (■ Fig. 21.5). The principles for both devices had been established by Galileo Galilei, a close friend. Galileo worked out the uniform periodicity of the swinging chandelier in the Cathedral of Pisa and comparing that to his own pulse rate. The results of this early biomedical-engineering collaboration, however, were ignored. The first scientific report of the pulse rate did not appear until English physician Sir John Floyer published “Pulse-Watch” in 1707. The first published course of fever for a patient was plotted by Ludwig Taube in 1852.

In 1896, Scipione Riva-Rocci introduced the sphygmomanometer (BP cuff), which permitted the fourth vital sign, systolic BP, to be measured. A Russian physician, Nikolai

Korotkoff, applied Riva-Rocci’s cuff with a stethoscope developed by the French physician Rene Laennec, which allowed the measurement of both systolic and diastolic arterial pressure. Harvey Cushing, a preeminent US neurosurgeon of the early 1900s, predicted the need for and later insisted on routine ABP monitoring in the OR. At the same time, Cushing also raised the following questions, which are still being asked today:

1. Are we collecting too much data?
2. Are the instruments used in clinical medicine too accurate?
3. Would not approximated values be just as good?

Cushing (1903) answered his own questions by stating that vital sign measurements should be made routinely and that their accuracy was important. In 1903, Willem Einthoven devised the string galvanometer for displaying and quantifying the ECG, for which he was awarded the 1924 Nobel Prize in physiology. The ECG has become an important adjunct to the clinician’s inventory of tests for both acutely and chronically ill patients. Continuous measurement of physiologic variables has become a routine part of the monitoring of critically ill patients.

At the same time that advances in monitoring were made, major changes in the therapy of life-threatening disorders were also occurring. Prompt quantitative evaluation of measured physiologic and biochemical variables became essential in the decision-making process as physicians applied new therapeutic interventions. For example, it is now possible, and in many cases essential, to use ventilators when a patient cannot breathe independently, for cardiopulmonary bypass equipment when a patient undergoes open-heart surgery, hemodialysis when a patient’s kidneys fail, and IV nutritional and electrolyte support when a patient is unable to eat or drink.

Since the 1920s, the four vital signs—temperature, respiratory rate, HR, and ABP—have been recorded in all patient charts and became the standard vital signs. In recent years a fifth vital sign, oxygen saturation, was added as a routine measurement.

### 21.3 Development of ICUs

Care of critically ill patients requires prompt and accurate decisions so that life-protecting and life-saving therapy can be appropriately applied. Because of these requirements, ICUs have become widely established in hospitals. Such units use computers almost universally for the following purposes:

1. To acquire physiologic data frequently or continuously, such as BP
2. To acquire information from remote data-producing systems to remote locations, eg, laboratory and radiology departments
3. To store, organize, and report patient information
4. To integrate, organize and correlate data from multiple sources
5. To provide clinical alerts and advisories based on multiple sources of data
6. To function as an automated decision support tool that health professionals may use in planning the care of critically ill patients
7. To measure the severity of illness for patient classification purposes
8. To analyze the outcomes of ICU care in terms of clinical effectiveness and cost effectiveness

Until about 1960, if patients had severe cardiac events, there were few treatment options available for physicians to provide care for them. As a consequence, many patients who had life-threatening acute cardiac or pulmonary problems died. However, in the early 1960's two major medical care treatment modalities were developed that provided treatment for previously fatal situations. Development of closed chest cardiopulmonary resuscitation (CPR); (Kouwenhoven et al. 1960) and closed chest defibrillation (Zoll et al. 1956; Lown et al. 1962) provided means for delivering life-saving treatment. Because of availability of these treatments, the demand for continuous monitoring of high-risk patients escalated. Hospitals began to cluster patients with complex disorders together into new organizational units, called ICUs, beginning in the early 1960s. Some of the earliest units were coronary care units where patients were

cared for after myocardial infarctions or other acute, life-threatening cardiac events.

Surgical ICUs had their beginnings in the late 1950s when postoperative patients were kept in the recovery rooms for extended time periods after cardiac or other high-risk surgery for close observation. Initially these recovery rooms did not have the benefit of cardiac monitoring. However, as more sophisticated monitoring became available, special units were created and designated as surgical ICUs or thoracic ICUs.

ICUs proliferated rapidly during the late 1960s and early 1970s. The types of units included coronary, thoracic surgery, surgical, medical, shock-trauma, burn, pediatric, neonatal, respiratory, and other multipurpose medical or surgical units. Today there are more than six million patients admitted each year into adult, pediatric, and neonatal ICUs in the United States alone. In the past three decades, the demand for ICU services in the United States has risen dramatically. Because of the complexity of care and the increased acuity of these patients, the need for specialized nursing care has increased dramatically. In a typical non-ICU acute patient care situation, one nurse may be responsible for the care up to six patients. However, because of the observations and care that these acutely ill ICU patients require, intensive care nurses typically are assigned one to three patients.

The average life expectancy is rising and estimates of the US population aged over 65 years (who use ICUs disproportionately more than the rest of the population) is estimated to increase by 50% by 2020 and 100% by 2030, thus continually increasing demand (Kelley et al. 2004; Groves et al. 2008) for ICU-level care.

### 21.4 Development of Bedside Monitors

A signature feature of each of these early ICUs was the bedside monitor (■ Fig. 21.6). The original bedside monitors were used primarily to acquire and display the ECG. The first modern bedside monitor, ICU 80, was

**Fig. 21.6** Waveforms on typical bedside monitor. Displays from the monitor show the real-time beat-by-beat ECG, pulse oximeter, and arterial, pulmonary artery,

and central venous blood pressures and their derived measures. (Courtesy of Royal Philips, with permission)

introduced by the Nihon Kohden company from Japan in 1967 and was as large as the patient bed.

As a result of the detailed ECG information provided by the new patient monitors, treatment for serious cardiac arrhythmias (heart rhythm disturbances) and cardiac arrest (abrupt cessation of heartbeat)—major causes of death after myocardial infarctions (heart attack)—became possible. Mortality rates from 1960 to 1970 were about 35%, dropped to about 23% between 1970 and 1980 and to about 20% between 1980 and 1990. During the 1990s reperfusion of the coronary arteries became common and mortality rate dropped to about 5% (Braunwald 1988; Rogers et al. 2000).

In the 1960s, bedside monitors were built using analog computer technologies. These systems amplified the ECG signal and displayed the results on an oscilloscope. Such systems required nurses or technicians to watch

the oscilloscope to determine if there was a cardiac arrest or other life-threatening cardiac rhythm. Soon after these analog systems were developed, methods for generating high- and low-HR alarm thresholds were included. The alarms were usually audible and very annoying. Unfortunately, since the beginning of the use of these alarms, the false-positive rate has far exceeded the true positive rate. As a result, many times alarm systems for bedside monitors are ignored or turned off. The problem of alert fatigue in hospitals is still considered a challenging technological problem and contributes to poor patient outcomes including deaths.

Teams from several cities in the United States in the 1960s introduced computers into the ICU to assist in physiologic monitoring, beginning in Los Angeles with Shubin and Weil (1966) followed by Warner et al. (1968) in Salt Lake City. These investigators had several objectives:

1. To increase the availability and accuracy of the physiologic data
2. To compute derived variables that could not be measured directly
3. To increase patient-care efficacy
4. To allow display of the time trends of the patient's physiologic data, and
5. To assist in computer-aided decision making

Each of these teams developed their applications on large **mainframe computer systems**, which required large computer rooms and trained staff to keep the system operational 24 hours a day. The computers used by these developers cost over \$200,000 each in 1965 dollars. During that time, other researchers were attacking more specific challenges in patient monitoring. For example, Cox (1972) at Barnes Hospital in St. Louis, developed algorithms to analyze the ECG for heart rhythm disturbances in real-time. The arrhythmia-monitoring system, which was installed in the Coronary Care Unit (CCU) in 1969, ran on a relatively inexpensive **mini-computer** rather than a mainframe computer. With the advent of **integrated circuits** and **microprocessors**, affordable computing power increased dramatically. What was considered computer-based patient monitoring by these pioneers in the late 1960s and early 1970s is now entirely built into bedside monitors and is considered simply a bedside monitor. Clemmer (2004) provides an important overview of “where we started and where we are now” to summarize the first four decades following the initiation of computers in the ICU.

## 21.5 Modern Bedside Monitors

The heart and lungs are crucial to normal body function. For example, if the heart stops (cardiac arrest) there is a cessation of normal circulation of the blood. Likewise, if there is a pulmonary arrest there is a cessation of breathing. Each of these situations leads to a reduced delivery of oxygenated blood (hypoxia) to the body, with major physiologic hazards. For example, brain injury will occur

if hypoxia is untreated within 5 minutes. As a consequence, detection of either of these situations is required if life-saving treatments are to be administered. The treatment for cardiac arrest is cardiopulmonary resuscitation (CPR), which provides circulatory and pulmonary support. Prompt use of a defibrillator increases the likelihood of reestablishment of a normal rhythm.

The typical bedside monitor can also display the ECG and the arterial waveform (■ Fig. 21.6).

### 21.5.1 ECG Signal Acquisition and Processing

The ECG provides a representation of the electrical activity of the human heart and is a very important tool for the diagnosis of disturbances of HR and rhythm. Original monitors allowed physicians and nurses the ability to watch the ECG trace on an oscilloscope. Since ECG signal measured on the skin is very small (1 mV), it is subject to artifacts (noise) caused by such things as patient movement, electrode movement, and electrical power interference. By using sophisticated analog and digital techniques and presenting data from multiple leads, the quality and reliability of the ECG signals monitored has improved dramatically (Weinfurt 1990; Gregg et al. 2008). At the same time, the demand for improved quality of the ECG signal and an increase in the number and types of parameters has increased. Initially, the ECG signal was processed to obtain HR and basic rhythm (periodicity of the beat) while today's monitors can detect signals from artificial heart pacemakers, complex arrhythmias, **myocardial ischemia** and disturbances in the conduction of electrical signals through the heart muscle.

Two types of computerized ECG analysis are in common use today:

1. The 12-lead ECG is typically performed in a physician's office or in the hospital. Usually a technician brings a recording device to the patient's bedside and attaches the leads, and records the signal during a

short interval while the patient is lying quietly in a supine position. From this 12-lead ECG, a wide variety of ECG diagnoses are made. Computer processing of these ECG signals taken at that moment in time has become the definitive practical option for ECG interpretation. Automated ECG analysis has become widespread in clinical practice since the mid-1980s although, in most hospitals, cardiologists will also read them to confirm the automated findings. Automated ECG analysis is quite accurate, especially in normal individuals, but disagreements with cardiologists are seen and may be clinically important (Guglin and Thatai 2006; Bogun et al. 2004). On the other hand, cardiologists are not perfect either (Clark et al. 2010)!

Today, physicians expert in ECG interpretation from multiple professional organizations such as the American Heart Association and the Electrocardiographic Society have come to consensus and established standards designed to improve computerized ECG interpretation. In biomedical informatics terminology, these experts have developed the knowledge base for diagnostic ECG interpretation. The detailed pattern recognition and signal processing does not need to occur in real-time. Thus the 12-lead ECG processing can be more sophisticated than with the requirements of real time monitoring situations (Gregg et al. 2008).

2. Continuous, real-time monitoring is required while the patient is in the ICU. Because of patient movement, caregiver activities such as administering medications, bathing and the like, the amount of artifact generated poses important challenges to real-time monitoring. To minimize these effects, filtering of the acquired ECG signal is performed. This filtering slightly distorts the ECG but at the same time makes it possible to process the signals on a beat-by-beat basis. Although standards for interpretation of ECG monitoring are more recent than those for 12-lead monitoring, they are now becoming more common and sophisticated (Drew and Funk 2006; Funk et al.

2010). The clinical experts who are establishing the knowledge base now include critical-care nurses, cardiologists, anesthesiologists, and thoracic surgeons (Crossley et al. 2011).

ECG processing in today's vendor-supplied bedside monitors continues to improve and become more reliable. Sophisticated pattern recognition and signal processing techniques are used to allow extraction of key parameters in real-time while adding the ability to measure the utility of new physiologic parameters (Crossley et al. 2011). Investigators have created publically available databases of ECG waveforms and other physiologic signals as well as other important data from actual patients to allow validation of these monitoring systems (Saeed et al. 2011; Burykin et al. 2011).

### 21.5.2 ABP Signal Acquisition and Processing

Accurate and continuous monitoring of ABP requires insertion of a catheter into an artery. Once the catheter is successfully inserted into an artery, the catheter is connected, via a length of sterile fluid-filled tubing, to a stopcock with a continuous flush device and a factory calibrated disposable BP transducer (Gardner 1996). The BP transducer is then connected to an amplifier and the pulsatile signal it detects is displayed on the screen of the bedside patient monitor. With the advent of inexpensive, disposable, accurate pressure transducers, the quality and accuracy of ABP monitoring has improved dramatically. However, two sources of inaccuracy of the ABP signal still depend on medical staff setup and validation: (1) zeroing is the process by which the monitor is informed when a port on the stopcock is opened to the atmosphere at mid-heart level – thus becoming the point from which pressure is measured; and (2) since the ABP signal contains pulsatile characteristics with frequencies up to 20 Hz that must be transmitted from the artery through the plumbing system to the transducer, the

dynamic response characteristics must be optimized. Optimization is typically done by doing a fast flush test (by pushing sterile saline through the tubing) to optimize the system by removing blood and very tiny air bubbles that can dramatically distort the ABP waveform and result in erroneous measures of systolic and diastolic pressure.

At least two types of artifacts in the ABP signal are commonly observed. If a patient rapidly moves or a care giver bumps the tubing, a pressure artifact is generated and transmitted to the transducer and displayed. In addition, when the clinical staff draws arterial blood for laboratory tests, they typically turn off the stopcock connected to the transducer and draw blood through the tubing, causing an immediate loss of the pulsatile ABP signal. The pressure sensed by the transducer then typically rises to that found in the pressurized flush solution. Thus, continuous vigilance on the part of nurses and other care givers is needed for the arterial catheter and monitoring systems to be properly maintained. As a historical note, the continuous flush device was developed over 50 years ago to prevent arterial catheters from clotting and to allow one of the pioneering computerized monitoring systems to become more reliable (Gardner et al. 1970). Since that time, investigators have developed computerized methods to minimize these “human caused artifacts” (Li et al. 2009; Gorges et al. 2009). Unfortunately, these strategies have seldom been implemented into commercially available bedside monitors.

Since the early 1900s, efforts have been made to estimate **cardiac output** from the pulsatile pressure in the arterial system by multiplying the HR with estimates of stroke volume (the volume of blood ejected from the heart during a single contraction) made from the pressure waveform. Warner and his colleagues at Mayo Clinic published some early work in 1953 (Warner et al. 1953) on the topic and followed up again in 1983 further substantiating the feasibility of the method. However, Cundick and Gardner (1980) showed that the widely varying mean BPs found in critically ill patients adversely affected the reliability of the method. Since that early work, multiple publications and commercially available

devices using the pulse-pressure method have appeared. The issue is still active, with such publications as Chen et al. (2009), Sun et al. (2009), and Gardner and Beale (2009). Other estimates of stroke volume and cardiac output have been made from determining the bioreactance – a measure of the degree of phase-shift in the electrical signal—across the chest. This method shows promise of being a rather simple, continuous and noninvasive method for measuring cardiac output (Keren et al. 2007).

Investigations have made assessments of delta pulse pressure, which measures the variability of the peak to peak arterial pressure pulse signal across the breathing cycle to make an estimate of a patient’s fluid balance. The supposition is that if there is larger variability in this delta pulse pressure marker the patient may require fluid administration (Deflandre et al. 2008).

It is clear that future methods that process available physiologic signals will be applied to enhance and improve the availability of important measures of cardiac function, a key parameter for making treatment decisions used by critical care caregivers.

### 21.5.3 Pulse Oximeter Signal Acquisition and Processing

One of the most common technologic devices used in hospitals today is the pulse oximeter; continuous monitoring of oxygen saturation became a standard of practice in the early 1990s (Brown et al. 1990). The pulse oximeter sensing device is usually placed on a finger and measures oxygen saturation and pulse rate, or HR (Clark et al. 2006). The modern device works by shining red and infrared light generated by two light emitting diodes through the tissue. With each arterial pulse there is a variation in the light as it passes through the tissue and is sensed by a light-sensitive photodiode on the opposite side. The more oxygenated the blood is, the more red light is transmitted, with less infrared light passing through. By calibrating these devices, reasonably accurate estimates of oxygen saturation ( $SpO_2$ ) can be determined. Although the pulse oximeter is convenient and easy to use, it has several

important limitations, including motion artifact, when the patient moves, and other physiologic considerations such as anemia, low perfusion state and low peripheral skin temperature. If the blood flow to the hand gets disturbed, by perhaps squeezing the arm during BP with a sphygmomanometer, the blood flow to the hand is interrupted and the pulsatile BP signal required for the pulse oximeter is no longer available. The pulse oximeter is one of ICU monitoring devices with most false alarms (Malviya et al. 2000).

#### 21.5.4 Bedside Data Display and Signal Integration

While colorful and dynamic, the displays on the bedside monitor can be complex. ■ Figure 21.6 shows a typical bedside monitor display as one example.

In 2018 Medtronic led the US patient monitoring device market by capturing the largest

segment of pulse oximetry monitoring after acquiring Covidien, the previous leader of pulse oximetry monitoring. With one of most extensive product lines, Philips Healthcare is leading multiparameter vital sign monitoring, wireless telemetry, and fetal/neonatal monitoring markets.

The other major manufacturers in the patient monitoring market are: GE Healthcare, Masimo, Edwards Lifesciences, Mindray Medical, Natus Medical, Welch Allyn, Omron Healthcare, Honeywell Life Sciences, Nihon Kohden, Spacelabs Healthcare, St. Jude Medical, Nonin Medical and Boston Scientific. Each vendor of bedside monitors has made a “best effort” at displaying the variety of physiologic signals derived. In most cases this consists of three channels: ECG, ABP, and pulse oximetry. Additional important physiologic parameters can be derived from these signals, as noted in ■ Table 21.1.

Today’s bedside monitors still present both waveforms and derived parameters in

■ Table 21.1 Bedside physiologic monitoring capabilities

Modality	Transducer	Frequency		Additional parameters		
ECG	Chest electrodes	Continuous	Heart rate	Heart rhythm	Complete ECG waveforms	Pacemaker signal
Arterial blood pressure invasive	Catheter & blood pressure transducer	Continuous	Heart rate	Systolic, diastolic & mean pressure	Estimates of cardiac output	Pulse pressure variation & fluid loading
Pulse oximeter	Finger probe	Continuous	Arterial oxygen saturation	Heart rate		
Temperature	Skin sensor	Continuous	Temperature			
Respiration	Chest belt	Continuous	Respiratory rate			
Bioreactance	Electrodes	Continuous	Cardiac output	Heart rate	Stroke volume	
Arterial blood pressure non-invasive	Inflatable cuff	Intermittent	Heart rate	Systolic, diastolic and mean pressure		

Abbreviation: ECG electrocardiogram

a single-sensor-single-indicator format. That is, for each individual sensor attached to the patient there is a single indicator, a waveform with derived values presented on the screen (Drews et al. 2008). One of the simplistic consequences of this display strategy is that each indicator is treated as if it had come from a different patient. For example, if ECG, ABP, and pulse oximeter signals were displayed, they would each have the capability of determining HR. Thus, three different HR measures might be displayed. Although there are physiologic reasons for such differences, the most common situation is that the HR should be an integrated assessment of the three signals since artifact is a far more common event than the unusual conditions that would cause the differences in HR. Studies suggest that there are better methods for designing hemodynamic monitoring displays (Doig et al. 2011; Drews et al. 2008).

A more important problem relates to the integration of data from multiple bedside devices. Two examples will illustrate the problem:

1. The patient's pulse oximeter has shown a recent increase of SpO<sub>2</sub>. However, the bedside monitor has no knowledge that the respiratory therapist has increased the FIO<sub>2</sub> from 30% to 40% on the ventilator.
2. The patient's HR has recently increased from a dangerously low value of 45 beats per minute to 72 beats per minute. Unfortunately, the bedside monitor has no way of knowing that a nurse has increased the drip rate of a cardioactive medication.

Patients in today's ICUs can have 50 or more electronic devices attached (Mathews and Pronovost 2011). Many of these electronic devices were developed by independent companies and do not easily interface or communicate with each other. However, even though the larger monitoring companies have purchased several of the specialty monitoring companies, problems still exist although it was understood more than three decades ago, and standards for bedside data interchange (CEN ISO/IEEE 11073) (Gardner et al. 1989, 1991) were developed. The Medical Information

Bus (MIB) is the simple term used to designate CEN ISO/IEEE 11073. So, why has the MIB been a commercial failure to this point? There are multiple reasons; unfortunately, the MIB standard was designed during the time when serial communications via RS-232 was the norm; there were no Universal Serial Bus (USB) interfaces or convenient wireless devices (Wi-Fi or Bluetooth) at the bedside. Furthermore, each vendor of bedside devices and ICU data management systems would like to be the "data integrator" (for a price) and thus has little incentive to adhere to standards that would allow other vendors to compete for the integrator role. The business model apparently has not worked (Kennelly and Gardner 1997; Mathews and Pronovost 2011).

In spite of the lack of interface standards, the group at Intermountain Healthcare, LDS Hospital (Salt Lake City, Utah) has been actively interfacing ventilators, IV pumps, and similar devices for over three decades (Dalto et al. 1997; Vawdrey et al. 2007). Another effort is The Medical Device "Plug-and-Play" Interoperability Program at Partners HealthCare (Boston, Massachusetts) – [▶ http://www.mdnp.org](http://www.mdnp.org). The open source result is OpenICE, implementation framework of an Integrated Clinical Environment.

### 21.5.5 Challenges of Bedside Monitor Alarms

Care of the critically ill is complex and challenging. Most of these patients have medical problems or injuries that are life threatening. They might have heart problems that within minutes could result in sudden death, or they might have breathing problems that require mechanical ventilation to maintain life. As a consequence, each of these situations requires intense minute-by-minute observation with real-time, continuous physiologic monitoring. For those conditions, the requirement for record keeping, monitoring, and alarming is intense.

There are clear expectation that bedside physiologic monitors, ventilators, IV pumps,

and similar devices attached to patients should provide true and valid alarms and that caregivers will be promptly notified and provide the needed care immediately for those patients (Kowalczyk 2011). On the other hand, a report from the *New England Journal of Medicine* outlines 24 electronic requirements for classification of a hospital as having a comprehensive electronic record system (Jha et al. 2009), yet recording of data from bedside physiologic monitoring systems with their alarming systems and data gathering from other bedside devices such as ventilators and IV pumps were not even mentioned.

So, currently there is a curious and inexplicable set of expectations being generated for care of the critically ill patients. As a consequence, there are niche vendors who have built their own data gathering and recording systems and nurse charting systems; in some cases these systems include simple interfaces to allow them to acquire laboratory data and perhaps data from the administrative admissions process. They may even include bedside computers or displays to allow care givers to have access to such things as radiographic images, dictated reports, and others. However, these systems are stand-alone devices and do not typically provide interfaces to *transmit* their physiologic data to the hospital's EMR.

In the past, the number of physiologic signals that can and are being monitored has grown. With each signal and derived parameter that is added there is typically a high and low alarm added to warn the clinical staff of actual or impending patient crisis. Alarms may be highlighted on the bedside monitor's screen by using a color change or flashing indicators. Most alarms also generate a sound.

Imhoff and Kuhls (2006) noted from 1.6 to 14.6 alarms for each ICU patient each hour; up to 90% of those alarms were false. Alarm overload is clearly a significant issue in ICU monitoring; from clinical informatics professionals working in the ICU is needed to minimize the number of false alarms. Just noting the titles of several editorials and articles should be informative:

1. Alarms in the intensive care unit: How can the number of false alarms be reduced? (Chambrin 2001)

2. Monitoring the monitors – beyond risk management (Thompson and Mahajan 2006)
3. Alarms and human behavior: Implications for medical alarms (Edworthy and Hellier 2006)
4. Alarms in the intensive care unit: Too much of a good thing is dangerous: Is it time to add some intelligence to alarms? (Blum and Tremper 2010)
5. Intensive care unit alarms – How many do we need? (Siebig et al. 2010)

■ Figures 21.7 and 21.8 give examples of the complexity of determining whether an alarm is true or false based on two life-threatening conditions. Alarms for ventricular tachycardia are shown in ■ Fig. 21.7. ■ Figure 21.7a shows a true ventricular tachycardia alarm condition while ■ Fig. 21.7b shows a false ventricular tachycardia condition. ■ Figure 21.7b has only a few seconds of ECG artifact, which causes the bedside monitors' alarm detection system to issues an alarm.

Arterial hypotension alarms are shown in ■ Fig. 21.8. ■ Figure 21.8a shows a true arterial hypotension alarm condition while ■ Figure 21.8b shows a false condition. If the monitor or human observer only watches the ABP signal, the two conditions appear similar. However, by simultaneously following the ECG signal, the human observer will note that for some unknown reason the ABP signal displays a false representation of the patient's pulsatile BP. The unknown reason is likely related to the catheter and tubing parts of the arterial monitoring system. Alerting the clinical staff to examine the catheter and transducer system is certainly appropriate.

Biomedical informatics specialists, biomedical engineers, and bedside monitor vendors have recently renewed their efforts to reduce false alarms and improve the relevance of existing alarms. Most of the false alarms are caused by noise or artifacts in the primary signals. To help minimize these problems, two examples are used to illustrate the challenges and opportunities to improve bedside alarms.

1. After observing over 200 hours of alarms from bedside monitors and ventilators in an adult medical ICU, Gorges and his

**Fig. 21.7** Ventricular tachycardia alarm conditions. **a** A true alarm; note that the ventricle is still pumping but that the arterial pulse pressure is dramatically

reduced. **b** A false alarm caused by artifact in the ECG signal; note the ABP waveform is stable during the same time interval. ABP indicates arterial blood Pressure, ECG electrocardiogram, v-tach ventricular tachycardia

colleagues (2009) used the data recorded to recommend a two-step process that would dramatically reduce the number of false alarms. The first step was to add a 19 second delay into the alarming system. That step by itself reduced the number of alarms by 67%. They then noted that by having some method for automatically detecting when a patient was being suctioned, repositioned, given oral care or being washed, there would be a further 13% reduction of ineffective alarms. By using these just these two methods, almost 80% of the false alarms could be eliminated.

- Using multiple signals to derive identical measures should be an effective method of reducing false alarms (Herasevich et al. 2013). As will be noted in [Fig. 21.7](#), there are five signals that can be used to

derive HR: ECG 1, ECG 2, ECG 3, ABP, and pulse oximeter. Since the probability of all those signals having an artifact is smaller than any single physiologic signal, smart alarm algorithms that are more robust should be possible. Two investigators have developed and tested such algorithms (Zong et al. 2004; Poon 2005). The Zong pressure alarm algorithm reduced false alarms from 26.8% to 0.5%. Poon found that the usual HR and rhythm alarm system produced 65.4% false alarms, while an algorithm that integrated multiple signals generated only 31.5% false alarms. Two other findings from the Poon study were also encouraging. By merely delaying the alarms by 10 seconds there was a 60% reduction in false alarms. In addition, he found that default settings for high and

**Fig. 21.8** Arterial hypotension alarm conditions. **a** A true alarm; note the normal ventricular beats followed by ventricular fibrillation that renders the heart unable to generate an effective blood pressure. **b** A false

alarm; note for some nonphysiologic reason the arterial pressure signal loses its pulsatile characteristics and then eventually it returns. ABP indicates arterial blood pressure, ECG electrocardiogram

low HR alarms were not optimized to prevent false alarms. For example, if a patient had an average HR of 65 beats per minute and the default low HR alarm was 60 beats per minute, there was an increased likelihood of false low HR alarms. Several bedside monitor vendors now provide these more sophisticated alarm algorithms in their newest monitors.

Still other informatics specialists have found different strategies to provide more accurate ABP and cardiac arrhythmia alarm rates (Aboukhalil et al. 2008; Zhang and Szolovitz 2008). Having electronic archives of physiologic waveforms that are publically available should permit development of even better smart alarm algorithms, which should lead to a reduced number of false alarms generated by bedside monitors (Saeed et al. 2011; Burykin et al. 2011).

## 21.5.6 Biomedical Sensors

One hundred years after the introduction of traditional vital signs they are still in use despite them not describing what exactly happens with patients. Current noninvasive technologies for rapid physiologic function do exist, but have not replaced traditional measurements. Heart function could be measured by stroke volume, arterial oxygenation by pulse oximetry, and ventilation using capnography.

## 21.5.7 Strategies for Incorporating Bedside Monitoring Data into an Integrated Hospital EMR

Three general strategies are currently used to transfer bedside monitoring data into the hospital's EMR.

The first is the simplest and still widely in use: nurses observe data presented on the bedside monitor screen and manually key-in the observations into an integrated EMR. As simple as this may be to implement, such manual data collection strategy is inefficient, error prone up to 15% when documented on paper and then typed into EMR (Wager et al. 2010), and does not collect representative data gathered by the bedside monitor.

The second strategy used by ICU information systems is to acquire vital sign data directly from the bedside monitoring system's network by using an HL7 feed (see ► Chap. 7). The information is automatically gathered by the ICU information system and nurses have the option of either accepting or modifying the data. In typical clinical settings, nurses perform the selection and transfer of bedside monitoring data from the ICU information system to the EMR about once an hour. These ICU information systems typically retain the high frequency bedside monitoring data and can achieve near-real-time computerized decision support. In many cases, the nurse's notes are also entered into the ICU information system – generally once per shift – and some summary vital sign information may find its way into those notes. Physician progress notes are also entered into ICU information systems in a similar fashion. Unfortunately, data in the ICU information system may never find its way into the hospital's EMR. For these systems, the ICU data are usually archived separately. As a consequence, these data cannot be used for real-time decision making by the hospital's EMR.

The third strategy is to have the ICU information system or the hospital's EMR system automatically transfer vital sign data from the bedside monitoring system to the EMR. Most systems that automatically gather data with this strategy take a median of the vital sign data over a 15 minute time interval to smooth the data (Warner et al. 1968; Gardner et al. 1991; Vawdrey et al. 2007). This strategy provides real-time data for computations and computerized decision support for the hospital's EMR and is the preferred strategy.

There are opportunities to improve the automated data gathering from bedside moni-

tors, especially if the false alarm rate can be minimized. In addition to acquiring 15-minute median data, one may wish to detect bedside alarms and record data in the intervals just before and just after these alarms. Thus, there is still opportunity for informaticians to make major improvements in both data recording and bedside monitoring alarms.

## 21.6 Monitoring and Advanced Information Management in ICUs

---

### 21.6.1 Early Pioneering in ICU Systems

---

As electronic information gathered in ICUs and hospitals started growing, problems with bedside monitors, alarms, and data integrations become more apparent. The next step in information management began 50 years ago at LDS Hospital where a team of people developed what was known as the HELP (Health Evaluation Through Logical Processing) System (Pryor et al. 1983; Kuperman et al. 1991; Gardner et al. 1999).

HELP was the first hospital information system to collect patient data needed for clinical decision making and at the same time incorporate a medical knowledge base and inference engine to assist the clinician in making decisions. The HELP system has been operational at LDS Hospital since 1967. The system initially supported a heart catheterization laboratory and a postoperative open heart ICU. Initially only physiologic data were acquired from the bedside monitors. Nursing note charting promptly followed with ability to chart medications ordered and given, including IV drip rates. Soon, it became apparent that much of the data needed to care for these critically ill patients came from the clinical laboratory and other sites such as radiology. As a consequence, multiple modules were added to the HELP system to support the ICUs.

Clinical decision making in the ICU is complex. Physicians, nurses, respiratory therapists, pharmacists, and others evaluate

**Table 21.2** Data used for ICU decision making and their sources

Data types	%	Data source

Abbreviations: *ICU* intensive care unit, *I/O* Intake and Output, *IV* intravenous

each patient using different types and modalities of data. In 1984, a study was performed to identify what data were used by the critical care team to make clinical care decisions (Bradshaw et al. 1984). The investigators were surprised to find that data from the physiologic monitor accounted for only 13% of the data used to make treatment decisions. Table 21.2 outlines the data types evaluated with the percentage of time that each type of data was used to make a care decision. Many of the data came from automated instruments in the laboratory, but a large number came from nurse observations and actions that were manually charted into the computerized record.

However, as described earlier, the physiologic monitor serves a very crucial function during life-threatening situations such as cardiac arrest. The observations showed the crucial need for a fast and reliable laboratory interface *and* the importance of data that came from nurse charting. Knowing what drugs the patient was receiving, when those drugs were given, and the types and administration rates of IV medications were crucial to clinical decision making.

## 21.6.2 Recent Advances in ICU Clinical Management Systems

We are now almost two decades after the Institute of Medicine's, "To Err is Human" report (Kohn et al. 2000) and still medical error remains one of the leading causes of poor outcome of hospitalized patients (Landrigan et al. 2010). Despite high hopes, the current generation of EMR has made things worse, particularly in acute settings where information overload poses a major challenge to timely, evidence-based patient care (Han et al. 2005; Pickering et al. 2012). When caring for unstable patients, providers often have only a few minutes to wade through medical records before making critically important decisions. Clinical decision-making is often hindered by patient information that is difficult to access and use in modern EMRs, which increases the potential for error and delays treatment.

Beginning in 2009 a group of clinicians, clinical informatics specialists, and computer programmers at Mayo Clinic (Rochester, Minnesota) developed Ambient Warning and Response Evaluation System (AWARE) system to address those challenges. AWARE is a data assimilation, communication, workflow, and decision support tool that has the ability to enhance EMR experience (Ahmed et al. 2011). The system is configured to allow a more rapid assessment of patient's clinical data, freeing time to focus on other important patient needs. AWARE has been designed, tested, and validated to foster the best clinical practice by specifically addressing the key clinical components known to improve patient outcomes (Olchanski et al. 2017).

A suite of tools is designed to address patients' needs and focus on acute patient-centered problems rather than organized around specific database or clinical services.

The main components of AWARE could be divided to five domains (Fig. 21.9):

1. Dashboards/viewers. Included are Multi-patient (MPV) and Single-patient viewers (SPV) to reduce information overload by

■ **Fig. 21.9** Essential elements and logical structure of the Ambient Warning and Response Evaluation System (AWARE) clinical management system

facilitating real-time access to key information needed for timely medical and interventional decision making at the point of care.

2. Sniffers or rule-based smart alerts. Continuously survey both the patient condition and provider actions detecting potential mismatches and preventing potential errors before they occur.
3. Communication tools. AWARE whiteboard, task-list, readiness for discharge and claim patient functions facilitate communication between team members and during transitions of care, thereby preventing common errors of communication omission.
4. Checklist/ rounding tool. Designed to assists providers in developing and executing a coordinated daily plan of care. The easy-to-use interface minimizes clerical burden while simultaneously assuring adherence to patient-centered best care practices and regulatory requirements.
5. Administrative dashboard. Feedback and reporting tool enables easy access to quality improvement metrics and patient outcomes for administrators and oversight groups, which facilitates rapid-cycle management changes based on continuous feedback.

### 21.6.3 Acquiring the Data: Quality and Timeliness

A fundamental part of any computerized decision support system, just as with any human clinical decision support system, is the acquisition of data. Clinicians develop observational, interpersonal, and technical skills as they collect accurate patient data. Likewise, a computerized decision support system depends on high-quality, timely data. In many ICUs today, much medical data still continues to be entered into computerized patient records as scanned PDF files or in a structured and coded formats while others (such as the progress note) are be stored in a free text format (either handwritten or typed) (Celi et al. 2001; Pickering et al. 2010; Ahmed et al. 2011; Hripcsak et al. 2011). As noted in ► Chap. 8, natural language processing of free text to obtain coded and structured information has seen great improvement over the past decades; however, the process is still far from perfect and all processing is delayed until data is entered to EMR. Such delays is limiting factor to use such free text data in real time monitoring systems.

As designers of clinical monitoring systems look at acquiring and entering clinical data they must decide:

1. *Who* should enter the data: automated acquisition from electronic instruments (such as the bedside monitor) versus manual entry using a keyboard, bar code reader, touch screen, voice input, or some similar method.
2. *When* to enter the data: accurate ICU decision making often requires data to be acquired in a timely manner, sometimes within 1 minute of an event to make a timely decision.
3. *Where to enter the data*: this automated data will naturally be acquired from the bedside monitor or instrument located at the bedside; manual data entry should optimally occur at the bedside as well.
4. *How* data should be collected: methods should take into account the occurrence of artifacts in the patient data; many EMR systems allow nurses to review and validate bedside vital sign data minutes to hours after they are collected, although this process does not meet the requirement for real-time data collection and can lead to “human” and computerized decision support errors (Nelson et al. 2005; Vawdrey et al. 2007)
5. *How much* data to collect: this is particularly an issue with systems such as bedside monitors that *can* generate an HR, systolic and diastolic BP value for each heartbeat, resulting in hundreds of thousands of values per day; except for special situations to use in automatic decision support systems, the collection of such intensive data in regular EMR is inappropriate.

The process of developing and implementing the systems for acquiring data involves not only technology, but adapting that technology to the human users; training those users to properly use the new system is complex and difficult. Consequently, developers and adopters of such systems should plan for and be prepared for challenges that may take years to implement and optimize system.

Despite modern protocols like HL7 and FHIR there are still major problems with

acquiring ICU data to EMR either automatically or manually (Gardner et al. 1989, 1991; Dalto et al. 1997; Nelson et al. 2005; Vawdrey et al. 2007). Data from bedside monitors, ventilators and IV pumps should be acquired automatically with a real-time technology. Data thus acquired is timely and by appropriate signal processing methods can be validated (Dalto et al. 1997; Vawdrey et al. 2007; Ahmed et al. 2011; Lilly et al. 2011). Changes in ventilator settings such as FIO<sub>2</sub> may only be present for a few minutes, but blood-gas measurements taken during that time interval will be misinterpreted if only manual electronic charting is used. Similar interpretation errors were found to occur with IV pump drip rate charting when manual charting methods were compared to automated acquisition. Gathering accurate, representative, and timely computerized ICU data requires attention to detail and careful planning to assure its quality. Bedside charting systems have the ability to capture near real-time data from bedside devices, but the presentation layer usually showed normalized and averaged values.

#### 21.6.4 Presentation of Data

Once data have been collected, their quality verified, and the results stored, one must decide how the data should be presented. Currently, most data are presented on a colorful screen. However, some care givers will still prefer a paper copy. Still others will prefer to view these reports on their smart phones or other mobile devices. For ICU patients, it is clear that specialized reports must be developed. The traditional method of segmented reporting (separate reports for laboratory data, vital signs reports, medication lists, etc.) has proven inadequate (Clemmer 2004; Ahmed et al. 2011). The ICU group at Mayo Clinic has developed and tested an ICU rounding tool (Pickering et al. 2010). Thus, one can see there is value in the integration of and presentation of data. As of this writing, there is probably not a single ICU summary report that will satisfy all ICU users. Thus, such reports will require special effort for each institution and perhaps even each

ICU within that institution. For example, the report generated for a thoracic ICU is unlikely to be identical to that required by the neonatal ICU. Accomplishing such tasks typically requires 6 months or more, with continuous ongoing effort to update the report as new data are acquired and caregivers needs evolve.

### 21.6.5 Establishing the Decision Rules and Knowledge Base

Deciding on the decision rules that should be installed in a computerized ICU decision support system is difficult. Health care is currently driven by implementing evidence-based protocols. However, few of these protocols have been computerized. The long-standing work with the HELP system and some exciting work done at Mayo Clinic and at the University of Massachusetts are exceptions (Clemmer 2004; Morris 2000; East et al. 1992; Ahmed et al. 2011; Lilly et al. 2011). Using a consensus process to develop treatment decisions is essential. However, generating a consensus is a tedious, difficult, and slow process. At the moment, the consensus process involving all the clinical caregivers in the ICU is the best approach, as rules developed by individuals are often not widely accepted or used. However, in some departments there may be trusted clinical leaders who become the “local expert.” Developing the rules for clinical decision support is complex and those rules are always subject to change. Development of appropriate rules can take up to 6 months and the rules will need to be continuously reviewed and updated (Gardner 2004; Ahmed et al. 2011; Lilly et al. 2011).

### 21.6.6 Clinical Charting Systems: Nurses, Pharmacists, Physicians, Therapists

The major portion (43%) of the data used at LDS Hospital for decision-making during ICU rounds came from clinical notes and data charted by nurses and other clinicians (Bradshaw et al. 1984). In a more recent study in

the ICU at Mayo Clinic, the team found that as they developed AWARE system, they required similar data content (Pickering et al. 2010).

At LDS Hospital, the computerized nurse charting module allows nurses to enter patient care tasks, qualitative and quantitative data, and a patient’s response to therapy (Willson 1994; Willson et al. 1994; Nelson et al. 2005). In addition, nurses interact with a pharmacy module to chart all given medications including IV drip rates (Pryor 1989; Kuperman et al. 1991).

Soon after the nurse charting was implemented at LDS Hospital, respiratory therapists chose to enter their qualitative and quantitative ventilator data and care given to patients (Andrews et al. 1985; Gardner 2004). The motivation for the online charting was to provide clinicians with access to timely and accurate data to make patient care decisions. In addition, these data could be used to implement protocol-controlled ventilator weaning systems (East et al. 1992; Morris 2001).

To optimize the performance of routine care deemed essential for ICU patient recovery, computerized reminders were generated (Oniki et al. 2003). For example, 1 of the goals of the reminders was to provide assistance in determining the required level of sedation while avoiding oversedation. By providing the computerized reminders to nurses, charting deficiencies were reduced by 40% and the number of deficiencies at the end of the shift was improved. To optimize care provided by the reminders, real-time charting was required. However, during a quality improvement process, it was determined that 29% of the medication errors that should have been prevented by online nurse charting were still present. A careful evaluation revealed that the actual nurse charting workflow was different than that envisioned by the system planners. Instead of charting the given medication using a bedside terminal, nurses administered the medication and then at some later time, at the central nursing station, charted that the medication had been given. Consequently, errors were occurring. After careful training and feedback with the nursing staff, the real-time charting rate increased from 40% to 75% and remained at that level a year later. This example shows that having computerized decision

support systems in place without having real-time data entry was ineffective. Conceptually, one could make the same logical observation if the ICU were operating as a tele-ICU, as discussed later in this chapter.

For generations, nurses and other caregivers who have used conventional paper records have had the notion that if their paper chart was up-to-date at the end of the shift then they had met their requirements for good patient care. Clearly, the above example shows that such a strategy is flawed. However, it is interesting that even today reports are being made about charting and use of data for end-of-shift nursing care exchanges and patient handovers, suggesting that the EMR still may not be real-time (Hripesak et al. 2011; Collins 2011). Collins (2011) found that clinicians preferred oral communications compared to EMR documentation and stated that the perceptions that the EMR was a shift behind might have only been a manifestation of the lack of real-time charting by nurses and acquisition of real-time data from bedside monitors in their ICU.

An early survey of nurses and physicians use of the HELP clinical expert system was conducted in 1994 (Gardner and Lundsgaarde 1994). The investigators were encouraged by a positive response from both nurse and physician users who appreciated having the data available with interpretation and alerting features provided by the HELP system. At the time the survey was conducted, ICU charting and decision support was a major feature of the HELP system. It is exciting to note that other institutions have begun to assess factors related to acceptance of an EMR in critical care (Carayon et al. 2011). The Carayon study showed that ease of use, as well as data presentation strategies, were major determinants of acceptability of their system.

### 21.6.7 Automated Data Acquisition From All Bedside Devices

Computer systems that support ICU patients are tightly integrated and data are automatically gathered and stored, primarily in a

coded format so that real-time computerized decision support can be used. ■ Figure 21.10 shows a schematic of the HELP system at LDS Hospital and ■ Fig. 21.11 shows AWARE system at Mayo Clinic as examples of such systems. Based on the data available to ICU management systems from these multiple data sources, its computerized decision support system makes and displays suggestions for optimum care for the specific problems such as sepsis and acute respiratory distress syndrome. The system provides audible and visual alerts for life-threatening situations. In addition, the system organizes and reports the large amount of data so that the medical team can make prompt and reliable treatment decisions. The patient's physicians are automatically alerted about life-threatening laboratory and other findings.

Much of the information required for ICU patient care comes from underlying laboratories and devices that automatically acquire data. In the upper right hand corner of the HELP system diagram, data from the ventilator, IV pumps, and the bedside monitor are noted. While most of the physiologic bedside monitor vendors now acquire ECG, BP, and pulse oximetry data, they do not provide access to data from ventilators or information from IV pumps. As a consequence, data from these devices must be obtained by developing hardware and software interfaces (Gardner et al. 1991; Dalto et al. 1997; Kennelly and Gardner 1997; Vawdrey et al. 2007). Based on those studies, it is clear that automatically collecting data from all of these devices in real-time is more timely and accurate than manually charted data collected by nurses or respiratory therapists. Although data from these devices can contain artifacts, methods for minimizing those artifacts have been implemented in operational systems.

Initially the MIB standard CEN ISO/IEEE 11073 was designed to help gather data from bedside devices, but has not been widely implemented (Mathews and Pronovost 2011). Fortunately, battery power and wireless communications with IV pumps are now widely available. By using wireless technology, inter-

**Fig. 21.10** Diagram of HELP the System Used by Intermountain Healthcare's Hospitals. At the center is the database for the electronic medical record (EMR). Data from a wide variety of clinical and administrative sources flow into the EMR. As the data flows into the EMR, the Data Driver capabilities of the HELP Decision Support Engine (red circle) are activated. In addition,

Time Driver decisions are also made. Shown schematically, in the upper right hand corner of the diagram are blocks representing ICU bedside devices including the physiologic monitor, ventilator, IV pumps and barcode scanner. ECG indicates electrocardiogram, HELP Health Evaluation Through Logical Processing, ICU intensive care unit, IV intravenous

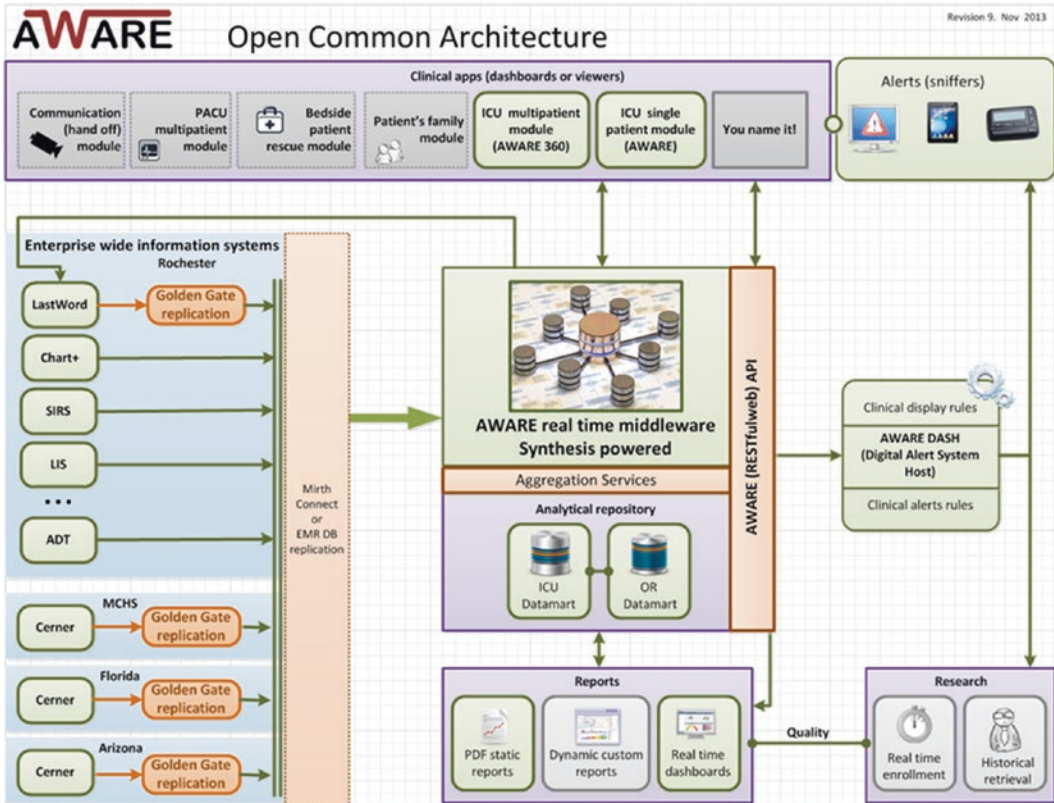

faces with the IV pumps are fast, mobile, and easy for nurses to implement and tangled wires are no longer an issue. In addition, communications with device can be carried throughout the hospital – in the OR, while on transport, and in the ICU.

Although early studies of nurses and therapists showed that computerized charting took longer than manual charting, it is almost certain with automated acquisition available today that charting takes less time and is more accurate. As a consequence, in institutions that have historically collected IV pump and ventilator data automatically, there is a commitment to collect data from every bedside monitoring device. These include measures of urine output, fluid drainage, and similar measures.

### 21.6.8 Rounding Process: Single Patient Viewer

The care of critically ill patients in the ICU requires collaboration among a diverse team of very competent caregivers to achieve the best care (Clemmer et al. 1998). The teamwork and communications is required in this complex care process.

The rounds activity at LDS Hospital is an example of the collaborative process. **Figure 21.12** shows the clinical care team during rounds. There are physicians, house officers, advanced practice clinicians, nurses, pharmacists, respiratory therapists, dieticians, case managers, and others who gather each day to assess each patient and make key care

■ Fig. 21.11 Diagram of AWARE system developed and used at Mayo Clinic. The core component is middleware database that cached data from hospital EMR systems (left). It utilized number of approaches such as DB stored procedures and HL7. Synthesis is Mayo Clinic home-grown API layer and DB. Data from discharged patients archived and stored in Datamart repository. Historical data is used for administrative reporting and cohort identification for research. The alerting module (right) is used for clinical sniffers and research enroll-

ment in clinical trials. On the top are schematically shown clinical applications or viewers that use data from middleware to generate user interfaces. ADT indicates; API; apps applications, AWARE Ambient Warning and Response Evaluation System, EMR DB Electronic Medical Record Database, HL7 Health Level Seven, ICU intensive care unit, LIS Laboratory Information System, MCHS Mayo Clinic Health System, OR operating room, PACU Post Anesthesia Care Unit, SIRS Surgical Information System

decisions. The rounds leader is usually a physician, but each team member is considered an equal partner, providing key information (most of it stored in the computer record) and given the opportunity to discuss their interpretation and make recommendations about the patient's care.

Over decades, the social process of conducting these rounds has created a very open and cooperative environment. The purpose of rounds is to reduce errors from human factors, to give structure to the evaluation, and to make sure all sides of the decision process are considered as each member considers the decisions from their point of view.

The information from the computer system is organized to support the process. The computerized record is *the* patient record. Information from other sources such as radiographic images and free-text reports are also readily available (Gurses and Xiao 2006).

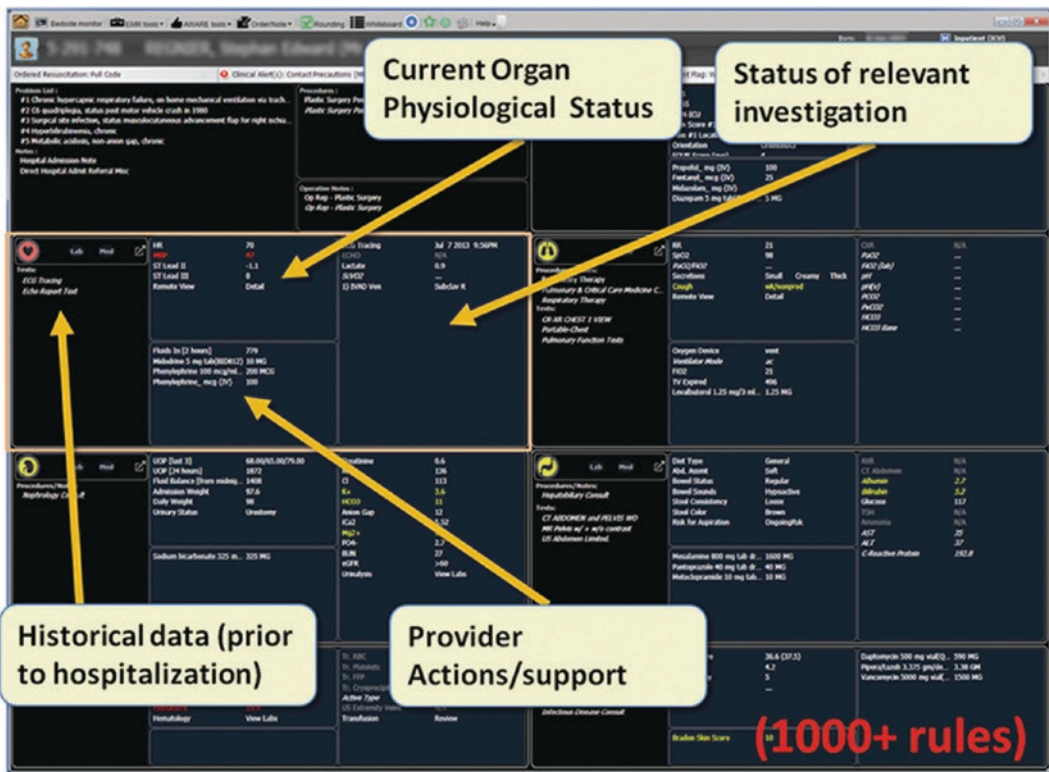

As a single patient viewer, AWARE extracts data relevant to the treatment of ICU patients and presents it to the provider in a systems-based information package (■ Fig. 21.13). AWARE content has been selected through the systematic observation of frontline provider information needs and profiling of provider data utilization patterns. The user interface has been optimized to sin-

**Fig. 21.12** ICU Rounds room at LDS Hospital in Salt Lake City. The computerized ICU rounds report is displayed by a projector on the wall to physicians, a nurse practitioner, medical students, a respiratory therapist, a pharmacist, and a patient's family member. An important laboratory result is highlighted in red by the rounds director. Note several laptops and paper notes used by each of the participants. ICU indicates intensive care unit

gle screen without scrollbars and can be used as an enhancement to the bedside monitor during treating critically ill patients.

User interface and organization of data elements on the screen was determined by considering how experts incorporate information into decision-making mental models. Reference ranges for laboratory abnormalities in AWARE are adjusted for critically ill patients based on expert consensus. All this information about reference ranges, alerts, and type of information represented on the interface is embedded in AWARE rules. It is part of DB and does not utilize any third-party rules engine. This approach decreased false-positive alerts without affecting the fraction of false-negative alerts (unchanged sensitivity and negative predictive value) (Kilickaya et al. 2014).

**Fig. 21.13** Overview of data on the AWARE single patient viewer organized around human organs and systems. Each block represents four elements. Reading from left the key organizational elements are clinical context pulled from the patient problem list, procedure, medications, and consults lists prior to the current hospitalization. System identifying icons with color-coded

status (red, required urgent intervention; yellow, abnormality; white, normal physiology and investigations). Middle top is physiologic status of organ current values for key variables. Middle bottom is organ supports, displays the critical care interventions which are supporting the current physiologic status. Right part of the block displays investigations

The popularization of checklists use in the clinical medicine began with the landmark publication by Dr. Atul Gawande team (Haynes et al. 2009). It has been shown to reduce errors and health care costs, increase compliance with evidence-based practice, and ultimately improve outcomes in critically ill patients (Weiss et al. 2011).

The smart checklist is a component of AWARE (■ Fig. 21.14). The system automatically detects patient characteristics to configure a patient's specific checklist. For example, if a patient is not on the ventilator, no ventilator-related questions are asked. In simulation, the study checklist significantly reduced provider workload and errors (Thongprayoon et al. 2016). Also, use of the checklist in the ICU was associated with increased number of occupational therapy/physical therapy consults in critically ill patients (Ali et al. 2017).

## 21.6.9 Collaborative Process, ICU Change-of-Shift, and Handover Issues

Cognitive scientists have taken an interest in, and have studied, the dynamic and distributed work environment in critical care medicine (Patel and Cohen 2008; Patel et al. 2008; Ahmed et al. 2011). They have studied issues such as provider task load, errors of cognition, and performance of clinicians involved in these complex tasks. The change-of-shift and handover times are especially critical and require complex exchanges of information that must occur rapidly and efficiently. These investigators have found that errors can occur during this time because of corruption of information and a failure to transfer crucial care facts. Having the majority of the patient record in electronic form and having that data timely and accurate should allow optimiza-

■ Fig. 21.14 Overview of AWARE checklist. It is a tool to aid during critical care rounds by helping apply best evidence care for every patient, generate meaningful

clinical notes, and collect data for precise administrative and quality reports. AWARE indicates Ambient Warning and Response Evaluation System

tion of computerized decision making tools and methods for sharing the patient data. The Rounds Report developed at LDS Hospital three decades ago and recent developments at Mayo Clinic provide laboratory models for better understanding the issues and improving efficiency and eliminating medical errors for ICU patients during shift changes and patient handover times. The AWARE system has incorporated a number of tools that support ICU change of shift and handover processes, including shared tasklist, claim the patient, and handover modules. Each tool is designed to decrease the number of errors including omission, as well as the cognitive load of providers.

One of the core components of AWARE is the multipatient viewer that is a population management tool (■ Fig. 21.15). The multipatient viewer shows the census and the geographic layout of patient rooms a specific ICU unit. By hovering over or clicking on the icons, clinical information can be accessed quickly. Each patient box has four distinct areas (■ Fig. 21.16). Workflow or administrative area is on the top and this includes the Task list and Checklist icons as well as the room number and readiness for discharge to the

floor in addition to problem list and current medications icons. The second row is alerting area with a purple circle with a line across that gives providers immediate knowledge that a patient's code status is Do not Resuscitate/Do Not Intubate. The middle section of the box contains patient information such as the patient's name, medical record number, age, number of days in the ICU, and teams caring for the patient. The lower section of the box contains the clinical information with the organ icons. These icons exist for the central nervous, cardiovascular, respiratory, gastrointestinal, renal, and hematologic systems. There is also an icon representing infectious diseases with relevant data including white blood cell counts and microbiologic specimen results. Organ icons are color coded the same as on single patient viewer. Second from bottom row has organs support icons. All icons were tested for recognition and recall by clinical providers (Litell et al. 2012). By clicking on a patient box it will be launched into the Single Patient Viewer.

The AWARE system was extensively tested. In cluster randomized trials the time spent on prerule data gathering decreased from 12 to 9 minutes per patient before and

■ Fig. 21.15 Overview of multipatient viewer. It is population management tool where boxes represent geographical view of patient rooms in the care unit

■ **Fig. 21.16** Patient box on the multipatient viewer includes four groups of icons described in the text

after AWARE implementation (Pickering et al. 2015). In another study, tool usage was associated with a 50% decrease in ICU length of stay, 37% in-hospital length of stay, and total charges for hospital stay decreased by 30% in a post-AWARE cohort (by \$43,745 after adjusting for patient acuity and demographics) (Olchanski et al. 2017).

## 21.7 Computerized Decision Support and Alerting

In addition to the alarms from bedside monitors, there are many other types of alerts and decision support tools that can be helpful for the care of hospitalized patients. A sampling of the types of decision support mechanism that have been reported is provided below to give the reader a sense for the breadth of capabilities that have been applied in intensive care as well as other care settings of hospitals. Key to the application of such computerized decision support tools is having access to an integrated, real-time, accurate, and coded EMR. Most of the examples noted are from the HELP system (Gardner et al. 1999). A key function of the HELP system is that the computerized decision support system is activated when new patient data are added to the patient's database, the process is called data-driven decision making. An example would be when the Po<sub>2</sub> is put into the medical record an instruction is given to the respiratory therapist to modify the FIO<sub>2</sub> or PEEP (Positive

end-expiratory pressure) accordingly. Some functions of the HELP system, such as alerts, require that computerized decision support be activated at specific times and that process is called time-driven decision making. An example would be to remind the nurse the next glucose check is due when the patient is on an insulin drip, or instructing the computer to automatically calculate today's APACHE (Acute Physiology, Age, Chronic Health Evaluation) score and update all the reports at 06:00 AM.

In the past, commercially available EMR/ICU systems did not have convenient methods for programming and execution of computerized decision support rules. However, recent surveys by Sitting and Wright have shown that more and more commercial vendor systems have improved capability for providing clinical computerized decision support (Sittig et al. 2011; Wright et al. 2011). Once computerized decisions are made, they must be used to notify clinicians so that the feedback can be used to more effectively care for patients. The most common notification method is presentation on the computer screen when a clinician is interacting with the computer in some task such as order entry or charting. However, the issues of *how* to notify and *who* to notify are much more challenging (Tate et al. 1995; Shabot 1995). Further, verifying that such feedback results in the appropriate care is becoming ever more important.

Research continues on identifying the most efficient and effective notification methods.

Just as with the false alarms generated by bedside monitors, alarm feedback from computer systems must present timely and accurate recommendations with a minimum number of false alarms.

### 21.7.1 Laboratory Alerts

During the developmental period of the HELP system in the 1980s, it became apparent that on occasion life-threatening laboratory results were not being acted upon promptly. On acute care nursing floors, the initial alert response time averaged from 5.1 to 58.2 hours (Bradshaw et al. 1989). By posting alerts on computer terminals on nursing floors, the average response time was reduced to 3.6 hours. Then a flashing light, similar to those found on road maintenance vehicles, was installed on each nursing floor. The average response time then decreased to 6 minutes but the light was very annoying to the nursing staff (Bradshaw et al. 1989). When a sophisticated nurse paging system was set up that paged the particular nurse caring for the patient with the laboratory alert and required nurses to acknowledge the alerts the new pager system was equally effective and less annoying to other patients and staff (Tate et al. 1995). Similar work was done by Shabot (1995) at Cedars-Sinai Hospital in Los Angeles using a Blackberry pager. Since that time, wireless communications technology has improved dramatically and a variety of even better feedback mechanisms are now available. However in a study by Harrison et al. (2017), the alert acknowledgement rate from the severe sepsis alert system was significantly better with traditional paging system.

### 21.7.2 Ventilator Weaning Management and Alarm System

Weaning patients from ventilators was one of the first applications of a computerized expert system to routine patient care at LDS Hospital. As a result of the nurse and respira-

tory therapist charting described earlier, it was possible to develop and test computerized ventilator management protocols. Patient therapy was controlled by protocol 95% of the time and 90% of the protocol instructions were followed by clinicians. Several of the computerized instructions not followed were due to ventilator charting errors. Patients cared for with the computerized protocol had required less positive pressure in the ventilator system, and physiologic measures were disturbed less. The investigators concluded that such protocols could make the ventilator weaning processes “less mystifying, simpler, and more systematic” (East et al. 1992). Since that early work, several other investigators have implemented similar ventilator weaning algorithms.

In the process of implementing automated charting of ventilator parameters at LDS Hospital (Vawdrey et al. 2007), it became clear that critical ventilator alarms were being missed. As discussed earlier, alarm sounds emitted from ventilators were blended with bedside monitor alarm sounds. As a consequence, when a patient became disconnected from a ventilator the alarms could be missed (Evans et al. 2005). Once this situation was recognized, an enhanced notification system was implemented. ■ Figure 21.17 illustrates a ventilator disconnect alarm presented on the patient’s bedside display and on every other computer display in the same ICU. The efficacy and user acceptance of the new alarm system has enhanced patient safety and allowed documentation of this important clinical event.

■ Fig. 21.17 Ventilator disconnect alarm. This alert is for the patient in Room E645 but it is displayed on every computer screen in the intensive care unit

### 21.7.3 Adverse Drug Event Detection and Prevention

Detection and prevention of **adverse drug events** (ADEs) has been a long-term goal of caregivers, the World Health Organization, and the U.S. Food and Drug Administration (Classen et al. 1991). Physicians, pharmacists, and informatics specialists at LDS Hospital developed a computer-based ADE monitor that detected a variety of triggers in the EMR that could indicate potential ADEs, such as sudden medication stop orders, medication antidote ordering, and specific abnormal laboratory and physiologic results. Pharmacists followed up on each ADE alert and each was verified and categorized. During an 18-month period, 36,653 hospitalized patients were monitored and 731 true ADEs occurred in 648 patients, 701 were classified as moderate or severe. Only 92 of the ADEs were identified by traditional voluntary reporting methods. Using this knowledge, the investigators developed methods for preventing ADEs. An example is the nurse charting work of Nelson et al. (2005).

Classen and colleagues (1997) followed up their earlier surveillance system for ADEs. They found that the attributable length of stay and costs of hospitalization for ADEs were substantial. If a patient had an ADE there was an increased length of stay of 1.74 days, an increased cost of \$2,013, and an increased risk of death of 1.88 (Classen et al. 1997).

Even with the enhanced computerized methods for detecting, preventing and monitoring ADEs, there is still room for improvement (Petratos et al. 2010). In a study over 200,000 medication alerts in an electronic prescribing system found more than 90% of drug alerts were overridden by physicians (Isaac et al. 2009). Critically ill patients are particularly susceptible to ADEs due to their unstable physiology, complex therapeutic medications, and the large percentage of IV medications (Hassan et al. 2010). Better systems must be developed and implemented to prevent ADEs.

### 21.7.4 IV Pump and Medications Monitoring

IV medication administration occurs in 90% of hospitalized patients; virtually every ICU patient is connected to an IV pump to receive fluids, nutrients, and medications. Although so-called smart pumps have been developed to minimize errors, those pumps are not yet integrated with the EMR and, as a result, are not capable of helping to prevent IV administration errors. Evans and associates (2010) at LDS Hospital have used cabled or wireless IV pumps integrated with the HELP system to enhance notification of IV pump programming errors. The medication charting system can detect and provide real-time alerts whenever an initial or potential pump rate programming error occurs. A set of 23 high-risk medications are monitored by the HELP system. Whenever IV pump flow rate for one of these medications is outside the acceptable range, a visual alert such as that shown in  Fig. 21.18 is presented on the bedside display and on all other computer displays in the same ICU. Over a 2-year period, they found that there were alerts on 4% of the initial or dose rate changes or about 1.4 alerts per day.

Pump Alert  
E601  
Pump #305

 **Fig. 21.18** Intravenous pump alert. This alert is for pump 305 located in Room E601, but it is displayed on every computer screen in the intensive care unit

Of those alerts, 14% were found to have prevented potential patient harm.

Clearly the monitoring and alerting system for ICU patients involves quite a different process and strategy than the usual bedside monitoring alarms. However, by having the integrated clinical record and the computerized decision support system available, these investigators have made major advances in minimizing ADEs and providing higher quality patient care.

## 21.8 Remote Monitoring and Tele-ICU

**Tele-ICU** is defined as the provision of care to critically ill patients by health care professionals located remotely. Tele-ICU clinicians use audio, video, and electronic links to assist the bedside caregivers in monitoring patients to help provide best practice and to help with the execution of optimized patient care plans. These types of systems have the potential of improving patient outcomes by having shorter response times to bedside monitor alarms and to abnormal laboratory values, initiating life-saving therapies, providing best practice more frequently, and providing expertise to smaller or remote ICUs where subspecialists are not readily available (Lilly et al. 2011). Historically, tele-ICU concepts date back to the mid-1980s, but it was not until the early 2000s that there was a dramatic increase in the use of such systems (Breslow 2007).

Tele-ICU has built on the concepts of computerized patient monitoring discussed earlier in this chapter. The real-time, EMR is fundamental to making tele-ICU care practical. The clinical information system is one of the keys to allow clinicians not physically present in the ICU to be able to suggest appropriate care. Enhanced bedside data acquisition and alarm systems, as well as clinical decision support systems (such as those described above) are required if remote clinicians are to provide practical and effective care for patients located in multiple remote ICUs (Rosenfeld et al. 2000; Celi et al. 2001; Breslow 2007, and Lilly et al. 2011). ■ Table 21.3 gives an

■ **Table 21.3** Comparison of typical ICU care processes with Tele-ICU care processes

Typical no EMR ICU	Tele-ICU
Bedside monitor alarms	Physiologic trend alerts
	Abnormal laboratory value alerts
	Review of response to alerts
	Off-site team rounds
Daily goal sheet	Electronic detection of nonadherence
	Real-time auditing
	Nurse manager audits
	Team audits
Telephone case review initiated by house staff or affiliate practitioner	Workstation review initiated by intensivists including EMR, imaging studies, interactive audio and video of patient, integrated with nurse and respiratory therapist, and assessment of responses to therapy

Adapted from Lilly et al. (2011)

Abbreviation: *EMR* electronic medical record, *ICU* intensive care unit

overview of the differences between a typical ICU with no electronic record compared with a tele-ICU.

Recent findings of the impact of tele-ICU are encouraging and exciting. Patients receiving such care have lower hospital and ICU mortality and shorter hospital and ICU lengths of stay. Measures of adherence to best care practices are increased and complication rates are decreased (Lilly et al. 2011). However, the investigators pointed out that they had to implement major process and culture changes in their reengineering activities to make their system work (Lilly et al. 2011). An editorial accompanying the Lilly article outlines challenges still to be studied and understood about tele-ICU (Kahn 2011a). Since many changes were made from the typical ICU to the tele-ICU intervention, simply add-

ing better electronic data recording, electronic physiologic surveillance, and computerized decision support may have provided the same benefit, independent of the telemedicine feature. Informatics specialists clearly have exciting opportunities to improve care of critically ill patients and answer important process and intervention questions.

### 21.9 Predictive Alarms and Syndrome Surveillance

---

One key factor for medical errors is information overload (Kohn et al. 2000). False alerts from electronic and monitoring systems continue contribute to problem. Ideal alerts should only be issued when events are clinically significant, undetected by providers, and there is opportunity for correction of the underlying problem (actionable alert) (Norris and Dawant 2001). There are a number of approaches to reduce false alerts. Machine learning and surveillance methods have been developed to assist clinician decision makers in the care of complex care situations (Lee and Mark 2010). The work of Lee and colleagues at Harvard/Massachusetts Institute of Technology presents a methodology that has great promise (Lee et al. 2010). These investigators used machine learning to see if they could use pattern recognition approaches to predict impending hypotension in ICU patients. Using the high-resolution vital sign trends from the MIMIC II (Multiparameter Intelligent Monitoring in Intensive Care) Database, they trained their system to predict impending hypotension. Although the results were not perfect, they were able to identify patients at higher risk for developing hypotensive episodes within the subsequent 2 hours, thus alerting busy clinicians to be vigilant to impending events. Intelligent rule-based alerts, or sniffers developed at Mayo Clinic by Herasevich and his associates (2009, 2010, 2011), used near real-time Multidisciplinary Epidemiology and Translational Research in Intensive Care Data Mart to detect high-risk syndromes

in patients and to alert clinicians if therapy has not yet been started. These investigators have provided excellent recommendations for development and use of large databases to allow better understanding of the complexities of patients who are critically ill. Advances in machine learning techniques showed promising results in predicting life-threatening situations (Evans et al. 2015) and death (Johnson and Mark 2018).

### 21.10 Opportunities for Future Development

---

Throughout this chapter, we have discussed many challenges and opportunities that remain in the field of patient monitoring systems. There are still important possibilities in the development of better and more effective bedside monitoring systems, especially in the area of maximizing true alarms and minimizing false alarms. Integrating clinical data from a broad variety of hospital and personal records is still challenging and important. Being able to apply computerized decision support systems to warn of life-threatening situations or advise care givers about optimum patient treatment strategies is still a relatively new aspect of health care. Development of patient care protocols and then having them be executable by computers, especially for ICU patients, is also an exciting field of endeavor.

Since the early 1950s, when physicians began to understand control system theory, there has been a fascination with having control systems that closed the loop without the need for any human intervention. Implantable defibrillators and pacemakers are examples closed-loop devices. The publication in 1957 started the idea of automating mechanical ventilation (Saxton and Myers 1957).

We still believe that applying informatics in the ICU is a “contact and team sport,” that you must be involved at the patient care level and work with the incredibly talented clinical teams to maximize the benefits that biomedical informatics specialists can provide.

### 21.10.1 Value of Computerized ICU Care Processes

Challenges and opportunities lie in proving the value of health information systems. There have been dramatic improvements in the adoption of EMR in recent years (Gardner RM 2016). A review by Chaudhry and associates (2006) assessing the impact of health information technology on the quality, efficiency, and cost of medical care is illustrative of the challenge. An even more sobering report was presented by Karsh and associates (2010). These investigators suggest that not only is rate of adoption of health information technology low, but such technology may not improve quality of care or reduce costs. Introducing a new EMR system can lead to change in workflow. There are documented increases in revenue after EMR implementation despite of productivity loss (less patient visits) (Howley et al. 2015). Thompson and colleagues (2015) systematic review “Impact of the Electronic Medical Record on Mortality, Length of Stay, and Cost in the Hospital and ICU” were not shown to have a substantial effect on those metrics. However, there was a significant effect of surveillance systems on in-hospital mortality.

### 21.11 Clinical Control Tower and Population Management

Clinical Control Tower is a newly-developed central alert-screening clinical surveillance system developed at Mayo Clinic. The concept behind the Clinical Control Tower is to serve as a centralized non-life-threatening alert and prediction “cockpit.”

This unified screening system is managed by a designated capsule communicator or “CapCom,” analogous to the US National Aeronautics and Space Administration ground-based astronaut who maintains contact with astronauts during space missions. The CapCom in the healthcare context is the clinician responsible for screening incoming alerts and notifications. As no alerts have 100% accuracy it is essential to perform initial vali-

ation of notifications before activating specific workflows with bedside providers. When the CapCom decides that an alert is valid, he or she communicates “down to the ground” to a bedside clinician and guides them through necessary and recommended tasks. Each step may be captured electronically in the control tower application. Workflow and actions are captured and analyzed using a feedback loop tool. Deviations from intended care processes may be identified. Control Tower is a tool designed to minimize errors and information overload in hospital practice.

As the COVID-19 pandemic hit the USA healthcare system, the Control Tower platform was modified and expanded to address the surveillance needs of hospitalized Covid-19 patients (■ Fig. 21.19). The system identifies the status of COVID lab tests, COVID results, patient isolation information and MEWS score.

The features required to facilitate reliable monitoring and management of acutely ill patient populations differ significantly from those required to manage single patient encounters. These demands are not easily met by the most common commercially available comprehensive electronic medical records and often require complementary alternative approaches such as the one illustrated in the Control Tower example above.

**Questions for Discussion**

- Describe how the integration of information from multiple bedside monitoring signals, the pharmacy, and clinical laboratory data can help improve alarm systems used in an ICU.
- How would you decide whether to buy a standalone ICU patient monitoring system versus an integrated EMR system?
- How do care providers impact the installation and optimization of real-time data collection and real-time decision support?
- Perhaps real-time data collection and computerized decision support are not necessary. How would you assess these issues? Is there sufficient literature to validate or disprove your supposition? If not, what is missing?
- How would you go about selecting the optimum data for monitoring and improving the care of a critically ill patient?
- How would you optimize a patient monitoring system that you were building or buying to provide the most accurate, timely, and helpful computerized decision support capabilities? Be specific and give literature references to support your optimization plan.

7. If you were the Chief Clinical Information Officer of a large hospital without data from the ICU integrated into your EMR system, what factors would you have to consider to implement such a system AND to apply computerized clinical decision support to optimize such a system? How long do you think it would take to implement such a system?

### Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What are the key components needed for Radiological Image interpretation?
- What are the roles of the Radiology Information System (RIS), Picture Archiving and Communication System (PACS), Computer-Aided Diagnosis (CAD), Vendor Neutral Archives (VNAs), and Advanced Visualization Systems (AVS) in a typical medical imaging department?
- How does the DICOM standard differ from HL-7 in the structure of its information model?

## 22.1 Introduction

In ► Chap. 10, we introduced the concept of **digital images** as a fundamental data type that, because of its ubiquity, must be considered in many applications. We furthermore defined biomedical **imaging informatics** as the study of methods for generating, manipulating, managing, extracting, and representing imaging information.

In this chapter, we continue the study of imaging informatics, begun in ► Chap. 10, by describing many of the methods for generating and manipulating images and discuss the relationship of these methods to structural informatics. We emphasize methods for managing and integrating images, focusing on how images are acquired from imaging equipment, stored, transmitted, and presented for interpretation. We also focus on how these processes and the image information are integrated with other clinical information and used in the health care enterprise, so as to have an optimal impact on patient care.

We discuss these issues in the context of Radiology, since imaging is the primary focus

of that field.<sup>1</sup> Yet imaging is an important part of many other fields as well, including Pathology, Hematology, Dermatology, Ophthalmology, Gastroenterology, Cardiology, Surgery (for minimally invasive procedures especially) and Obstetrics, which often do their own imaging procedures; most other fields that use imaging rely on Radiology and Pathology for their imaging needs.

The distribution of imaging responsibility has given rise to the need of many departments to address issues of image acquisition, storage, transmission, and interpretation. As these modalities have become increasingly digital in form, the development of electronic systems to support these tasks has been needed.

We begin by describing some of the roles of imaging across all of biomedicine, then concentrate on image management and integration in radiology systems, bringing in illustrative examples from other disciplines where appropriate. Many Radiology departments are becoming highly distributed enterprises, with acquisition sites in intensive care units, regular patient floors, emergency departments, vascular services, screening centers, ambulatory clinics, and in affiliated community-based practice settings. Interpretation of images may be in those locations when dedicated onsite radiologists are needed, such as for local interventional procedures. Increasingly, however, high-speed networks are enabling interpretation at sites far from acquisition, either in a central location or in widely distributed locations according to the different capabilities or time zones of the organization. This is possible because image acquisition and interpreta-

---

1 The name Radiology is itself a misnomer, since the field is involved in using ultrasound, magnetic resonance, optical, thermal, and other non-radiation imaging modalities when appropriate. Radiology departments in some institutions are thus referred to alternatively as Departments of Medical Imaging or Diagnostic Imaging.

tion can be effectively decoupled. Independent imaging centers in a community face some of the same issues and opportunities, although to a lesser degree, so we focus primarily on the distributed medical center-based Radiology department in this chapter.

## 22.2 Basic Concepts and Issues

### 22.2.1 Roles for Imaging in Biomedicine

Imaging is a central part of the healthcare process for diagnosis, treatment planning, image-guided interventions, assessment of response to treatment, and prediction of outcome. In addition, it plays important roles in medical communication and education, as well as in research.

#### 22.2.1.1 Detection and Diagnosis

The primary uses of images are for the detection of medical abnormalities, for diagnosing the nature of those abnormalities, and for planning and guiding therapeutic interventions. Detection focuses on identifying the presence of an abnormality, but in the case where the findings are not sufficiently specific to be characteristic of a particular disease, other information is required for actual diagnosis. This is the case, for example, with mammograms, which are often used to screen for breast cancer; once a suspicious lesion is detected, a biopsy procedure is usually required for diagnosis. In other circumstances, the image finding is diagnostic: for example, the finding of focal stenosis or obstruction of an artery during angiography. Most often there is a continuum between detection and diagnosis, with imaging detecting a lesion with some range of confidence, and suggesting some possibilities, known as the **differential diagnosis** (see ► Chap. 2).

Diagnosis and detection can be done with a wide variety of imaging procedures. Images produced by visible light can be used by ophthalmologists for retinal photography, but also by dermatologists to view skin lesions, or by pathologists for light microscopy. The visible-

light spectrum is also responsible for producing images seen endoscopically, typically captured as video images or sequences (movies). Sound energy, in the form of echoes from internal structures, is used to form images in ultrasound, a modality used heavily in cardiac, abdominal, pelvic, breast, thyroid, testes, and obstetrical imaging. In addition, **Doppler shifts** of sound frequency can measure blood flow velocity in both arteries and veins and newer microvascular imaging methods can measure perfusion in capillary beds. X-ray energy produces radiographic and **computed-tomography (CT)** images of most parts of the body: the differential absorption of X-rays by various tissues produces the varying densities that enable radiographic images to portray normal and abnormal structures. More recent techniques that separate the various energies of the X-ray beam allow for more precise characterization of tissue composition, a simple form being known as dual-energy CT, and more advanced forms known as spectral CT. Emission of radioactive particles by isotopes that are incorporated into various types of molecules are used to produce nuclear-medicine images, which reflect the differential concentration of those molecules in various tissues. **Magnetic-resonance imaging (MRI)** depicts energy fluctuations of certain atomic nuclei—usually hydrogen—when they are aligned in a magnetic field and then perturbed by a radiofrequency pulse. Parameters such as proton density, the rate at which the nuclei return to alignment (T1), the rate of loss of phase coherence after the pulse (T2), diffusion of water, and even the concentration of certain chemicals (MR Spectroscopy) can be measured. These quantities differ in various tissues under normal conditions, with more variations due to disease, thus enabling MRI to distinguish among them. ■ Figure 22.1 shows some example images. It is also possible to use MRI methods to accentuate and measure the flow of fluids like blood or CSF, known as Magnetic Resonance Angiography (MRA).

#### 22.2.1.2 Assessment and Planning

In addition to being used for detection and diagnosis, imaging is often used to assess a patient's health status in terms of progression of a disease process (such as determination of

**Fig. 22.1** Examples of the types of images discussed in the text. (a) is a microscopic image of tissue stained with hematoxylin and eosin; (b) is an ultrasound image of the thyroid; (c) is a contrast-enhanced CT image of the abdomen; (d) is contrast-enhanced MRI of the brain; (e) is an MR angiogram of the cervical vessels; (f) is an FDG PET-CT image of the upper body; (g) is a photograph of an eye (Dermatopath, US, CDUS, CT, MRI, MRI-DWI)

tumor stage), response to treatment, and estimation of prognosis. One can analyze cardiac status by assessing the heart's size and motion echocardiographically. Similarly, one can use ultrasound to assess fetal size and growth. Computed tomography is used frequently to determine approaches for surgery or for radiation therapy. In the latter case, precise calculations of radiation-beam configuration can be optimized to maximize dose to the tumor while minimizing absorption of radiation by surrounding tissues. This calculation is often performed by simulating multiple radiation-beam configurations and iterating to a best treatment plan. For surgical planning, three-dimensional volumes of CT or MRI data can be constructed and presented for viewing from different perspectives to facilitate determination of the most appropriate surgical approach. More recently, creation of 3D printed models using 3D printers has become very popular for surgical planning and patient education. In some cases, the printed object is even used to guide incisions or implanted as a scaffold for tissue ingrowth.

### 22.2.1.3 Image-Guided Procedures

Images can provide real-time guidance when virtual-reality (VR) images are superimposed on a surgeon's visual perspective on the appropriate image view in the projection that demonstrates the abnormality, a technique known as augmented reality (AR). With endoscopic and minimally invasive surgery, this kind of imaging can provide a localizing context for visualizing and orienting the endoscopic findings, and can enable monitoring of results of interventions such as focused ultrasound, cryosurgery, or thermal ablation. It is also possible to use intra-operative imaging to update the position and appearance of pre-operative imaging used for procedural planning. ■ Figure 22.2 shows an example of a CT-guided biopsy of a lesion in the neck. High quality imaging allows precise targeting of small targets such as diseased lymph nodes with little risk of damaging important nearby structures like the aorta or carotid artery.

Improvements in robotics technology and wide-area network capability have enabled minimally invasive procedures to be conducted at a distance (see ► Chap. 20), although it is

■ Fig. 22.2 Example of a CT-guided biopsy of a lesion in the neck. High quality imaging allows precise targeting of small targets even near important structures like the carotid artery

still practical to do so only in limited settings. Because the abnormality is viewed through a video display, the image source can be physically remote, a technique called **telepresence**. Similarly, the manipulation of the endoscope itself can be controlled by a robotic device that reproduces the hand movements of a remote operator, and can provide **haptic feedback** reproducing the sensations of tissue textures, margins, and resistance. This technology is not too different from the robotic surgery methods that have become quite common today, though the practical limits noted above have limited its use.

### 22.2.1.4 Communication

Medical decision-making, including diagnosis and treatment planning, is often aided by allowing clinicians to visualize images concurrently with textual reports and discussions of interpretations. Thus, we consider imaging to be an important adjunct to communication and images to be a desirable component of a multimedia electronic medical record. Because medical imaging is an essential element of the practice of medicine, support for transmission and remote image viewing is also a critical component of telemedicine

(► Chap. 20). Medical images can also be helpful in doctor-patient communication, to enable the provider to illustrate an abnormality or explain a surgical procedure to a patient (► Chap. 11).

### 22.2.1.5 Education and Training

Images, whether 2D, 3D (either 3 spatial dimensions or 2D plus time), or 4D (3 spatial dimensions plus time) are an essential part of medical education and training because so much of medical diagnosis and treatment depends on imaging and on the skills needed to interpret such images (see ► Chap. 24). Case libraries, tutorials, atlases, quiz libraries, and other resources using images can provide this kind of educational support. Three-dimensional printed models of both normal structures and various pathologic conditions are now being routinely created for patient and physician education. The ability to hold the structure in one's hand, and manipulate it have proven very valuable, particularly in cases that are unusual such as congenital deformities.

Taking a history, performing a physical examination, and conducting medical procedures also demand appropriate visualization and observation skills. Training in these skills can be augmented by viewing images and video sequences, as well as through practice in simulated situations. An example of the latter is an approach to training individuals in endoscopy techniques by using a mannequin and video images in conjunction with tactile and visual feedback that correlate with the manipulations being carried out.

As noted in the previous section, patients increasingly expect to understand more about their disease, and patient communications can be more effective by including relevant images. Imaging also has a consumer/patient education benefit, since access to appropriate images can be included along with the provision of instructions and educational materials to patients, whether that is about their disease, the procedures to be performed, required follow-up care, or about healthy lifestyles.

■ **Fig. 22.3** Example of a detailed segmentation of the brain into various anatomic structures by the FreeSurfer package. It uses a combination of image intensities and expected shapes for the brain and substructures to produce its output

### 22.2.1.6 Research

Imaging is also a critical component of many aspects of research. An example is structural modeling of DNA and proteins, including their 3D and 4D configurations (see ► Chap. 9). Images obtained in molecular or cellular biology can show the distributions of fluorescent or radioactively tagged molecules through time or space. The study of **morphometrics**, which is literally the measurement of shape, depends on the use of imaging methods. ■ Figure 22.3 shows an example of a detailed segmentation of the brain into various anatomic structures by the FreeSurfer package.<sup>2</sup> It uses a combination of image intensities and expected shapes for the brain and substructures to produce its output. **Functional mapping**—for example, of the human brain—relates specific sites on images to particular functions. While such quantitative imaging efforts often begin in the laboratory, translation of such quantitative methods is increasingly important to the practice of medicine. ■ Figure 22.4 provides an example of functional mapping of a patient with a brain tumor, where functional mapping is used to identify critical structures, and thus to guide surgical therapy.

2 ► <http://surfer.nmr.mgh.harvard.edu/> (Accessed 4/27/2018).

■ Fig. 22.4 Example of functional mapping of a patient with a brain tumor, where functional mapping is used to identify critical structures, and thus guide surgical therapy

### 22.2.2 The Radiologic Process and its Interactions

As noted in the introduction, we concentrate in this chapter on the subset of imaging that falls under the purview of **Radiology**. Radiology departments are engaged in all aspects of the healthcare process, from detection and diagnosis to treatment, follow-up and prognosis assessment. Radiology also illustrates well the many issues involved in acquiring and managing images, interpreting them, and communicating those interpretations. Space does not permit us to discuss the other disciplines that utilize imaging, but the processes involved and issues faced which we discuss in the context of radiology, pertain to the other disciplines also. Additional examples are also provided in ► Chap. 10. Occasionally, we intersperse examples from other areas, where we wish to emphasize a particular point, and imaging for educational purposes is discussed at length in ► Chap. 25.

The primary function of a Radiology department is the acquisition, analysis, and interpretation of medical images but also increasingly, the conduct of minimally inva-

sive image-guided procedures, an area usually referred to as **Interventional Radiology**. Through imaging, healthcare personnel obtain information that can help them to establish diagnoses, to plan or administer therapy, and to follow the courses of diseases or therapies.

Diagnostic studies in the Radiology department are typically performed at the request of referring clinicians, who then use the information for subsequent decision-making. The Radiology department produces the images, and the radiologist provides the primary analysis and interpretation of the radiologic findings. Thus, radiologists play a direct role in clinical problem-solving and in diagnostic-work-up planning for many patients. Interventional radiology and image-guided surgery (if done by the radiologist) are activities in which the radiologist plays a primary role in treatment.

The complete radiologic process (Greenes 1989) is characterized by seven kinds of tasks, each of which involves information exchange, which may be augmented by information technology, as illustrated in ■ Fig. 22.5. The first five tasks occur in sequence, whereas the

■ **Fig. 22.5** The radiologic interpretation process

final two are done in parallel and are ongoing and support the other five.

1. The process begins with an evaluation by a clinician of a clinical problem and determination of the need for an imaging procedure. Decision-support tools (► Chap. 24) are commonly used to help determine if, and what type of, testing should be performed.
2. The procedure is requested and scheduled, the indication for the procedure is stated, and relevant clinical history is made available.
3. The imaging procedure is carried out, and images are acquired. An important step for many types of examinations is the ‘protocoling’ in which the precise way that the images are acquired are specified by the radiologist. For example, whether oral or IV contrast are administered, the imaging plane(s), slice thickness, and contrast properties are also specified.
4. The radiologist reviews the images in the context of the clinical history and indications for the examination and may measure structures in the images, segment components of the image (e.g. measure volumes such as the left ventricle), or manipulate the images (e.g. create 3D renderings or perform processing such as conversion of a series of images into a new parametric image like a blood volume image). This task actually involves inter-related subtasks: (a) detection of the relevant findings and (b) interpretation of those findings in terms of clinical meaning and significance.
5. The radiologist creates a report and may also directly communicate the results to the referring clinician, as well as making suggestions for further evaluation as needed. In the past, this was free text, but there is increasing use of templates that result in a consistent pattern in the report, or structured reports in which the textual report also exists in a form with codes for all concepts in the textual report. The annotation and markup of images can be very helpful in communicating locations of findings and serves as helpful landmarks for subsequent exams, and for surgical or radiation procedures.
6. Quality control and monitoring are carried out throughout the process, with the aim of improving the foregoing processes. Factors such as patient waiting times, workloads, numbers of exposures obtained per procedure, quality of images (such as ones degraded by patient motion or incorrect acquisition parameters), radiation dose, yields of procedures, incidence of complications, and quality of reports are measured, reported and adjusted to optimize individual and overall quality.

7. Continuing education and training are carried out through a variety of methods, including access to atlases, review materials, teaching-file cases, and feedback of subsequently confirmed diagnoses to interpreting radiologists. Peer review of previously reported cases is now a common expectation or requirement in most radiology practices as well as medical board agencies like the American Board of Radiology.

All these tasks are now, in a growing number of departments, computer-assisted or automated, and most of them involve images in some way. In fact, radiology is one branch of medicine in which even the basic data are usually produced by computers and stored directly in computer memory. Radiology has also contributed strongly to advances in computer-aided instruction (see ► Chap. 25), in technology assessment (see ► Chap. 13), and in clinical decision support (see ► Chap. 24). Speech recognition is commonly used for report creation.

### 22.2.3 Electronic Imaging Systems

#### 22.2.3.1 Image Acquisition

The first radiographs used an integrated detection, recording and display system—that is, the glass plate (and later, plastic film)

served both to detect the X-ray photons, to record them in a permanent form, and also to display the data (with the aid of a light-box). This integrated arrangement existed for about a century. Today, most radiographs are either (a) recorded in a latent form (i.e., they are not directly visible, but are acquired as an electronic signal on a charged plate) where a ‘reader’ then scans the plate to create a digital image (known as **computed radiography** or CR) or (b) the photons are directly converted to digital images (known as **digital radiography** or DR). The digital image can then be transmitted and stored like any digital data, using conventional networks and storage systems. The matrix size of the images is variable, ranging from as low as 64 x 64 for some nuclear medicine images, up to 5000 x 4000 picture elements (pixels) for mammograms. The size of typical radiology images and examinations is shown in ■ Table 22.1. CT, MR, US, NM, and PET all use computer to convert the acquired raw signal to a digital image and thus they also exist as direct or nearly direct digital modalities.

#### 22.2.3.2 DICOM

The first medical devices to produce digital images routinely were CT scanners, and soon after, MRI scanners. The availability of digital data that represented a three-dimensional

■ Table 22.1 Typical sizes for radiology examinations

Modality <sup>a</sup>	Image size (pixels/image)	Images/exam	Exam size (MB)
CR/DR	5000,000	3	29
CT	262,144	500	250
MRI	65,536	500	63
US	262,144	50	25
Mammography	20,000,000	4	153
Interventional/fluoro	1,048,576	50	100
Nuclear medicine	16,384	25	1

Note that there is variability in image size and images per examination, and these numbers should be viewed as very rough estimates. Furthermore, there is a strong trend for both increased image resolution (increasing image size) and more images per examination since the emergence of digital imaging

<sup>a</sup>CR computer radiography, DR digital radiography, CT computed tomography, MRI magnetic resonance imaging, US ultrasound

image stimulated the field of medical image processing and 3D rendering. An early challenge to such investigations was that the medical device vendors used half-inch tape media for storing the data, but each vendor (and usually each model of scanner) had its own format. Such formats were proprietary, and required each investigator to reverse engineer the format of the tape just to gain access to the data. Although computer networks were used in hospitals at that time, few if any scanners supported network connections.

The need to write all data to tape, and then read it into a different computer using software unique to each scanner resulted in significant unnecessary effort. The need to exchange images efficiently demanded that they be represented in a standard fashion. This need was recognized by the American College of Radiology (ACR) and the National Electrical Manufacturer's Association (NEMA), and led to the development of the ACR/NEMA standard for medical images in 1985. As other imaging devices started to produce digital images, and as the information about the images became richer, the second version was published in 1989. That standard described both a model that described the data, and prescribed a special connector for transferring image data between devices. This was demonstrated at the 1990 Radiological Society of North America (RSNA) conference. Soon after, **TCP/IP** became a widely accepted network standard, and while the ACR/NEMA standard did not describe a method for transferring data over TCP/IP, investigators fairly quickly implemented this, and it worked well. Continued improvements in the information model, as well as extension to medical specialties other than radiology, and standards for storage on physical media like compact disks demanded further revisions. The addition of non-radiology images also demanded a name change, and thus 'ACR/NEMA 3.0' was rebranded as **DICOM**, which stands for Digital Image Communications in Medicine.

To promote adoption, the RSNA commissioned the creation of **Central Test Node (CTN)** software, for demonstrating use of the standard for transmitting images over a

local area network at RSNA 1992, followed by increasingly sophisticated versions over the next 2 years. The RSNA also made that software available for free public access as a model for understanding the standard and design of utilities and tools by developers. During the mid 1990's, the RSNA annual meetings hosted a major digital image interoperability demonstration that became progressively more sophisticated and demanding. RSNA and its meetings accordingly facilitated demonstration of the interconnection of vendor products through the Internet, promoted DICOM compatibility as a feature that could be visualized at participating vendor exhibits, and created a model Request For Proposals (**RFP**) for radiology practices and hospitals to use to craft a DICOM requirement as part of the procurement of imaging systems. Later this interoperability testing was done separate from the RSNA annual meeting, and became known as the 'Connectathon'. These efforts turned out to be extremely successful in transforming the marketplace from one that was dominated by proprietary formats to one that was standards-based and interoperable.

DICOM continues to be updated and improved through an international committee process. While it is hard for any standard to be both widely accepted and perfectly up-to-date, the DICOM governance has done a remarkable job of adapting to rapid advances in imaging technology. The governance continues to reflect its roots of combining industry and medical experts who are interested in providing the best technology that can be put into commercial products.

### 22.2.3.3 Image Transmission, Storage, and Display

Digital image capture provides the opportunity to display and store the images in digital form. In the early days, the size of the images represented a challenge—the amount of data was quite large relative to the capacity of storage devices. As a consequence, there was intense interest in using compression methods that could reduce the amount of storage that was required—as well as increase the speed of network transmission of images. Even with

compression, the amount of storage used for images is quite large relative to non-image data stored in a hospital. A hospital must therefore carefully consider how images are stored. In the early days of **Picture Archiving and Communications Systems (PACS)**, there was little choice about how and where images were stored, because the storage system was tightly integrated with the display and transmission. This was done because the high demands on storage, transmission, and display all required special hardware. As computer technology caught up with medical image sizes, there was less need for specialized versions of networks, archives, and displays.

The military was an early adopter/driver of PACS technology, and released an RFP in the 1990's requiring that 'any image be displayed anywhere on the network within 2 seconds.' To address this requirement, early PACS utilized either uncommon standard technologies or proprietary networking methods to provide high bandwidth transmission. An example of proprietary transmission technology is the PACS developed by LORAL, which leveraged technology developed for its defense applications. Its network was a hybrid of (standard) 10 Mbps **Ethernet**, which provided control signaling, and a (proprietary) unidirectional hub to spoke optical network that had lossless compression built into the network card. The optical network signaled at 100 Mbps, and because it was unidirectional, it routinely realized its nominal speed. Other vendors utilized **FDDI**, which also was an optical fiber network that signaled at 100 Mbps. However, its handling of contention was much less effective, and its performance suffered. Today, standard Ethernet signaling at either 100 Mbps or 1 Gbps can provide adequate performance, as long as reasonable attention is paid to network layout and implementation.

While the display component of PACS drove networking advances in the 1990's, the migration of PACS data from one system to another during an upgrade drove the next major change—the Vendor Neutral Archive, or VNA. In the early days of PACS, updating the system to take advantage of new workstation or network technology meant that the whole system, including the archive, needed

to be updated or migrated. Because the data were not stored in a standard format, it was necessary to get the cooperation of the vendor to migrate the data to the new system (which might be from another vendor!). Because workstations rapidly change, but archive contents do not, there was perceived value in separating these two functions (Erickson and Hangiandreou 1998). Today, several companies sell **vendor-neutral archives (VNAs)** that leverage the DICOM standard. These allow a wide variety of image-producing and image-consuming systems to access the archive in a standard fashion. It also enables storing images from outside the radiology department on the same infrastructure. In fact, the use of a VNA is now the norm rather than the exception at any major hospital system because it allows sharing of resources across departments.

Because the image datasets are quite large, there is interest in finding ways to reduce storage requirements. Image compression does exactly this, in one of two ways. There are **lossless compression** methods, which encode redundancy in the image in a way that allows the original to be *exactly* reproduced. **Lossy** (or irreversible) **compression** produces an image that is visually similar to the original. Exactly how similar depends on the algorithm and user-selectable settings that reflect the trade-off between fidelity and compression ratio (the ratio of original size to compressed size). The major challenge is that one cannot select a given setting, reliably get images that are not visibly altered, and also achieve a good compression ratio. Lossless compression methods typically achieve compression ratios of about 2.5, while lossy compression can achieve as much as 40:1 compression without a perceptible or diagnostic loss, *for certain types of images*. While the size of imaging examinations continues to increase, the decrease in storage cost is more rapid, lessening the demand for lossy compression. The use of lossy compression is more widely accepted in non-radiology specialties, such as cardiology and pathology, in part because of the greater uniformity of image characteristics, allowing easy specification of acceptable ratios. A key goal of lossy compression is that

it not have an adverse impact on diagnostic value to the human or to computer aided diagnostic algorithms (Zheng et al. 2000). Thus, lossy methods are usually tuned to the specific diagnostic task so as not to have adverse impacts. In fact, monitoring the performance of CAD as the ratio is changed is one method to select the optimal compression ratio.

Early PACS also required specialized display devices. At the time, standard computer displays were often 640 x 480. Medical images were often more than 2048 pixels in each direction. Liquid crystal technology for large displays was also not developed, meaning that the displays were large cathode ray tubes. These displays were large, heavy, produced much heat, and degraded rather rapidly. Nearly all were monochrome. Imaging also required a higher luminance for detection of subtle gray level distinctions than was available with consumer-grade displays. Today, flat panel technology that meets the demands of radiological interpretation is widely available at reasonable prices. We note here that while consumer grade displays can be used, it is important that quality displays are used with appropriate calibration. A DICOM committee has established display requirements for medical purposes (ACR-NEMA 2006). Medical grade monitors typically have hardware built into the display to perform such calibration in an automated way.

## 22.2.4 Integration with Other Healthcare Information

### 22.2.4.1 Radiology Information Systems (RIS)

A **Radiology Information System**, or RIS, is responsible for much of the text information in a radiology department. Core functions of a RIS include capture of the interpretation for a given examination and records the status of an imaging examination. A RIS may do more, depending on what other systems are available and preferred for a given situation: some of the functions that might be performed by a RIS include ordering, scheduling, and billing. These functions are usually performed

by the HIS or EHR system when available such as in a hospital or large outpatient practice; they are usually performed by the RIS in cases where there is no HIS or EHR (such as many outpatient imaging centers).

### 22.2.4.2 Speech Recognition

In the past, the RIS would provide a means for a transcriptionist to type the text of the report into the RIS as the radiologist dictated it (either live or via dictation system). Today, the vast majority of radiologists use speech recognition to convert their speech into text. In some cases, the text is immediately reviewed by the radiologist and approved as final. This model has the advantages of rapid **turn-around time**—the time from when the examination is ready to be reported to the time it has a final report available. In this model, a separate application (the speech recognition system) converts the audio to an HL-7 message, which is sent to the RIS along with the final (or other appropriate status). In other cases, a ‘correctionist’ reviews the text created by the speech recognition system, and corrects it based on listening to the audio file. In this case, the radiologist must then review the text again to make it final, which will degrade turn-around-time.

There are two major advantages to using speech recognition: First, it enables rapid turn-around time. Before speech recognition, turn-around times of 1 week were common, but now, turn-around times of less than 1 hour is common (Hart et al. 2010; Krishnaral et al. 2010; Mattern et al. 1999). This improvement in turn-around time undoubtedly improves the quality of care provided to patients. Second, it reduces staffing for radiology departments or hospitals by reducing the number of transcriptionists/correctionists needed. Of course, some decrease in productivity is commonly observed for radiologists at the time of implementation, which reduces the economic benefit (Langer 2002; Strahan and Schneider-Kolsky 2010).

Over the years, many efforts have attempted to enable radiologists to generate templated or **structured reports** (SR) from a selection of choices in forms, and through use of drop-down entries in the text, macros that produce

predetermined text phrases, and other techniques. Some of these are now used in specific situations, especially where reports have a largely anticipated format and structure, e.g., mammography and obstetrical ultrasound, and macros are used in conjunction with speech recognition approaches for certain “canned” sections or reports. Such reports enable efficient capture of the information for later data analysis, and there are also several reports showing that most referring physicians prefer templated reports because of the consistency in where key information can be found. In fact, some ultrasound devices will send many of the key measurements to the reporting system to ‘pre-populate’ a structured report with many of the measurements made during image acquisition.

#### 22.2.4.3 Computer-Aided Diagnosis (CAD)

We have described that the interpretation task consists of detection, description, and diagnosis. In some cases, the detection task can be quite challenging, particularly for screening tasks involving mammography and chest X-rays because the incidence is rather low, and the volume is high. Particularly at the end of a long shift, human observers probably have decreased performance due to fatigue. For these cases, computer algorithms that highlight suspicious regions of an image may be useful to assure that important findings aren’t missed. Some have called this role ‘computer-aided diligence’.

During the first decade of **computer-aided diagnosis (CAD)**, the algorithms searched for specific features that radiologists thought were important, and therefore the value was either minimal (diligence), or provides benefit readers less familiar with the importance of various features (Gur and Sumkin 2006). In the case of mammography, the lack of a clear benefit for experienced readers, combined with the reduction in productivity has resulted in its near complete abandonment, and also its loss of reimbursement. This is a sobering example that computer assistance must be implemented in ways that truly add value.

Another role for CAD is in assisting with diagnosis (the lesion is detected, but unsure if it is cancer or infection). A common application is in determination the nature of lesions on high resolution CT images of the chest.

■ Figure 22.6 shows an image of the output of the experimental algorithm CALIPER, rendered as a 3D image, to show the distribution and change of different degrees of interstitial lung disease in a patient.

More recently, a machine learning technique referred to as ‘Deep Learning’, has become popular. This technique uses neural networks and derives its ‘deep’ name because it typically uses many (50+) layers in the network. In addition to having many more layers than traditional neural networks, some forms include several convolutional layers (hence the name convolutional neural networks or CNNs) at the input that learn the features that produce the best output. This means that it learns the best features to use, rather than requiring a human to pre-compute them.

Deep Learning methods have proven very effective for many of the traditional CAD tasks (mammography and chest CT lesion detection) and for classification of lesions. They also excel at automated organ segmentation (U-Nets) that can be useful for many tasks, and this easy access to quantitative data will likely increase the quantitative content in radiology reports.

Perhaps more interesting is that CNNs have also proven effective at predicting molecular properties of tissues using routine images, even in cases where humans are not able to identify any differentiating features. Examples include the prediction of IDH-1 mutation, 1p19q chromosomal status, and MGMT methylation in brain tumors using routine T2-weighted MR.

#### 22.2.4.4 Advanced Visualization

CT and MR scanners provide images that can be thought of as 3D images, even if they are not always truly acquired as 3D, but rather, as a series or ‘stack’ of 2D images. Some imaging devices can acquire a 3D image directly and repeatedly, thus producing a 4D image (time

**Fig. 22.6** Image of the output of the experimental algorithm CALIPER, rendered as a 3D image, to show the distribution and change of different degrees of interstitial lung disease in a patient. (a) shows the overall disease burden of the lungs; (b) shows the disease category as a 3D rendering of the lungs; (c) shows the disease category on a coronal section of the lungs; (d) shows the disease category labels

is the fourth dimension). In particular, cardiac imaging benefits from 4D capability so that the beating heart can be examined throughout the cardiac cycle. Such 3D and 4D data sets are large, and proper demonstration of the important findings requires visualization of the data. For instance, if one wishes to see a skeletal finding using CT, one can set a threshold to select bony structures, and then render it using traditional computer rendering methods. This can be done at multiple time points to produce movies of moving structures.

The great challenge in medical visualization is **segmentation**—deciding whether a

volume element (voxel) is a part of the structure of interest or not. In the case of a CT image of bone, segmentation is rather easy. If intravascular contrast is administered during the examination, that can make it fairly straightforward to select vessels (arteries and/or veins depending on the timing). Soft tissue organs like livers, kidneys, and muscles have been more challenging, but are now much more feasible with deep learning techniques. A description of the rendering algorithms and their trade-offs is provided in ► Chap. 10.

A recent advance in visualization tools is to have the computation done on a central

■ **Fig. 22.7** Example advanced visualization of the abdominal aorta, distributed via a web client, which allows vascular surgeons to better plan surgical options in their own office

server, with interactive segmentation and rendering viewed using web browsers. This allows a much larger population of physicians to have access, and can be valuable for surgeons contemplating surgery, as well as for patient education. ■ Figure 22.7 provides an example advanced visualization of the spine, distributed via a web client, which allows surgeons to better plan and review treatment options in their own office, with the patient.

#### 22.2.4.5 Advanced Reporting

While textual reports have served medical practice well for the past century, there are opportunities to improve reporting. Multimedia reports provide a richer representation of the information present in the examination, and might include links from portions of the text report to specific images and locations on the images, moving images ('video'), or audio files such as the heart sounds. In some diseases, it can be important to have specific measurements made, and possibly tracked over time. If these measurements are encoded in a specific way (using Structured Reporting or SR), it will be easier to extract and use that information elsewhere in the medical record, and for other purposes like research. **Lexicons**, such as RadLex, can be helpful in conveying some of the information. There is great inter-

est in routinely collecting more quantitative information from images, because it appears that for an increasing number of diseases, quantitation is receiving increased attention in clinical realms.

An SR is produced when the concepts of a report are represented using coded terminology. There is a DICOM specification for SR, though adoption has been limited. This is because there are currently not efficient user interfaces for creation of structured reports in most areas of radiology. BIRADS is a standardized way to report breast imaging, with an accepted scale for findings. However, those findings are usually not also stored in an encoded format, but rather with highly consistent text. Because BIRADS has truly enabled much better care of patients and research, other areas of imaging are adopting standardized reporting (e.g. TIRADS for thyroid, LIRADS for liver, PIRADS for prostate, just to name a few). The most widely adopted example of SR is probably the sending of specific measurements from ultrasound scanners to reporting systems. Of course, this is not the entire content of the report, and the radiologist usually adds and may edit the SR content. Another example where DICOM SR may be used is for reporting radiation dose, but again, that is not even the main content

of the radiological report. Some would also argue that DICOM SR is more correctly thought of as structured results rather than structure reports.

#### 22.2.4.6 Workflow Management (Including Dashboards)

The ability to monitor and control events in an imaging department is critical to efficient and effective operation. **Dashboards** have been applied in many business arenas to give quick visual displays of **Key Performance Indicators (KPIs)** for that business. Such dashboard technology is now becoming widely used within imaging departments for monitoring such KPIs as report turn-around time, patient waiting time, number of days out to schedule examinations, and revenue days-outstanding. The dashboards give people a quick view of what is happening, and can alert them to problem areas. ■ Figure 22.8 is an example of a radiology dashboard that shows important departmental metrics, including report

turn-around time, compliance with notification requirements, and patient waiting times.

Most dashboards provide a mechanism to ‘drill down’ on a particular measurement. For instance, if the patient waiting time monitor goes ‘red’, clicking on that indicator light might show the waiting time by location (maybe just one facility is causing the problem), total patient volume (maybe the site is experiencing a spike in patient volume), or examination time (maybe the complexity of examinations is going up). Such information is critical to enabling a timely and effective response to performance that is outside expected service levels.

The popularity of deep-learning-based artificial intelligence (AI) tools for image interpretation has also driven the need for workflow orchestration: the application of workflow management technology to collect data needed by an AI algorithm, assure its execution on the images and other data, and then collect and distribute the results. There

■ **Fig. 22.8** Example of a radiology dashboard that shows important departmental metrics, including report turn-around time, compliance with notification requirements, and patient waiting times

are many reports showing AI can improve efficiency (such as for quantitation of organ or tumor size) and to improve the quality of care in radiology departments.

#### 22.2.4.7 Teleradiology

**Teleradiology** is the practice of interpreting images at a location that is physically distant from the place where the images are collected. Initially, this referred to transmitting images from the hospital to the radiologist's home in the middle of the night so that the physician did not need to drive in to see the image onsite. While this is still done, it is now common for a hospital to contract with a 'nighthawk' service that will provide these night-time interpretations. A nighthawk service contracts with many hospitals—enough to keep a team of radiologists busy during the night. Having a team continuously operating is usually more efficient, and allows for specialization of image interpretation. Teleradiology is now also practiced during the day to balance clinical workload and to provide specialized interpretation on a routine basis. The technology to rapidly transmit images across large distances is widely available and inexpensive. The greatest challenges to teleradiology are licensing/credentialing issues, especially if films are read across state lines or internationally (radiologists may be licensed to practice where they review the films but not in the location where the patients were located when the images were acquired). Teleradiology is a term that is not heard very often mostly because transmission of images to the best site for interpretation has become routine, and implemented as a part of the PACS network.

#### 22.2.4.8 Enterprise Integration (Including HL7, Decision Support)

Medicine is an information-rich business, and providing access to the relevant information in a timely fashion is critical to success. Integration of systems with the relevant pieces of information is necessary, and in hospitals this is generally done with HL-7 messages (see ► Chap. 7). Both RIS and PACS will typically be able to use HL7 messages, and an increasing number of EHRs are 'image enabled' mean-

ing that they can receive DICOM images, and display them for clinicians.

#### 22.2.4.9 Decision Support

Because medical imaging has been a major component of increases in total healthcare costs, there has been much attention paid to assuring that only necessary examinations are performed. To help assure this, decision-support systems to guide proper ordering have been developed that have been shown to have an impact on utilization of imaging studies (Sistrom et al. 2009). Such systems have been shown to decrease the total number of examinations performed, and in particular to decrease the number of examinations that appear to be unnecessary. In addition to alerting the user to a potentially improper order, educational materials are often provided to help the ordering physician understand when and what imaging examinations might be appropriate for the given indication. In addition, such systems can provide management reports to improve the understanding of ordering practices.

### 22.3 Imaging in Other Departments

---

#### 22.3.1 Cardiology

---

Cardiac imaging has many similarities to radiological imaging, and in many cases is performed either by radiology departments or in conjunction with radiology. The primary imaging modalities for cardiology include echocardiography (ultrasound), catheterization (interventional/vascular, involving fluoroscopy and angiography, i.e., vessel visualization via contrast dye administration), MR, CT, and PET. The workflow can be similar, but can be different in those cases where the imaging is performed by the same department and even by the same individual as the person who ordered it. In such cases, there can be less formal ordering, scheduling, and reporting. However, as the imaging is increasingly a part of the general enterprise, such informality will become a greater challenge.

Cardiology has been aggressive in its use of lossy compression. This is primarily because the nature of cardiac imaging is much more stereotyped (allowing better prediction of appropriate compression). The primary focus is the heart, whereas in radiology many different organs with very different appearances can challenge compression methods. The echocardiographic and interventional images are also much more like video—usually being motion-oriented rather than focused on static capture, and that redundancy in content enables effective compression. In fact, the major cardiovascular societies have published and supported the use of specific compression technologies and settings for cardiac imaging (Simon et al. 1994; ACC/ACR/NEMA Ad hoc Group 1995).

Because the focus is primarily on the heart and its function, cardiac imaging is more advanced in structured reporting. The primary variables that are of interest in cardiac imaging (left ventricular volumes, stroke volumes) are of interest in most cases, and are routinely measured and reported. This has driven the acceptance of structured reporting for the common measurements in cardiac imaging—particularly echocardiography.

### 22.3.2 Obstetrics and Gynecology

---

Obstetrical and gynecological imaging is rather like cardiac imaging, except that it is nearly always ultrasound imaging. Much like cardiac imaging, there are a well-defined and accepted set of measurements and observations expected for the routine obstetric exam, and as such, structured reports for these findings are widely used. Estimates of fetal gestational age and development are typically automatically computed, on the basis of measurements using well-tested prediction models.

### 22.3.3 Intraoperative/Endoscopic Visible Light

---

It is now common to capture still images and video of endoscopic procedures as well as traditional open surgical procedures. These

images are valuable for documenting the important findings (or lack thereof) during a procedure. They are also useful for educational purposes, including informing the patient of the findings and procedures carried out. Some surgeons have suggested that medicolegal demands will require routine capture of entire surgical procedures.

Such images can be more graphic and revealing than radiological images, and in some cases have driven the expectation of need for an additional level of privacy protection. In one institution, for instance, all photographic images from the Plastic Surgery department are protected from access—only physician members of the Plastic Surgery department can routinely view those images, with a process for granting temporary access to other care providers (Erickson et al. 2007).

### 22.3.4 Pathology and Dermatology

---

Pathology and dermatology have similar needs, except that dermatology includes photographic visible light images of skin lesions. For these purposes, consumer-grade photographs can be sufficient, but transporting those images (usually in JPEG form) to a medical-grade imaging system will usually require an import process. This process will require confidence about the accuracy of patient and site location information. Often, the JPEG images are then ‘wrapped’ with DICOM information to assure that the connection between a photograph and a patient exists at the file level, rather than via a link to a filename. Image viewers require color capability, but otherwise are not substantially different from what is provided in most radiological image viewers. If images are converted to DICOM, the archive system is usually able to store them without difficulty.

Microscopic images represent a bigger challenge. At this point, there are 2 strategies for the capture of microscope images: the first is **whole slide digitization** in which the entire specimen is digitized; the other is capture of specific views that are of interest. In both cases, though more so in whole-slide imaging, there is a need for multi-resolution viewing.

That is because the workflow is very different. Whole-slide scanning is usually done *prior* to the pathologist reviewing the images, while the spot-capture is done by the pathologist at the time of viewing. In the former case, the computer performs the pan-zoom function, while in the latter case the optical microscope performs that function. In the former, the computer is a diagnostic device, while in the latter, it is used mostly for documentation purposes.

Whole-slide scanning is of greater interest, because it has greater possibilities for improving healthcare delivery by allowing the slides to go to the pathologist. It also represents a much greater challenge, because much larger amounts of data must be stored and the associated computer-based viewing application requires the ability to display low resolution and high resolution images. Such images are typically 1GB in size. Computing low resolution images from high resolution images can be computationally expensive.

Another important issue differentiating pathology imaging from radiological imaging is that retrieval of old images is much less common in pathology. Follow-up of disease is biopsy is much less common than with radiological imaging, so comparison with priors is much less common. Recall would usually only occur when there is a medicolegal issue, or possibly in case of disease recurrence or metastasis, where there is a need to compare the older sample with a newer one.

## 22.4 Cross-Enterprise Imaging

---

### 22.4.1 CD Image Exchange

---

When images were stored on film, sharing images with another hospital required that the films be either physically transferred or copied. Copying a film was labor-intensive and expensive. Therefore, it was standard practice to 'loan' films to other facilities when needed.

With digital images, it is much easier to copy the digital data onto media like a compact disc (CD) and give that to the patient. There are well-accepted standards (DICOM) for how to store the images on a CD. However,

it is challenging for most hospitals to use the images on CDs. In some cases, the images can be imported into the PACS, but that can cause confusion about where the study was done, and can be challenging for the RIS to represent this (who ordered the CD exam, and where the report is located). In addition, there are important data integrity issues—as much as 0.1% of CDs have been shown to include images for patients other than the intended patient (Erickson 2011), leading to important health delivery and legal risks.

### 22.4.2 Direct Network Image Exchange

---

The problems with CD image exchange noted above, as well as the time delays and costs, have driven many institutions to use internet transfer mechanisms. In cases where there is a high volume and a high level of trust, one can establish **virtual private networks (VPNs)** that allow secure transfer between two institutions. While this allows rapid and low-cost transfer, it still requires confident patient identification, and a method for importing the images into some form of clinical viewer. It also requires a hospital set up an extensive network of VPNs, which is something that can be difficult to secure.

This has led to the creation of the 'image sharing' industry. This industry has developed internet tools that allow images to be securely transferred from one hospital to another. The transport mechanism is usually proprietary, so transfer between hospitals is most efficient if both use the same vendor system. However, nearly all provide a 'Dropbox'-like method where a weblink can be used to either send or receive images. There are also efforts to develop standard interchange methods that are both efficient and secure.

## 22.5 Future Directions for Imaging Systems

---

The increasing capabilities of mobile devices and the increasing expectations of ready access to medical professionals have driven

imaging onto mobile devices. At present, the FDA has limited the use of such devices for diagnosis. On the other hand, these devices can be extremely useful for consultation on specific areas of an image, or when therapeutic options are being considered, or for patient communication. As the bandwidth and display qualities improve, these devices will likely play an increasing role in both diagnosis and therapy planning.

**Cloud technology** is becoming an important technology for image archival and transfer. The ability to leverage efficiencies of scale is an important economic driver that is pushing many smaller imaging providers to use cloud-based storage. The use of cloud methods for image exchange was also described above. The increasing use of computation intensive diagnostic aids has also driven the use of cloud-based CAD tools.

**Phenome characterization** (see ► Chap. 26) is becoming an important aspect of the move to individualizing medicine sometimes referred to as ‘precision medicine’. Deep learning is a technology that will likely cause rapid advancement, as it allows both rapid automated segmentation of all major organs in an image, but also characterization of tissue textures. The ability to predict genomic information from such images will likely produce a new generation of ‘precision imaging’ applications.

### Suggested Readings

- Birkfellner, W. (2010). *Applied medical image processing: A basic course*. CRC Press. As the title says, this is an introductory book, with many excellent explanations and example code (mostly MatLab).
- Branstetter, B. F. (2009). *Practical imaging informatics*. New York: Springer. As its title implies, this book is a practice-oriented book primarily aimed at those responsible for implementing and maintaining a digital imaging practice. The format of the book is an outline with many practical tips from a wide variety of experts.
- Dougherty, G. (2009). *Digital image processing for medical applications*. Cambridge University Press. This is an excellent, practical book on concepts of image processing algorithms used in medical imaging.
- Dreyer, K. J. (2006). *PACS: A guide to the digital revolution*. New York: Springer. This is also a book focused on the practical aspects of implementing and maintaining a digital imaging department. Its format is that of a traditional textbook, and covers a broad range of topics.
- Liu, Y., & Wang, J. (2011). *PACS and Digital Medicine*. Boca Raton: CRC Press. This book goes into greater detail of the technology of PACS, and to a lesser degree RIS and EMR. This is a very good resource for those interested in more details of DICOM and how a PACS can be configured to address specific needs.

### Questions for Discussion

1. What are the Pros and Cons of a highly structured technology like DICOM? DICOM has been highly successful in terms of adoption as a standard, and virtually all image communication utilizes it. This differs markedly from some other standards. What are factors that have contributed to this success, and what lessons can be drawn from this in terms of how to promote adoption of standards in the future?
2. If one were to design medical imaging systems today, would the optimal design continue to have PACS and RIS as separate systems, or would they be combined into one system? Should these be separate from the EHR?
3. What are the ways in which radiology reports of examination interpretations can be generated, and what are the advantages and disadvantages of each approach, in terms of ease and efficiency of report creation, timeliness of availability of report to clinicians, usefulness for retrieval of cases for research and education?
4. In these days of high bandwidth and low storage costs, is there still a good reason to use lossy compression in medical imaging? What kinds of trends are likely to affect image growth, as part of the patient’s medical record?
5. What are the arguments for maintaining raw rather than compressed data (not

only for imaging data but for compression or summarization of other types of data)?

6. Describe a classification of ways in which image data are used in medical decision making.
7. What are the data management implications of using a separate advanced visualization system for clinicians that is distinct from the PACS used by radiologists for interpretations? What if the radiologists use that system in addition to the PACS?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What types of online knowledge-based information are available and useful to clinicians, biomedical researchers, and consumers?
- What are the major components of the information retrieval process?
- What are the major categories of available knowledge-based information?
- How do techniques differ for indexing various types of knowledge-based biomedical information?
- What are the major approaches to retrieval of knowledge-based biomedical information?
- How effectively do searchers use information retrieval systems?
- What are the important research directions in information retrieval?
- What are the major challenges to making digital libraries effective for health and biomedical users?

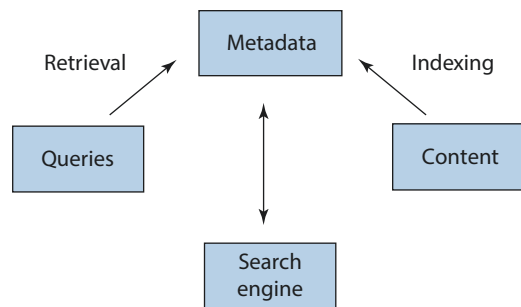

## 23.1 Introduction

**Information retrieval (IR)**, sometimes called **search**, is the field concerned with the acquisition, organization, and searching of knowledge-based information (Hersh 2020). Although biomedical IR has traditionally concentrated on the retrieval of text from the biomedical literature, the domain over which IR can be effectively applied has broadened considerably with the advent of multimedia publishing and vast storehouses of images, video, chemical structures, gene and protein sequences, and a wide range of other digital material and artifacts of relevance to biomedical education, research, and patient care. With the proliferation of IR systems and online content, the notion of the library has changed substantially, and new **digital libraries** have emerged (Lindberg and Humphreys 2005).

IR systems and digital libraries historically existed to store and disseminate knowledge-based information. What exactly

does that mean? Although there are many ways to classify biomedical information and the informatics applications that use them, in this chapter we will broadly divide them into two categories. **Patient-specific information** applies to individual patients. Its purpose is to document and increasingly analyze for health care providers, administrators, and researchers about the health and disease of a patient. This information historically came from the patient's medical record but now can come from many different sources, including mobile and wearable devices. The second category of biomedical information is **knowledge-based information**. This is information that has been derived and organized from observational or experimental research. In the case of clinical research, this information provides clinicians, administrators, and researchers with knowledge derived from experiments and observations, which can then be applied to individual patients. This information has historically been provided in books and journals but can take a wide variety of other forms, including clinical practice guidelines, consumer health literature, Web sites, and so forth. The distinction between these two types of information is blurred by the growing amount of data that comes from people and is used to derive knowledge.

A basic overview of the IR process is shown in ■ Fig. 23.1 and forms the basis for most of this chapter. The overall goal of IR or search is to find content that meets a person's

■ Fig. 23.1 Basic overview of the information retrieval process. Retrieval is made possible via metadata, which is produced via indexing and applied in queries by users. The metadata is used by the search engine, which directs the user to the content

information needs. This is done by posing a *query* to the IR system. A **search engine** matches the query to content items through **metadata**, which is “data about data” that describes the content items (Foulonneau and Riley 2008). There are two intellectual processes of IR. **Indexing** is the process of assigning metadata to content items, while **retrieval** is the process of the user entering his or her query and retrieving content items.

## 23.2 Evolution of Biomedical Information Retrieval

As with many chapters in this volume, IR has changed substantially over the five editions of this book. In the first edition, this chapter was titled “Bibliographic-Retrieval Systems,” reflecting the predominant type of knowledge that was accessible at the time. The second edition saw the emergence of the **World Wide Web (WWW or Web)** as a delivery mechanism for knowledge-based information. In the third edition, “Digital Libraries” was added to the chapter name, reflecting that the entire biomedical library and beyond was now part of available online knowledge. The fourth edition reflected the ubiquitous nature of information on computers, smartphones, tablets, and other devices. This fifth edition recognizes that digital data, information, and knowledge have become their primary medium, i.e., even though the world still has plenty of paper, the source of most information in modern times is digital. Essentially all articles, books, patient records, etc. are primarily in digital form and mainly printed for the convenience of reading.

Although this chapter focuses on the use of computers to facilitate IR, methods for finding and retrieving information from medical sources have been in existence for nearly a century and a half. In 1879 Dr. John Shaw Billings created **Index Medicus** to help medical professionals find relevant journal articles (DeBakey 1991). Journal article citations were indexed by author name(s) and subject heading(s) and then aggregated in bound volumes. A scientist or practitioner seeking an article on a topic could manually search the

index for the single best-matching subject heading and then be directed to citations of published articles.

The printed *Index Medicus* served as the main biomedical IR source until 1971, when the **National Library of Medicine (NLM)**<sup>1</sup> unveiled an electronic version, the **Medical Literature Analysis and Retrieval System (MEDLARS)**, which had been cataloging bibliographic records since 1966 (Miles 1982). Because computing power and disk storage were very limited, MEDLARS and its follow-on **MEDLARS Online (MEDLINE)**, stored only limited information for each article, such as author name(s), article title, journal source, and publication date. In addition, the NLM assigned to each article a number of terms from its **Medical Subject Headings (MeSH)** vocabulary. Searching was done by users having to mail a paper search form to the NLM and receiving results back a few weeks later. Only librarians who had completed a specialized course were allowed to submit searches.

As computing power grew and disk storage became more plentiful in the 1980s, full-text databases began to emerge. These new databases allowed searching of the entire text of medical documents. Although lacking graphics, images, and tables from the original source, these databases made it possible to retrieve the full text of important documents quickly from remote locations. Likewise, with the growth of computer networks, end users were now allowed to search the databases directly, though at a substantial cost.

In the early 1990s, the pace of change in the IR field quickened. The advent of the Web and the exponentially increasing power of computers and networks brought a world where vast quantities of medical information from multiple sources with various media extensions were now available over the global Internet (Berners-Lee et al. 1994). In the late 1990s, the NLM made all of its databases available to the entire world for free. Also during this time, the notion of digital libraries developed, with the recognition that the

1 [▶ https://www.nlm.nih.gov/](https://www.nlm.nih.gov/)

entire array of knowledge-based information could be accessed using this technology (Borgman 1999).

Into the twenty-first century, use of IR systems and digital libraries has become ubiquitous. Estimates vary, but among individuals who use the Internet in the United States, over 80% have used it to search for information relevant to their own health or that of an acquaintance (Fox 2011; Taylor 2010). Virtually all physicians use the Internet (Anonymous 2012). Furthermore, access to systems has gone beyond the traditional personal computer and extended to new devices, such as smartphones and tablet devices.

### 23.3 Knowledge-Based Information in Health and Biomedicine

Knowledge-based information can be subdivided into two categories. Primary knowledge-based information (also called *primary literature*) is original research that appears in journals, books, reports, and other sources. This type of information reports the initial discovery of health knowledge, usually with either original data or reanalysis of data (e.g., systematic reviews, sometimes with meta-analysis). Secondary knowledge-based information consists of the writing that reviews, condenses, and/or synthesizes the primary literature. The most common examples of this type of literature are books, monographs, and review articles. Secondary literature includes the growing quality of patient/consumer-oriented health information that is increasingly available via the Web. It also encompasses opinion-based writing (such as editorials and position or policy papers), clinical practice guidelines, narrative reviews, and health information on Web pages. In addition, it includes the plethora of pocket-sized manuals that were formerly a staple for practitioners in many professional fields. As will be seen later, secondary literature is the most common type of literature used by physicians.

Libraries have been the historical place where knowledge-based information has been

stored. Libraries actually perform a variety of functions, including the following:

- Acquisition and maintenance of collections
- Cataloging and classification of items in collections to make them more accessible to users
- Serving as a place where individuals can get assistance with seeking information, including information on computers
- Providing work or study space (particularly in universities)

Digital libraries provide some of the same services, but their focus tends to be on the digital aspects of content.

#### 23.3.1 Information Needs and Information Seeking

Different users of knowledge-based information have differing needs based on the nature of their information need and available resources. The information needs and information seeking of physicians have been most extensively studied. Gorman defined four states of **information need** in the clinical context (Gorman and Helfand 1995):

- Unrecognized need—clinician unaware of information need or knowledge deficit
- Recognized need—clinician aware of need but may or may not pursue it
- Pursued need—information seeking occurs but may or may not be successful
- Satisfied need—information seeking successful

There is a great deal of evidence that the majority of information needs are not being satisfied and that IR applications may help. Among the reasons that physicians do not adhere to the most up-to-date clinical practices is that they often do not recognize that their knowledge is incomplete. While this is not the only reason for such practices, the evidence is compelling. For example, physicians do not always provide patients with most up-to-date care (McGlynn et al. 2003), do not adhere to established guidelines (Diamond

and Kaul 2008), and vary widely in how they provide care (Wennberg 2010).

Studies from the late twentieth century found that when physicians recognize an information need, they were likely to pursue only a minority of unanswered questions. These studies found that physicians in practice had unmet information needs on the order of two questions for every three patients seen and only pursued answers for about 30% of these questions (Covell et al. 1985; Ely et al. 1999; Gorman and Helfand 1995). When answers to questions were actually pursued, these studies showed that the most frequent source for answers to questions was colleagues, followed by paper-based textbooks. Therefore, it is not surprising that barriers to satisfying information needs remain (Ely et al. 2002). Physicians use electronic sources more now than were measured in these earlier studies, with the widespread use of the **electronic health record (EHR)** as well as ubiquity of portable smartphones and tablets, although less research is undertaken in modern times assessing their needs. Another approach to facilitating access to knowledge-based information has been to link it more directly with the context of the patient in the EHR (Cimino and delFiol 2007).

The information needs of other users have been less well-studied. For consumers, surveys found about 80% of all Internet users searched for personal health information (Fox and Duggan 2013). The most common type of search focuses on a specific disease or medical problem (66% of all who have searched), followed by a specific medical treatment or procedure (56%). Consumers also use the Web to search for physicians, health care institutions, and health insurance. Even less studied have been the information needs of researchers, but one recurrent finding is the idiosyncratic nature of their use of IR and other systems (Bartlett and Toms 2005).

### 23.3.2 Changes in Publishing

The Internet and the Web have had a profound impact on the publishing of knowledge-based information. The technical impediments

to electronic publishing of journals have been overcome, such that virtually all scientific journals are published electronically now. A modern Internet connection is sufficient to deliver most of the content of journals. When available in electronic form, journal content is easier and more convenient to access. Furthermore, since most scientists have the desire for widespread dissemination of their work, they have incentive for their papers to be available electronically.

The technical challenges to electronic scholarly publication have been replaced by economic and political ones (Hersh and Rindfleisch 2000; Sox 2009). Printing and mailing, tasks no longer needed in electronic publishing, comprised a significant part of the “added value” from publishers of journals. There is still however value added by publishers, such as hiring and managing editorial staff to produce the journals, and managing the peer review process. Even if publishing companies, as they currently exist today, were to vanish, there would still be some cost to the production of journals. Thus, while the cost of producing journals electronically is likely to be less, it is not zero, and even if journal content is distributed “free,” someone has to pay the production costs. The economic issue in electronic publishing, then, is who is going to pay for the production of journals (Sox 2009). This introduces some political issues as well. One of them centers around the concern that much research is publicly funded through grants from federal agencies such as the National Institutes of Health (NIH) and the National Science Foundation (NSF). In the current system, especially in the biomedical sciences (and to a lesser extent in other sciences), researchers turn over the copyright of their publications to journal publishers. The political concern is that the public funds the research and the universities carry it out, but individuals and libraries then must buy it back from the publishers to whom they willingly cede the copyright. This problem is exacerbated by the general decline in funding for libraries.

One solution to this problem has been the emergence of **open-access (OA) publishing**. The premise of the OA model is that the

content is made freely available electronically, with the costs of production covered by other funding sources (Frank 2013). The most common funding source is the research funder, and most funders consider OA publishing costs to be an allowable expense on research grants. While some have expressed concern that OA may give rise to financial incentives for excess publishing, many OA journals have over a decade of experience demonstrating traditional peer review is compatible with OA publishing. Another concern has been the ability of resource-poor scientists to afford OA publishing, although most OA journals have “hardship” policies that allow waiver of the publication fee.

There has been the emergence of two models of OA publishing (Frank 2013). One is OA Gold, where the author (usually through the research funding) pays the cost of production. Publishing charges are typically only a tiny fraction of the overall cost of research, estimated to be about 0.3% (Zerhouni 2004). Two early publishers operating under this model were *Biomed Central* (BMC, now owned by Springer)<sup>2</sup> and the *Public Library of Science* (PLOS).<sup>3</sup> Many commercial publishers now offer authors the ability to publish under OA, and some journals have developed “Open” sister journals, such as JAMA, BMJ, and JAMIA.

A second model is OA Green, where authors are required to deposit the manuscript, either the published manuscript or the last draft of the manuscript prior to typesetting, into public repositories such as *PubMed Central* (PMC).<sup>4</sup> PMC is a repository of life science research that provides free access while allowing publishers to maintain copyright and even optionally keep the papers housed on their own servers. A lag time of up to 6 months is allowed so that journals can reap the revenue that comes with initial publication. The National Institutes of Health (NIH)<sup>5</sup> now requires all research funded by

its grants to be submitted to PMC, either in the form published by publishers or as a PDF of the last manuscript prior to journal acceptance.<sup>6</sup> Publishers have expressed concern that copyrights give journals more control over the integrity of the papers they publish (Drazen and Curfman 2004). An alternative approach, advocated by non-commercial (professional society) publishers is the *Washington DC Principles for Free Access to Science*,<sup>7</sup> which advocates:

- Reinvestment of revenues in support of science.
- Use of open archives such as PMC as allowed by business constraints.
- Commitment to some free publication, access by low-income countries, and no charges to publish.

One adverse outcome of OA publishing has been the emergence of so-called **predatory journals** (Haug 2013). These journals exist mainly to make money, allowing authors to publish in impressive-sounding titles with little or no peer review. Predatory journals offer inexpensive publishing and send massive emails to academic faculty members offering to publish or even serve on editorial boards. Some authors have exposed the process by writing clearly fake papers (McCool 2017), while others have issued calls for efforts to stop it (Moher and Moher 2016).

Some consider OA to be part of larger “open science,” consisting of (Anonymous 2018b):

- Open data – all data collected in research
- Open source – all software code developed and used
- Open methodology – clear and detailed description; availability of all surveys and other tools
- Open peer review – all comments of peer reviewers

The move to predominant electronic publication of science has led many to advocate for growing access to the underlying data from

7 ▶ <http://www.dcprinciples.org/>

research studies. While this has been a standard practice in genomics and related areas for many years (i.e., depositing genome sequences in GenBank as a condition of publication), there have been concerns that have impeded this approach in clinical studies.

The case for requiring publication of scientific data is strong. As most research is taxpayer-funded, it only seems fair that those who paid are entitled to all the data for which they paid. Likewise, all of the subjects were real people who potentially took risks to participate in the research, and their data should be used for discovery of knowledge to the fullest extent possible. In addition, new discoveries may emerge from re-analysis of data. For these reasons, the International Committee of Medical Journal Editors (ICMJE) called for de-identified data from randomized controlled trials to be shared as condition of publication (Taichman et al. 2017). Other have called for data access to be FAIR (findable, accessible, interoperable, and reusable) (Wilkinson et al. 2016).

Some researchers, however, have pushed back on this notion. They argue that those who carry out the work of designing, implementing, and evaluating experiments certainly have some exclusive rights to the data generated by their work. Some also question whether the cost is a good expenditure of limited research dollars, especially since the demand for such data sets may be modest and the benefit is not clear. One group of 282 researchers in 33 countries, the International Consortium of Investigators for Fairness in Trial Data Sharing, notes that there are risks, such as misleading or inaccurate analyses as well as efforts aimed at discrediting or undermining the original research (Anonymous 2016). They also express concern about the costs, given that there are over 27,000 RCTs performed each year. As such, this group calls for an embargo on reuse of data for 2 years plus another half-year for each year of the length of the RCT. Even those who support data sharing point out the requirement for proper curation, wide availability to all researchers, and appropriate credit to and involvement of those who originally obtained the data (Merson et al. 2016).

### 23.3.3 Quality of Information

---

In the early days of the growth of the Internet and the Web, another concern was the quality of information available. A large fraction of Web-based health information has always been aimed at nonprofessional audiences. Many lauded this development as empowering those most directly affected by health care—those who consumed it (Eysenbach et al. 1999). Others expressed concern about patients misunderstanding or being purposely misled by incorrect or inappropriately interpreted information (Jadad 1999). Some clinicians also lamented the growing amount of time required to go through stacks of printouts downloaded by patients and brought to their offices. The Web was inherently democratic, allowing anyone to post information. However, this was potentially at odds with the operation of a professional field, particularly one like health care, where practitioners were ethically bound and legally required to adhere to the highest standard of care. Thus, a major concern with health information on the Web is the presence of inaccurate or out-of-date information. An early systematic review of studies assessing the quality of health information found that 55 of 79 studies came to the conclusion that quality of information was a problem (Eysenbach et al. 2002). More recent studies continue to show the variable quality of health information on the Web (Kitchens et al. 2014).

A more recent problem, extending beyond health care, has been the proliferation of “fake news” and “alternative facts,” often promulgated by those understanding how to manipulate search engines and social media (Vosoughi et al. 2018; Wenzel 2017). A related area is “adversarial” IR, where the goal is to not retrieve information the user does not want to see or should not see (Castillo and Davison 2011). One major research organization has lamented the larger societal impacts of such “truth decay,” lamenting “erosion of civil discourse, political paralysis, alienation and disengagement of individuals from political and civic institutions” (Kavanagh and Rich 2018).

The impact of poor-quality health information is unclear. People were harmed by incorrect and misleading health information long before the emergence of digital information. One well-known self-help expert argued that patients and consumers actually are savvy enough to understand the limits of quality of information on the Web. This view held that patients and consumers should be trusted to discern quality using their own abilities to consult different sources of information and to communicate with health care practitioners and with others who share their condition(s) (Ferguson 2002). Indeed, the ideal situation may be a partnership among patients and their health care practitioners, as it has been shown that patients desire that their practitioners be the primary source of recommendations for online information (Tang et al. 1997).

This concern about quality of information led a number of individuals and organizations to develop guidelines for assessing the quality of health information. One of the earliest and most widely quoted set of criteria was published in JAMA (Silberg et al. 1997). These criteria stated that Web pages should contain the name, affiliation, and credentials of the author; references to the claims made; explicit listing of any perceived or real conflict of interest; and date of most recent update. Another early set of criteria was the *Health on the Net* (HON)<sup>8</sup> codes, a set of voluntary codes of conduct for health-related Web sites. Sites that adhere to the HON codes can display the HON logo. Another approach to insuring Web site quality is accreditation by a third party. URAC (formerly, the *Utilization Review Accreditation Commission*) has a process for such accreditation.<sup>9</sup> The URAC standards cover six general issues: health content editorial process, disclosure of financial relationships, linking to other Web sites, privacy and security, consumer complaint mechanisms, and internal processes required to maintain quality over time.

9 ► <https://www.urac.org/programs/health-web-site-accreditation>

### 23.3.4 Evidence-Based Medicine

The growing quantity of clinical information available in IR systems and digital libraries requires new approaches to select that which is best to use for clinical decisions. The philosophy guiding this approach is **evidence-based medicine** (EBM), which can be viewed as a set of tools to inform clinical decision-making. It allows clinical experience (“art”) to be integrated with best clinical science (Guyatt et al. 2014, 2015). Also, EBM makes the medical literature more clinically applicable and relevant. In addition, it requires the user to be facile with computers and IR systems. The process of EBM involves three general steps:

- Phrasing a clinical question that is pertinent and answerable.
- Identifying evidence (studies in articles) that address the question.
- Critically appraising the evidence to determine whether it applies to the patient.

The phrasing of the clinical question is an often-overlooked portion of the EBM process. There are two general types of clinical question: background questions and foreground questions (Guyatt et al. 2014, 2015).

**Background questions** ask for general knowledge about a disorder, whereas **foreground questions** ask for knowledge about managing patients with a disorder. Background questions are generally best answered with textbooks and classical review articles, whereas foreground questions are answered using EBM techniques. There are four major foreground question categories:

- Therapy (or intervention)—benefit of treatment or prevention.
- Diagnosis—test diagnosing disease.
- Harm—detrimental health effects of a disease, environmental exposure (natural or man-made), or medical intervention.
- Prognosis—outcome of disease course.

Identifying evidence involves selecting the best evidence for a given type of question. EBM proponents advocate, for example, that randomized controlled trials or a **systematic review** (with or without **meta-analysis**) that

combines multiple trials provide the best evidence for or against particular health care interventions. Likewise, diagnostic test accuracy is best assessed with comparison to a known gold standard in an appropriate spectrum of patients to whom the test will be applied (see ► Chap. 3). Questions of harm can be answered by randomized controlled trials when it is ethical to do so; otherwise they are best answered with observational case control or cohort studies. There are checklists of attributes for these different types of studies that allow their critical appraisal and applicability to a given patient in the EBM resources described above.

The original approach to EBM has evolved over time, with less emphasis on critically appraising original evidence and more on synthesized evidence being made readily available to clinicians, usually through electronic sources, including clinical decision support systems (see ► Chap. 26) (DiCenso et al. 2009; Hersh 1999). There have also been a number of criticisms of EBM, with arguments that it may ignore clinical expertise (Haynes et al. 2002), patient values (Guyatt et al. 2004), and other ways of “knowing” (Sim 2016). Others express concerns that its methods have been “distorted” (Greenhalgh et al. 2014), “hijacked” by commercial forces and other self-interest (Ioannidis 2016a, 2017), and subverted by the political process (Patashnik et al. 2017). A final criticism is the proliferation of systematic reviews, not all of which may be motivated by objective science (Ioannidis 2016b).

## 23.4 Content of Knowledge-Based Information Resources

The previous sections of this chapter have described some of the issues and concerns surrounding the production and use of knowledge-based information in biomedicine. It is useful to classify the information to gain a better understanding of its structure and function. In this section, we classify content into bibliographic, full-text, annotated, and aggregated categories, although some content does not neatly fit within them.

### 23.4.1 Bibliographic Content

The first category consists of **bibliographic content**. It includes what was for decades the mainstay of IR systems: **literature reference databases**. Also called **bibliographic databases**, this content consists of citations or pointers to the medical literature (i.e., journal articles). The best-known and most widely used biomedical bibliographic database is MEDLINE, which contains bibliographic references to all of the biomedical articles, editorials, and letters to the editors in approximately 5000 scientific journals. The journals are chosen for inclusion by an advisory committee of subject experts convened by NIH. At present, over 800,000 references are added to MEDLINE yearly. It contained over 24 million references by the end of 2017.<sup>10</sup>

The current MEDLINE record contains over 60 fields.<sup>11</sup> A clinician may be interested in just a handful of these fields, such as the title, abstract, and indexing terms. But other fields contain specific information that may be of great importance to other audiences. The Supplementary Information (SI) field contains links to records in many different data banks, from clinical trials registries to genomics and other “omics” databases.<sup>12</sup> Even the clinician may, however, derive benefit from some of the other fields. For example, the Publication Type (PT) field can help in the application of EBM, such as when one is searching for a practice guideline or a randomized controlled trial.

MEDLINE records are also assigned other identifiers. The PubMed ID (PMID) is a unique identifier for records in the database. Another identifier in MEDLINE is the PubMed Central ID (PMCID), assigned to records whose articles have been deposited into PMC. MEDLINE also contains an Author Identifier (AUID) field, which allows three possible identifiers, the most common of

10 ► [https://www.nlm.nih.gov/bsd/index\\_stats\\_comp.html](https://www.nlm.nih.gov/bsd/index_stats_comp.html)

11 ► <https://www.nlm.nih.gov/bsd/mms/medlineelements.html>

12 ► [https://www.nlm.nih.gov/bsd/medline\\_data\\_bank\\_source.html](https://www.nlm.nih.gov/bsd/medline_data_bank_source.html)

which is the ORCID identifier,<sup>13</sup> a unique identifier for scientific authors (e.g., 0000-0002-4114-5148 for this author). A growing number of journals and other publications make use of the ORCID.

MEDLINE can be accessed without charge via the **PubMed** system,<sup>14</sup> produced by the **National Center for Biotechnology Information (NCBI)**<sup>15</sup> of the NLM. Some other information vendors, such as Ovid Technologies,<sup>16</sup> license the content of MEDLINE and other databases and provide value-added services that can be accessed for a fee by individuals and institutions.

The NLM used to offer a number of other, more focused bibliographic databases, but these have all been folded into MEDLINE. A number of other publishers offer biomedical bibliographic databases. The major non-NLM database for the nursing field is the **Cumulative Index to Nursing and Allied Health Literature (CINAHL)**,<sup>17</sup> which covers nursing and allied health literature, including physical therapy, occupational therapy, laboratory technology, health education, physician assistants, and medical records. Another well-known bibliographic database is **EMBASE**,<sup>18</sup> which is produced by the commercial publisher, Elsevier (Amsterdam, Netherlands). EMBASE contains over 28 million records and covers a superset of journals from MEDLINE. These journals are often important for those carrying out systematic reviews and meta-analyses, which need access to all the studies published across the world.

A second, more modern type of bibliographic content is the **Web catalog**. There are increasing numbers of such catalogs, which consist of Web pages containing mainly links to other Web pages and sites. It should be noted that there is a blurry distinction between Web catalogs and aggregations (the fourth

category; see ► Sect. 23.4.4, below). In general, the former contains only links to other pages and sites, while the latter include actual content that is highly integrated with other resources. Some well-known Web catalogs include:

- HON Select<sup>19</sup>—a European catalog of quality-filtered, clinician-oriented Web content from the HON foundation.
- Translating Research into Practice (TRIP)<sup>20</sup>—a database of content deemed to meet high standards of EBM.

A specialized registry specific to healthcare was the *National Guidelines Clearinghouse* (NGC). Produced by the Agency for Healthcare Research and Quality (AHRQ), it contained exhaustive information about clinical practice guidelines. In 2018, AHRQ shut down the National Guidelines Clearinghouse (Munn and Qaseem 2018). The original contractor developing the NGC was the non-profit research firm, ECRI, which developed a new site, ECRI Guidelines Trust.<sup>21</sup>

A final kind of bibliographic-like content consists of **RSS feeds** (originally RDF Site Summary, often dubbed “Really Simple Syndication”), which are short summaries of Web content, typically news, journal articles, blog postings, and other content. Users set up an RSS aggregator, which can be through a Web browser, email client, or standalone software, configured for the RSS feed desired, with an option to add a filter for specific content. There are two versions of RSS (1.0 and 2.0) but both provide:

- Title—name of item
- Link—URL to content
- Description—a brief description of the content

### 23.4.2 Full-text Content

The second type of content is **full-text content**. A large component of this content origi-

21 ► <https://guidelines.ecri.org/>

nally consisted of the online versions of books and periodicals. As already noted, just about all traditionally paper-based medical content, from journals to textbooks, is now available electronically. The electronic versions usually have identical content to paper versions but may be enhanced by measures ranging from the provision of supplemental data in a journal article to linkages and multimedia content in a textbook. The final component of this category is the Web site. Admittedly, the diversity of information on Web sites is enormous, and sites may include every other type of content described in this chapter. However, in the context of this category, “Web site” refers to the vast number of static and dynamic Web pages at a discrete Web location.

One of the fields in MEDLINE is the uniform resource locator (URL) for the publisher’s full text of the article, allowing linkage directly from the bibliographic database to the full text. This link is active when the PubMed record is displayed, but users may be met by a password screen if the article is not available for free. Many sites allow both access to subscribers or a pay-per-view facility. Many academic organizations now maintain large numbers of subscriptions to journals available to faculty, staff, and students. Other publishers, such as Ovid, provide access within their own password-protected interfaces to articles from journals that they have licensed for use in their systems.

The most common secondary literature source is textbooks, almost all of which are available in electronic form. A common approach with textbooks is bundling them, sometimes with linkages across the bundled texts. An early bundler of textbooks was Stat!Ref<sup>22</sup> that, like many, began as a CD-ROM product and then moved to the Web. Most other large publishers have now similarly aggregated their libraries of textbooks and other content. Another collection of textbooks is the NCBI Bookshelf,<sup>23</sup> which contains many volumes on biomedical research topics. Initially published by NCBI but now a

standalone reference is Online Mendelian Inheritance in Man (OMIM),<sup>24</sup> which is continually updated with new information about the genomic causes of human disease.

Electronic textbooks offer additional features beyond text from the print version. While many print textbooks do feature high-quality images, electronic versions offer the ability to have more pictures and illustrations. They also have the ability to use sound and video, although few do at this time. As with full-text journals, electronic textbooks can link to other resources, including journal references and the full articles. Many Web-based textbook sites also provide access to continuing education self-assessment questions and medical news. Finally, electronic textbooks let authors and publishers provide more frequent updates of the information than is allowed by the usual cycle of print editions, where new versions come out only every few years.

As noted above, Web sites are another form of full-text information. Probably the most effective provider of Web-based health information is the U.S. government. Not only do they produce bibliographic databases, but the NLM, AHRQ, the National Cancer Institute (NCI), Centers for Disease Control (CDC), and others have also been innovative in providing comprehensive full-text information for health care providers and consumers. One example is the popular CDC Travel site.<sup>25</sup> Some of these will be described later as aggregations, since they provide many different types of resources.

A large number of commercial biomedical and health Web sites have emerged in recent years. On the consumer side, they include more than just collections of text; they also include interaction with experts, online stores, and catalogs of links to other sites. Some well-known examples include Mayo Clinic<sup>26</sup> and WebMD.<sup>27</sup> There are also Web sites, either from medical professional societies or companies, which provide information geared toward

24 ► <http://www.omim.org/>

25 ► <https://wwwnc.cdc.gov/travel>

26 ► <https://www.mayoclinic.org>

27 ► <https://www.webmd.com>

22 ► <http://statref.com/>

23 ► <https://www.ncbi.nlm.nih.gov/books>

health care providers, typically overviews of diseases, their diagnosis, and treatment; medical news and other resources for providers are often offered as well.

Other sources of on-line health-related content include encyclopedias, the so-called **body of knowledge** (BOK; the complete set of concepts, terms and activities that make up a professional domain), and **Weblogs** or **blogs**. A well-known online encyclopedia with a great deal of health-related information is Wikipedia,<sup>28</sup> which features a distributed authorship process whose content has been found to be reliable (Giles 2005; Nicholson 2006) and frequently shows up near the top in health-related Web searches (Laurent and Vickers 2009). A growing number of organizations have a body of knowledge, such as the *American Health Information Management Association* (AHIMA)<sup>29</sup>. Blogs tend to carry a stream of consciousness but often high-quality information is posted within them.

### 23.4.3 Annotated Content

The third category consists of **annotated content**. These resources are usually not stored as freestanding Web pages but instead are often housed in database management systems. This content can be further subcategorized into discrete information types:

- Image databases—collections of images from radiology, pathology, and other areas
- Genomics databases—information from gene sequencing, protein characterization, and other genomic research
- Citation databases—bibliographic linkages of scientific literature
- EBM databases—highly structured collections of clinical evidence
- Other databases—miscellaneous other collections

A great number of biomedical image databases are available on the Web. Some examples from the NLM include:

- Visible Human Project<sup>30</sup> – collection of three-dimensional representations of normal male and female bodies, consisting of cross-sectional slices of cadavers, with sections of 1 mm thickness in the male and 0.3 mm thickness in the female (Spitzer et al. 1996). Also available from each cadaver are transverse computerized tomography and magnetic resonance images.
- Images from the History of Medicine<sup>31</sup> – online access to images from the historical collections of the NLM.
- Open-I<sup>32</sup> – collection of images from PubMed Central papers (Demner-Fushman et al. 2012).

Many genomics databases are available on the Web. The first issue each year of the journal *Nucleic Acids Research* (NAR) catalogs and describes these databases, and is now available by open access means (Rigden and Fernández 2020). NAR also maintains an ongoing database of such databases, the Molecular Biology Database Collection.<sup>33</sup> Among the most important of these databases are those available from NCBI (Anonymous 2018a). All their databases are linked among themselves, along with PubMed and OMIM, and are searchable via the **NCBI Search** system.<sup>34</sup> More details on the specific content of genomics databases is provided in ► Chap. 28.

Citation databases provide linkages to articles that cite others across the scientific literature. The earliest citation databases were the Science Citation Index (SCI) and Social Science Citation Index (SSCI), which are now part of the larger Web of Science (Clarivate Analytics, Philadelphia, PA). Two well-known bibliographic databases for biomedical and health topics that also have citation links include SCOPUS<sup>35</sup> and Google Scholar.<sup>36</sup> A

28 ► [https://en.wikipedia.org/wiki/Main\\_Page](https://en.wikipedia.org/wiki/Main_Page)

29 ► <http://bok.ahima.org/>

30 ► [https://www.nlm.nih.gov/research/visible/visible\\_human.html](https://www.nlm.nih.gov/research/visible/visible_human.html)

31 ► <https://www.nlm.nih.gov/hmd/ihm/index.html>

32 ► <https://openi.nlm.nih.gov/>

33 ► <http://www.oxfordjournals.org/nar/database/a/>

34 ► <https://www.ncbi.nlm.nih.gov/search/>

35 ► <https://www.scopus.com/>

36 ► <https://scholar.google.com/>

final citation database of note is CiteSeer,<sup>37</sup> which focuses on computer and information science, including biomedical informatics.

EBM databases are devoted to providing annotated evidence-based information. Some examples (all available with through subscription fees) include:

- *Cochrane Database of Systematic Reviews*—one of the original collections of systematic reviews<sup>38</sup>
- *BMJ Best Practice*<sup>39</sup>
- *JAMA Evidence*<sup>40</sup>
- *Up-to-Date*—content centered around clinical questions<sup>41</sup>
- *Essential Evidence Plus*<sup>42</sup>

There is a growing market for a related type of evidence-based content in the form of clinical decision support order sets, rules, and health/disease management templates. Publishers include EHR vendors whose systems employ this content as well as other vendors such as Zynx<sup>43</sup> and Provation.<sup>44</sup>

There are a variety of other annotated content. The *ClinicalTrials.gov* database<sup>45</sup> began as a database of clinical trials sponsored by NIH. After concerns about clinical trials having their protocols altered after the start of trials, ClinicalTrials.gov expanded its scope to be a registry of all clinical trials (DeAngelis et al. 2005; Zarin et al. 2017) and to contain actual results of trials (Zarin et al. 2011). Another important database for researchers is *NIH RePORTER*,<sup>46</sup> which is a database of all grant awards funded by NIH. An additional annotated resource is *DataMed*,<sup>47</sup> which aims to catalog and pro-

vide linkage for use of data sets from biomedical research (Ohno-Machado et al. 2017).

#### 23.4.4 Aggregated Content

The final category consists of **aggregations** of content from the first three categories. The distinction between this category and some of the highly-linked types of content described above is admittedly blurry, but aggregations typically have a wide variety of different types of information serving the diverse needs of users. Aggregated content has been developed for all types of users from consumers to clinicians to scientists.

Probably the largest aggregated consumer information resource is **MedlinePlus**<sup>48</sup> from the NLM. MedlinePlus includes all of the types of content previously described, aggregated for easy access to a given topic. MedlinePlus contains health topics, drug information, medical dictionaries, directories, and other resources. Each topic contains links to health information from the NIH and other sources deemed credible by its selectors. There are also links to current health news (updated daily), a medical encyclopedia, drug references, and directories, along with a preformed PubMed search related to the topic.

Another well-known group of aggregations of content for genomics researchers is the **model organism databases**. These databases bring together bibliographic databases, full text, and databases of sequences, structure, and function for organisms whose genomic data have been highly characterized. One of the oldest and most developed model organism databases is the Mouse Genome Informatics resource.<sup>49</sup> More details are provided in ► Chap. 28.

### 23.5 Indexing

As noted at the beginning of the chapter, indexing is the process of assigning metadata

37 ► <http://citeseerx.ist.psu.edu>

38 ► <https://www.cochranelibrary.com>

39 ► <https://bestpractice.bmj.com/info/evidence-information/>

40 ► <https://jamaevidence.mhmedical.com>

41 ► <https://www.uptodate.com/home>

42 ► <http://www.essentialevidenceplus.com>

43 ► <https://www.zynxhealth.com/>

44 ► <https://www.provationmedical.com/order-set-management>

45 ► <https://clinicaltrials.gov/>

46 ► <http://projectreporter.nih.gov/reporter.cfm>

47 ► <https://datamed.org>

48 ► <https://medlineplus.gov/>

49 ► <http://www.informatics.jax.org/>

to content to facilitate its retrieval. Most modern commercial content is indexed in two ways:

1. **Manual indexing**—where human indexers, usually using a controlled terminology, assign indexing terms and attributes to documents, often following a specific protocol.
2. **Automated indexing**—where computers make the indexing assignments, usually limited to breaking out each word in the document (or part of the document) as an indexing term.

Manual indexing is done most commonly with bibliographic databases and annotated content. In this age of proliferating electronic content, such as online textbooks, practice guidelines, and multimedia collections, manual indexing has become either too expensive or outright unfeasible for the quantity and diversity of material now available. Thus there are increasing numbers of databases that are indexed only by automated means. Before covering these types of indexing in detail, let us first discuss controlled terminologies.

### 23.5.1 Controlled Terminologies

A **controlled terminology** contains a set of terms that can be applied to a task, such as indexing. When the terminology defines the terms, it is usually called a **vocabulary**. When it contains variants or synonyms of terms, it is also called a **thesaurus**. Before discussing actual terminologies, it is useful to define some terms. A **concept** is an idea or object that exists in the world, such as the condition under which human blood pressure is elevated. A **term** is the actual string of one or more words that represent a concept, such as “Hypertension” or “High Blood Pressure”. One of these string forms is the preferred or **canonical form**, such as “Hypertension” in the present example. When one or more terms can represent a concept, the different terms are called **synonyms**.

A controlled terminology usually contains a list of terms that are the canonical representations of the concepts. If it is a thesaurus, it

contains relationships between terms, which typically fall into three categories:

- **Hierarchical**—terms that are broader or narrower. The hierarchical organization not only provides an overview of the structure of a thesaurus but also can be used to enhance searching (e.g., MeSH tree explosions that add terms from an entire portion of the hierarchy to augment a search).
- **Synonym**—terms that are synonyms, allowing the indexer or searcher to express a concept in different words.
- **Related**—terms that are not synonymous or hierarchical but are somehow otherwise related. These usually remind the searcher of different but related terms that may enhance a search.

The MeSH terminology is used to manually index most of the databases produced by the NLM (Coletti and Bleich 2001). The latest version contains over 28,000 subject headings (the word MeSH uses for the canonical representation of its concepts). It also contains over 90,000 synonyms to those terms, which in MeSH jargon are called **entry terms**. MeSH also contains Supplementary Concept Records, representing 230,000 additional chemicals, drugs, genes, organisms, etc. that indexers encounter in indexing process and map to MeSH headings.

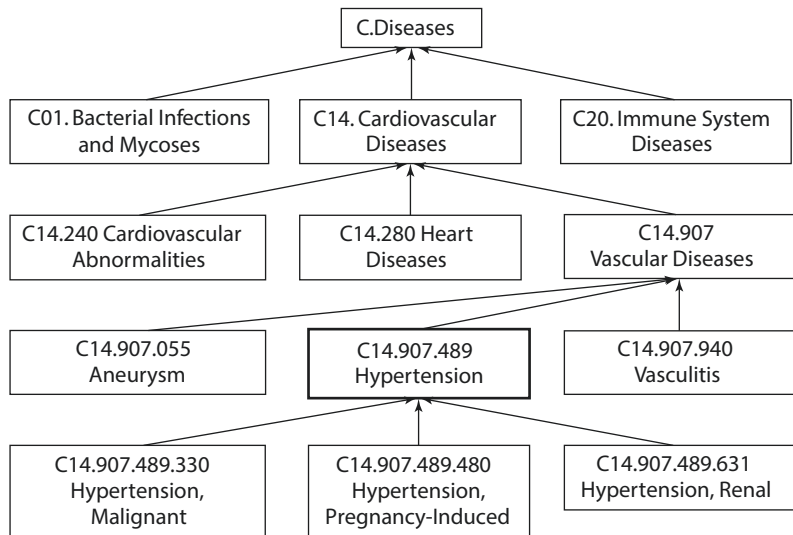

MeSH contains the three types of relationships described previously:

- **Hierarchical**—MeSH is organized hierarchically into 16 trees, such as Diseases, Organisms, and Chemicals and Drugs
- **Synonym**—MeSH contains a vast number of entry terms, which are synonyms of the headings
- **Related**—terms that may be useful for searchers to add to their searches when appropriate are suggested for many headings

The MeSH terminology files, their associated data, and their supporting documentation are available on the NLM’s MeSH Web site.<sup>50</sup> There is also a browser that facilitates explo-

50 ► <http://www.nlm.nih.gov/mesh/>

**Fig. 23.2** A slice through the Medical Subject Headings (MeSH) hierarchy for “Hypertension” and related terms, showing the location of the term in the C. Diseases. The arrows show links to broader terms in the hierarchy, while the codes give the tree address used internally by the MeSH system. (Courtesy of National Library of Medicine, with permission)

ration of the terminology<sup>51</sup> as well as a tool for mapping text to MeSH terms, called MeSH on Demand.<sup>52</sup> Figure 23.2 shows a slice through the MeSH hierarchy for “Hypertension” and related cardiovascular diseases in the C. Diseases tree.

There are features of MeSH designed to assist indexers in making documents more retrievable. One of these is **subheadings**, which are qualifiers of subject headings that narrow the focus of a term. In Hypertension, for example, the focus of an article may be on the diagnosis, epidemiology, or treatment of the condition. Another feature of MeSH that helps retrieval is **check tags**. These are MeSH terms that represent certain facets of medical studies, such as age, gender, human or nonhuman, and type of grant support. Related to check tags are the geographical locations in one particular part of the MeSH hierarchy (called the “Z tree”, because their term codes start with “Z”). Indexers must also include these, like check tags, since the location of a study (e.g., Oregon) must be indicated. Another feature gaining increasing importance for EBM and other purposes is the **publication type**, which describes the type of publication or the type of study. A searcher who wants a review of a topic may choose the

publication type Review or Review Literature. Or, to find studies that provide the best evidence for a therapy, the publication type Meta-Analysis, Randomized Controlled Trial, or Controlled Clinical Trial would be used.

MeSH is not the only thesaurus used for indexing biomedical documents. A number of other thesauri are used to index non-NLM databases. CINAHL, for example, uses the **CINAHL Subject Headings**, which are based on MeSH but have additional domain-specific terms added. EMBASE has a terminology called **EMTREE**,<sup>53</sup> which has many features similar to those of MeSH.

One problem with controlled terminologies, not limited to IR systems, is their proliferation. As already described in ► Chap. 8, there is great need for linkage across these different terminologies. This was the primary motivation for the **Unified Medical Language System (UMLS) Project**,<sup>54</sup> which was undertaken in the 1980s to address this problem (Humphreys et al. 1998). There are three components of the UMLS Knowledge Sources: the **Metathesaurus**, the **Semantic Network**, and the **Specialist Lexicon**. The Metathesaurus component of the UMLS links parts or all of over 100 terminologies (Bodenreider 2004).

**Fig. 23.3** Concepts, terms, and strings for the Metathesaurus concept atrial fibrillation. Each string may occur in more than one vocabulary, in which case each would be an atom. (Courtesy of National Library of Medicine, with permission)

In the Metathesaurus, all terms that are conceptually the same are linked together as a concept. Each concept may have one or more terms, each of which represents an expression of the concept from a source terminology that is not just a simple lexical variant (i.e., differs only in word ending or order). Each term may consist of one or more strings that represent all the lexical variants that are represented for that term in the source terminologies. One of each term's strings is designated as the preferred form, and the preferred string of the preferred term is known as the canonical form of the concept. There are rules of precedence for determining the canonical form, the main one being that the MeSH heading is used if one of the source terminologies for the concept is MeSH.

Each Metathesaurus concept has a single concept unique identifier (CUI). Each term has one term unique identifier (LUI), all of which are linked to the one (or more) CUIs with which they are associated. Likewise, each string has one string unique identifier (SUI), which is likewise linked to the LUIs in which they occur. In addition, each string has an atomic unique identifier (AUI) that represents information from each instance of the string in each vocabulary. **Figure 23.3** depicts the English-language concepts, terms, and strings for the Metathesaurus concept atrial fibrillation. (Each string may occur in more than one vocabulary, in which case each would be an atom.) The canonical form of the concept and one of its terms is atrial fibrillation. Within

both terms are several strings that vary in word order and case.

The Metathesaurus contains a wealth of additional information. In addition to the synonym relationships between concepts, terms, and strings described earlier, there are also non-synonym relationships between concepts. There are a great many attributes for the concepts, terms, strings, and atoms, such as definitions, lexical types, and occurrence in various data sources. Also provided with the Metathesaurus is a word index that connects each word to all the strings it occurs in, along with its concept, term, string, and atomic identifiers.

### 23.5.2 Manual Indexing

Manual indexing is most commonly done for bibliographic and annotated content, although it is sometimes for other types of content as well. Manual indexing is usually done by means of a controlled terminology of terms and attributes. Most databases utilizing human indexing usually have a detailed protocol for assignment of indexing terms from the thesaurus. The MEDLINE database is no exception. The principles of MEDLINE indexing were laid out in the two-volume MEDLARS Indexing Manual (Charen 1976, 1983). Subsequent modifications have occurred with changes to MEDLINE, other databases, and MeSH over the years. The major concepts of the article, usually from

two to five headings, are designed as main headings, and designated in the MEDLINE record by an asterisk. The indexer is also required to assign appropriate subheadings. Finally, the indexer must also assign check tags, geographical locations, and publication types. Although MEDLINE indexing is still manual, indexers are aided by a variety of electronic tools for selecting and assigning MeSH terms.

Few full-text resources are manually indexed. One type of indexing that commonly takes place with full-text resources, especially in the print world, is that performed for the index at the back of the book. However, this information is rarely used in IR systems; instead, most online textbooks rely on automated indexing (see ► Sect. 23.5.3, below).

Manual indexing of Web content would likewise be challenging. With billions of pages of content, manual indexing of more than a fraction of it is not feasible. On the other hand, the lack of a coherent index makes searching much more difficult, especially when specific resource types are being sought. A simple form of manual indexing of the Web takes place in the development of the Web catalogs and aggregations as described earlier. These catalogs contain not only explicit indexing about subjects and other attributes, but also implicit indexing about the quality of a given resource by the decision of whether to include it in the catalog.

Two major approaches to manual indexing have emerged on the Web that are often complementary. The first approach, that of applying metadata to Web pages and sites, is exemplified by the **Dublin Core Metadata Initiative (DCMI)**<sup>55</sup> (Weibel and Koch 2000). The goal of the DCMI has been to develop a set of standard data elements that creators of Web resources can use to apply metadata to their content. The specification has defined 15 elements, as shown in ■ Table 23.1. The DCMI was recently approved as a standard by the National Information Standards Organization (NISO) with the designation Z39.85. It is also a standard with the

International Organization for Standards (ISO), ISO Standard 15836:2009.

There have been some medical adaptations of the DCMI. The most developed of these is the Catalogue et Index des Sites Médicaux Francophones (CISMeF)<sup>56</sup> (Darmoni et al. 2000). A catalog of French-language health resources on the Web, CISMeF has used DCMI to catalog Web pages, including information resources (e.g., practice guidelines, consensus development conferences), organizations (e.g., hospitals, medical schools, pharmaceutical companies), and databases. The Subject field uses the French translation of MeSH but also includes the English translation. For Type, a list of common Web resources has been enumerated.

While Dublin Core Metadata was originally envisioned to be included in **Hypertext Markup Language (HTML)** Web pages, it became apparent that many non-HTML resources exist on the Web and that there are reasons to store metadata external to Web pages. For example, authors of Web pages might not be the best people to index pages or other entities might wish to add value by their own indexing of content. An emerging standard for cataloging metadata is the **Resource Description Framework (RDF)** (Akerkar 2009).

A second approach to manually indexing content on the Web has been to create directories of content. The first major effort to create these was for use in the Yahoo! search engine,<sup>57</sup> which created a subject hierarchy and assigned Web sites to elements within it. When concern began to emerge that the Yahoo directory was proprietary and not necessarily representative of the Web community at large, an alternative movement sprung up: the Open Directory Project (dmoz.org). Due to increasing growth of the Web, these projects were eventually disbanded.

Manual indexing has a number of limitations, the most significant of which is inconsistency. Funk and Reid (Funk and Reid 1983) evaluated indexing inconsistency in

55 ► <http://dublincore.org/>

56 ► <http://www.chu-rouen.fr/cismef/>

57 ► <https://www.yahoo.com/>

**Table 23.1** Elements of Dublin Core Metadata

Element	Definition
DC.title	The name given to the resource
DC.creator	The person or organization primarily responsible for creating the intellectual content of the resource
DC.subject	The topic of the resource
DC.description	A textual description of the content of the resource
DC.publisher	The entity responsible for making the resource available in its present form
DC.date	A date associated with the creation or availability of the resource
DC.contributor	A person or organization not specified in a creator element who has made a significant intellectual contribution to the resource but whose contribution is secondary to any person or organization specified in a creator element
DC.type	The category of the resource
DC.format	The data format of the resource, used to identify the software and possibly hardware that might be needed to display or operate the resource
DC.identifier	A string or number used to uniquely identify the resource
DC.source	Information about a second resource from which the present resource is derived
DC.language	The language of the intellectual content of the resource
DC.relation	An identifier of a second resource and its relationship to the present resource
DC.coverage	The spatial or temporal characteristics of the intellectual content of the resource
DC.rights	A rights management statement, an identifier that links to a rights management statement, or an identifier that links to a service providing information about rights management for the resource

MEDLINE by identifying 760 articles that had been indexed twice by the NLM. The most consistent indexing occurred with check tags and central concept headings, which were only indexed with a consistency of 61–75%. The least consistent indexing occurred with subheadings, especially those assigned to non-central-concept headings, which had a consistency of less than 35%. A repeat of this study in more recent times found comparable results (Marcetich et al. 2004). Manual indexing also takes time. While it may be feasible with the large resources the NLM has to index MEDLINE, it is probably impossible with the growing amount of content on Web sites and in other full-text resources. Indeed, the NLM has recognized the challenge of continuing to have to index the growing body of biomedical literature and is investigating automated and

semiautomated means of doing so (Mork et al. 2017).

### 23.5.3 Automated Indexing

In automated indexing, the indexing is done by a computer. Although the mechanical running of the automated indexing process lacks cognitive input, considerable intellectual effort may have gone into development of the system for doing it, so this form of indexing still qualifies as an intellectual process. In this section, we will focus on the automated indexing used in operational IR systems, namely the indexing of documents by the words they contain.

Some might not think of extracting all the words in a document as “indexing,” but from

the standpoint of an IR system, words are descriptors of documents, just like human-assigned indexing terms. Most retrieval systems actually use a hybrid of human and word indexing, in that the human-assigned indexing terms become part of the document, which can then be searched by using the whole controlled term or individual words within it. With the development of full-text resources in the 1980s and 1990s, systems that allowed only word indexing began to emerge. This trend increased with the advent of the Web.

Word indexing is typically done by defining all consecutive alphanumeric sequences between white space (which consists of spaces, punctuation, carriage returns, and other non-alphanumeric characters) as words. Systems must take particular care to apply the same process to documents and the user's query, especially with characters such as hyphens and apostrophes. Many systems go beyond simple identification of words and attempt to assign weights to words that represent their importance in the document (Salton 1991).

Many systems using word indexing employ processes to remove common words or conflate words to common forms. The former consists of filtering to remove **stop words**, which are common words that always occur with high frequency and are usually of little value in searching. The stop word list, also called a **negative dictionary**, varies in size from the seven words of the original MEDLARS stop list (and, an, by, from, of, the, with) to the list of 250–500 words more typically used. Examples of the latter are the 250-word list of van Rijsbergen (1979), the 471-word list of Fox (1992), and the PubMed stop list.<sup>58</sup> Conflation of words to common forms is done via **stemming**, the purpose of which is to ensure words with plurals and common suffixes (e.g., -ed, -ing, -er, -al) are always indexed by their stem form (Frakes 1992). For example, the words cough, coughs, and coughing are all indexed via their stem cough. Both stop word remove and stemming reduce the size of indexing files and lead to more efficient query processing.

A commonly used approach for term weighting is **TF\*IDF weighting**, which combines the **inverse document frequency (IDF)** and **term frequency (TF)**. The IDF is the logarithm of the ratio of the total number of documents to the number of documents in which the term occurs. It is assigned once for each term in the database, and it correlates inversely with the frequency of the term in the entire database. The usual formula used is:

$$IDF(\text{term}) = \log \frac{\text{number of documents in database}}{\text{number of documents with term}} + 1 \quad (23.1)$$

The TF is a measure of the frequency with which a term occurs in a given document and is assigned to each term in each document, with the usual formula:

$$TF(\text{term}, \text{document}) = \frac{\text{frequency of term in document}}{\text{document}} \quad (23.2)$$

In TF\*IDF weighting, the two terms are combined to form the indexing weight, **WEIGHT**:

$$WEIGHT(\text{term}, \text{document}) = TF(\text{term}, \text{document}) * IDF(\text{term}) \quad (23.3)$$

Another automated indexing approach generating increased interest is the use of **link-based** methods, fueled by the success of the Google search engine.<sup>59</sup> This approach gives weight to pages based on how often they are cited by other pages. The **PageRank (PR) algorithm** is mathematically complex, but can be viewed as giving more weight to a Web page based on the number of other pages that link to it (Brin and Page 1998). Thus, the home page of the NLM or a major medical journal is likely to have a very high PR, whereas a more obscure page will have a lower PR.

General-purpose search engines such as Google and Microsoft Bing use word-based approaches and variants of the PageRank algorithm for indexing. They amass the content in their search systems by “crawling” the Web, collecting and indexing every object they

58 ► <https://www.ncbi.nlm.nih.gov/books/NBK3827/table/pubmedhelp.T.stopwords/>

59 ► <https://www.google.com/>

find on the Web. This includes not only HTML pages, but other files as well, including Microsoft Word, Portable Document Format (PDF), and images.

Word indexing has a number of limitations, including:

- Synonymy—different words may have the same meaning, such as high and elevated. This problem may extend to the level of phrases with no words in common, such as the synonyms hypertension and high blood pressure.
- Polysemy—the same word may have different meanings or senses. For example, the word lead can refer to an element or to a part of an electrocardiogram machine.
- Content—words in a document may not reflect its focus. For example, an article describing hypertension may make mention in passing to other concepts, such as congestive heart failure (CHF) that are not the focus of the article.
- Context—words take on meaning based on other words around them. For example, the relatively common words high, blood, and pressure, take on added meaning when occurring together in the phrase high blood pressure.
- Morphology—words can have suffixes that do not change the underlying meaning, such as indicators of plurals, various participles, adjectival forms of nouns, and nominalized forms of adjectives.
- Granularity—queries and documents may describe concepts at different levels of a hierarchy. For example, a user might query for antibiotics in the treatment of a specific infection, but the documents might describe specific antibiotics themselves, such as penicillin.

► Chapter 9 on Natural Language Processing (NLP) describes automated methods for addressing these limitations.

## 23.6 Retrieval

---

There are two broad approaches to retrieval. Exact-match searching allows the user precise control over the items retrieved. Partial-match

searching, on the other hand, recognizes the inexact nature of both indexing and retrieval, and instead attempts to return to the user content ranked by how close it comes to the user's query. After general explanations of these approaches, we will describe actual systems that access the different types of biomedical content.

### 23.6.1 Exact-Match Retrieval

---

In exact-match searching, the IR system gives the user all documents that exactly match the criteria specified in the search statement(s). Since the **Boolean operators** AND, OR, and NOT are usually required to create a manageable set of documents, this type of searching is often called Boolean searching. Furthermore, since the user typically builds sets of documents that are manipulated with the Boolean operators, this approach is also called **set-based searching**. Most of the early operational IR systems in the 1950s through 1970s used the exact-match approach, even though Salton was developing the partial-match approach in research systems during that time (Salton and McGill 1983). Currently, exact-match searching tends to be associated with retrieval from bibliographic and annotated databases, while the partial-match approach tends to be used with full-text searching.

Typically the first step in exact-match retrieval is to select terms to build sets. Other attributes, such as the author name, publication type, or gene identifier (in the secondary source identifier field of MEDLINE), may be selected to build sets as well. Once the search term(s) and attribute(s) have been selected, they are combined with the Boolean operators. The Boolean AND operator is typically used to narrow a retrieval set to contain only documents with two or more concepts. The Boolean OR operator is usually used when there is more than one way to express a concept. The Boolean NOT operator is often employed as a subtraction operator that is applied to a pair of sets, with the result being the documents found in the first set but not in the second set. Some systems more accurately call this the ANDNOT operator.

Some systems allow terms in searches to be expanded by using the wild-card character, which adds all words to the search that begin with the letters up until the wild-card character. This approach is also called truncation. Unfortunately, there is no standard approach to using wild-card characters, so syntax for them varies from system to system. PubMed, for example, allows a single asterisk at the end of a word to signify a wild-card character. Thus the query word *can\** will lead to the words *cancer* and *Candida*, among others, being added to the search.

### 23.6.2 Partial-Match Retrieval

Although **partial-match searching** was conceptualized very early, it did not see widespread use in IR systems until the advent of Web search engines in the 1990s. This is most likely because exact-match searching tends to be preferred by “power users” whereas partial-match searching is preferred by novice searchers. Whereas exact-match searching requires an understanding of Boolean operators and (often) the underlying structure of databases (e.g., the many fields in MEDLINE), partial-match searching allows a user to simply enter a few terms and start retrieving documents.

The development of partial-match searching is usually attributed to Salton, who pio-

neered the approach in the 1960s (Salton and McGill 1983). Although partial-match searching does not exclude the use of non-term attributes of documents, and for that matter does not even exclude the use of Boolean operators (e.g., Salton et al. 1983), the most common use of this type of searching is with a query of a small number of words, also known as a **natural language query**. Because Salton’s approach was based on vector mathematics, it is also referred to as the **vector-space model** of IR. In the partial-match approach, documents are typically ranked by their closeness of fit to the query. That is, documents containing more query terms will likely be ranked higher, since those with more query terms will in general be more likely to be relevant to the user. As a result this process is called **relevance ranking**. The entire approach has also been called **lexical-statistical retrieval**.

The most common approach to document ranking in partial-match searching is to give each a score based on the sum of the weights of terms common to the document and query. Terms in documents typically derive their weight from the TF\*IDF calculation described above. Terms in queries are typically given a weight of one if the term is present and zero if it is absent. The following formula can then be used to calculate the document weight across all query terms:

$$\text{Document weight} = \sum_{\text{all query terms}} \text{Weight of term in query} * \text{Weight of term in document} \quad (23.4)$$

This may be thought of as a giant OR of all query terms, with sorting of the matching documents by weight. The usual approach is for the system to then perform the same stop word removal and stemming of the query that was done in the indexing process. (The equivalent stemming operations must be performed on documents and queries so that complementary word stems will match).

A number of other ranking algorithms have been developed over the years. The BM25 approach has been found to be effec-

tive for many diverse test collections (Robertson and Walker 1994). Another approach showing efficacy in research has been the use of language modeling techniques (Zhai and Lafferty 2004). More recently, the learning-to-rank approach has found value for machine learning approaches in the relevance ranking process (Li 2011). The large search engines such as Google make use of other information in their results, such as aiming to provide answers to queries that are likely to be questions (e.g., defining words or

listing airplane flights) and using other features of Web pages, such as their geographic location (e.g., a user querying for restaurants).

### 23.6.3 Retrieval Systems

This section describes searching systems used to retrieve content from the four categories previously described in ► Sect. 23.4.

As noted above, PubMed is the system at NLM that searches MEDLINE and other bibliographic databases. Although presenting the user with a simple text box, PubMed does a great deal of processing of the user's input to identify MeSH terms, author names, common phrases, and journal names (described in the on-line help system of PubMed). In this

automatic term mapping, the system attempts to map user input, in succession, to MeSH terms, journals names, common phrases, and authors. Remaining text that PubMed cannot map is searched as text words (i.e., words that occur in any of the MEDLINE fields). A results screen for a search combining the disease congestive heart failure (CHF) and the angiotensin converting enzyme (ACE) inhibitor class of drugs is shown in ■ Fig. 23.4.

PubMed allows the use of wild-card characters. It also allows phrase searching whereby two or more words can be enclosed in quotation marks to indicate they must occur adjacent to each other. If the specified phrase is in PubMed's phrase index, then it will be searched as a phrase. Otherwise the individual words will be searched. PubMed allows speci-

fication of other indexing attributes via “Limits.” These include publication types, subsets, age ranges, and publication date ranges. These are accessed from the left-hand side of the results screen, with the most commonly used ones shown and the others accessible by additional mouse clicks.

As in most bibliographic systems, users can also search PubMed by building search sets and then combining them with Boolean operators to tailor the search. This is called the PubMed Advanced Search Builder. Consider a user searching for studies assessing the reduction of mortality in patients with CHF through the use of ACE inhibitors. A simple approach to such a search might be to combine the terms ACE inhibitors and CHF with an AND. The easiest way to do this is to

enter the search string congestive heart failure and ACE inhibitors. **Figure 23.5** shows the PubMed Advanced Search Builder screen such a searcher might develop. This searcher has limited the output (using some of the limits shown in **Fig. 23.4**) with various publication types known to contain the best evidence for this question. Also note that the search does not require the “and,” as PubMed determines the Boolean operator should be placed there automatically.

Most MEDLINE systems have ranked output sorted by reverse chronological order, based on the notion that the most recent articles have the mostly timely and complete information. PubMed has also featured relevance-ranked output and recently improved its algorithms (Fiorini et al. 2018).

The screenshot shows the NCBI search interface. At the top, there is a navigation bar with 'NCBI Resources' and 'How To' links, and a 'Sign in to NCBI' link. Below this is a search bar with a 'Search' button. The main content is divided into several categories, each with a list of databases and their descriptions:

- Literature**
  - Books: books and reports
  - MeSH: ontology used for PubMed indexing
  - NLM Catalog: books, journals and more in the NLM Collections
  - PubMed: scientific & medical abstracts/citations
  - PubMed Central: full-text journal articles
- Health**
  - ClinVar: human variations of clinical significance
  - dbGaP: genotype/phenotype interaction studies
  - GTR: genetic testing registry
  - MedGen: medical genetics literature and links
  - OMIM: online mendelian inheritance in man
  - PubMed Health: clinical effectiveness, disease and drug reports
- Genomes**
  - Assembly: genome assembly information
  - BioCollections: museum, herbaria, and other biorepository collections
  - BioProject: biological projects providing data to NCBI
  - BioSample: descriptions of biological source materials
  - Clone: genomic and cDNA clones
  - dbVar: genome structural variation studies
  - Genome: genome sequencing projects by organism
  - GSS: genome survey sequences
  - Nucleotide: DNA and RNA sequences
  - Probe: sequence-based probes and primers
  - SNP: short genetic variations
  - SRA: high-throughput DNA and RNA sequence read archive
  - Taxonomy: taxonomic classification and nomenclature catalog
- Genes**
  - EST: expressed sequence tag sequences
  - Gene: collected information about gene loci
  - GEO DataSets: functional genomics studies
  - GEO Profiles: gene expression and molecular abundance profiles
  - HomoloGene: homologous gene sets for selected organisms
  - PopSat: sequence sets from phylogenetic and population studies
  - UniGene: clusters of expressed transcripts
- Proteins**
  - Conserved Domains: conserved protein domains
  - Protein: protein sequences
  - Protein Clusters: sequence similarity-based protein clusters
  - Structure: experimentally-determined biomolecular structures
- Chemicals**
  - BioSystems: molecular pathways with links to genes, proteins and chemicals
  - PubChem BioAssay: bioactivity screening studies
  - PubChem Compound: chemical information with structures, information and links
  - PubChem Substance: deposited substance and chemical information

PubMed has an additional approach to finding the best evidence, which is through the use of its **Clinical Queries** function,<sup>60</sup> where the subject terms are limited by search statements designed to retrieve the best evidence based on principles of EBM. There are two different approaches. The first uses strategies for retrieving the best evidence for the four major types of clinical questions. These strategies arise from research assessing the ability of MEDLINE search statements to identify the best studies for therapy, diagnosis, harm, and prognosis (Haynes et al. 1994). The second approach to retrieving the best evidence aims to retrieve evidence-based resources that are syntheses and synopses, in particular meta-analyses, systematic reviews, and practice guidelines. The strategy derives in part from research by Boynton et al. (Boynton et al. 1998). When the clinical queries interface is used, the search statement is processed

by the usual automatic term mapping and the resulting output is limited (via AND) with the appropriate statement.

A growing number of search engines allow searching over many resources. The general search engines Google, Microsoft Bing, and others allow retrieval of any types of documents they have indexed via their Web crawling activities. Other search engines allow searching over aggregations of various sources, such as NCBI Search,<sup>61</sup> which allows searching over all NLM NCBI databases and other resources in one simple interface, as shown in ■ Fig. 23.6.

## 23.7 Evaluation

There has been a great deal of research over the years devoted to evaluation of IR systems. As with many areas of research, there is con-

60 ► <https://www.ncbi.nlm.nih.gov/pubmed/clinical>

61 ► <https://www.ncbi.nlm.nih.gov/search/>

trovery as to which approaches to evaluation best provide results that can assess searching in the systems they are using. Many frameworks have been developed to put the results in context. One of those frameworks organized evaluation around six questions that someone advocating the use of IR systems might ask (Hersh and Hickam 1998):

1. Was the system used?
2. For what was the system used?
3. How well did they use the system?
4. Were the users satisfied?
5. What factors were associated with successful or unsuccessful use of the system?
6. Did the system have an impact?

While early evaluation studies asked questions about whether IR systems would be used if made available, in modern times their use is ubiquitous. A study by Google and Manhattan Research found that essentially all physicians reported searching on digital devices daily, with most searching resulting in action, such as changing treatment decisions or sharing with a colleague or patient (Anonymous 2012). Similarly, a recent study of internal medicine residents at three sites found that nearly all responding to the survey searched daily, with the most common resource searched being UpToDate (Duran-Nelson et al. 2013). The next most frequent source of information was consultation with attending faculty, followed by the Google search engine, the Epocrates drug reference, and various other “pocket” references. Another study of family medicine resident and attending physicians found universal use of smartphones and tablet devices daily in their practices (Yaman et al. 2016).

Patient and consumer searching of the Web for health information also continues to

be reported high. In the most recent update of her ongoing survey of health-related searching, Fox found that 72% of US adult Internet users (59% of all US adults) have looked for health information in the last year (Fox and Duggan 2013). Earlier research found that the most common types of searches done by these users was for a specific disease or medical condition and for a certain medical treatment or procedure (Fox 2011). Three focus groups convened by Mayo Clinic researchers asked consumers about their online searching use and needs, finding that subjects reported searching, filtering, and comparing information retrieved, with the process stopping due to saturation and fatigue (Fiksdal et al. 2014).

Most evaluation research has focused on the third question from the above list, i.e., how well did search systems or their users perform? The rest of this section on evaluation will focus on studies of that question, grouping approaches and studies into those that are system-oriented, i.e., the focus of the evaluation is on the IR system, and those that are user-oriented, i.e., the focus is on the user.

### 23.7.1 System-Oriented Evaluation

There are many ways to evaluate the performance of IR systems, the most widely used of which are the relevance-based measures of **recall** and **precision**. These measures quantify the number of relevant documents retrieved by the user from the database and in his or her search. Recall is the proportion of relevant documents retrieved from the database:

$$\text{Recall} = \frac{\text{number of retrieved and relevant documents}}{\text{number of relevant documents in database}} \quad (23.5)$$

In other words, recall answers the question, for a given search, what fraction of all the relevant documents have been obtained from the database?

One problem with Eq. (23.5) is that the denominator implies that the total number

of relevant documents for a query is known. For all but the smallest of databases, however, it is unlikely, perhaps even impossible, for one to succeed in identifying all relevant documents in a database. Thus most studies use the measure of **relative recall**, where the

denominator is redefined to be the total number of unique, relevant documents identified by one or more searches on the query topic.

Precision is the proportion of relevant documents retrieved in the search:

$$\text{Precision} = \frac{\text{number of retrieved and relevant documents}}{\text{number of documents retrieved}} \quad (23.6)$$

This measure answers the question, for a search, what fraction of the retrieved documents is relevant?

One problem that arises when one is comparing systems that use ranking versus those that do not is that nonranking systems, typically using Boolean searching, tend to retrieve a fixed set of documents and as a result have fixed points of recall and precision. Systems with relevance ranking, on the other hand, have different values of recall and precision depending on the size of the retrieval set the system (or the user) has chosen to show. The problem has been addressed by the development of aggregate measures that combine recall and precision and that account for ranking. One of the most common measures used is **mean average precision (MAP)**, which measures precision at each point that a relevant document is retrieved, and then provides a mean of all the average precision values (Buckley and Voorhees 2005).

Another challenge for IR evaluation occurs with large collections, where every possible item retrieved cannot be judged for relevance. If there is concern that there are large numbers of unjudged documents, the **B-Pref** measure can be used, which only makes use of unjudged documents in its calculations (Buckley and Voorhees 2004). An additional measure increasingly used in **normalized distributed cumulative gain (NDCG)**, which allows differential value of retrieved documents, e.g., a value of 2 for highly relevant and 1 for partially relevant documents (Jarvelin and Kekalainen 2002).

A good deal of evaluation in IR is done via **challenge evaluations**, in which a common IR task is defined and a **test collection** of documents, topics, and **relevance judgments** are developed. The relevance judgments define

which documents are relevant for each topic in the task, allowing different researchers to compare their systems with others on the same task and improve them. The longest running and best-known challenge evaluation in IR is the **Text REtrieval Conference (TREC)**,<sup>62</sup> which is organized by the U.S. National Institute for Standards and Technology (NIST).<sup>63</sup> Started in 1992, TREC has provided a testbed for evaluation and a forum for presentation of results. TREC is organized as an annual event at which the tasks are specified and queries and documents are provided to participants. Participating groups submit “runs” of their systems to NIST, which calculates the appropriate performance measure(s). TREC is organized into “tracks” geared to specific interests. A book summarizing the first decade of TREC provides more information on this important IR initiative that is still ongoing (EM Voorhees and Harman 2005).

While TREC has been mostly focused on retrieval of general information sources (e.g., newswire, government documents, Web pages, etc.), there have been a number of tracks over the years devoted to biomedical IR. These tracks tended to reflect areas of biomedicine that were emerging importance. The first TREC track specific to the biomedical domain was the Genomics Track, due to the emergence at the time of the sequencing of human genome and the rise of the area of bioinformatics. A variety of literature retrieval tasks were developing, focused on journal article abstracts (from MEDLINE records) or full text (Hersh and Bhupatiraju 2003; Hersh

62 ▶ <https://trec.nist.gov/>

63 ▶ <https://www.nist.gov/>

et al. 2004, 2005, 2006, 2007; Hersh and Voorhees 2009; Roberts et al. 2009).

A second track from the biomedical domain aimed to leverage the growing interest in processing medical records text around the onset of the HITECH Act. The Medical Records Track used a collection of de-identified patient records for a task aiming to retrieve patients who might be candidates for clinical studies (Voorhees 2013; Voorhees and Hersh 2012; Voorhees and Tong 2011).

The next biomedical domain track was the Clinical Decision Support (CDS) Track, which aimed to retrieve full-text journal articles from a snapshot of PubMed Central to identify knowledge relevant to diagnosis, testing, or treatment (Roberts et al. 2015, 2016a, b; Simpson et al. 2014). The CDS Track was refined into the Precision Medicine Track, which aimed to retrieve information relevance to the precision medicine paradigm (Roberts et al. 2017).

Another annual challenge evaluation, based in Europe, has been the Conference and Labs of the Evaluation Forum (CLEF, originally known as the Cross-Language Evaluation Forum). Since 2013, one focus of CLEF has been eHealth, with tasks focused not only in IR, but also information extraction and information management.<sup>64</sup> The track has had a patient-centered retrieval task since 2013, a cross-language retrieval task since 2014, and a systematic review task starting in 2017. An additional challenge evaluation emanating from CLEF and focused on image retrieval, which has included a medical image retrieval component, has been ImageCLEF.<sup>65</sup> Some recent overviews of the state of the art of image retrieval have been published (Li et al. 2018; Müller and Unay 2017).

Some system-oriented studies have focused on specific use cases for IR systems. One area gaining a good deal of attention has been reducing the workload of performing systematic reviews, which require high recall to retrieval all possibly relevant studies. This

comes at a cost of low precision, so a question is how to reduce the work of systematic reviews by increasing precision while minimally impacting recall. Early work in this area was carried out by Cohen et al. (2009, 2015), demonstrating value for machine learning approaches. A systematic review task was added to CLEF eHealth in 2017 (Kanoulas et al. 2017, 2018, 2019).

A number of researchers have criticized or noted the limitations of relevance-based measures. While no one denies that users want systems to retrieve relevant articles, it is not clear that the quantity of relevant documents retrieved is the complete measure of how well a system performs (Harter 1992; Swanson 1988). Hersh (1994) noted that clinical users are unlikely to be concerned about these measures when they simply seek an answer to a clinical question and are able to do so no matter how many other relevant documents they miss (lowering recall) or how many nonrelevant ones they retrieve (lowering precision). This has led to more focus on user-oriented evaluation.

### 23.7.2 User-Oriented Evaluation

What alternatives to relevance-based measures can be used for determining performance of individual searches? Some alternatives have focused on users being able to perform various information tasks with IR systems, such as finding answers to questions (Egan et al. 1989; Hersh and Hickam 1995; Hersh et al. 1996; Mynatt et al. 1992; Wildemuth et al. 1995). For several years, TREC featured an Interactive Track that had participants carry out user experiments with the same documents and queries (Hersh 2001). A number of user-oriented evaluations have been performed over the years looking at users of biomedical information.

When end-user retrieval systems first appeared, a number of studies appeared aiming to measure search performance by clinicians. One of the original studies compared the capabilities of librarian and clinician searchers (Haynes et al. 1990). In this study, 78 searches were randomly chosen for replica-

64 ▶ <https://sites.google.com/site/clefehealth/>

65 ▶ <https://www.imageclef.org>

tion by both a clinician experienced in searching and a medical librarian. The results showed that the experienced clinicians and librarians achieved comparable recall in the range of 50%, although the librarians had better precision. The novice clinician searchers had lower recall and precision than either of the other groups. This study also assessed user satisfaction of the novice searchers, who despite their recall and precision results said that they were satisfied with their search outcomes. A follow-up study noted that different searchers tended to use different strategies on a given topic. The different approaches replicated a finding known from other searching studies in the past, namely, the lack of overlap across searchers of overall retrieved citations as well as relevant ones. Thus, even though the novice searchers had lower recall, they did obtain a great many relevant citations not retrieved by the two expert searchers. Furthermore, fewer than 4% of all the relevant citations were retrieved by all three searchers.

Recognizing the limitations of recall and precision for evaluating clinical users of IR systems, subsequent studies assessed the ability of systems to help students and clinicians answer clinical questions. The rationale for these studies is that the usual goal of using an IR system is to find an answer to a question. While the user must obviously find relevant documents to answer that question, the quantity of such documents is less important than whether the question is successfully answered. In fact, recall and precision can be placed among the many factors that may be associated with ability to complete the task successfully.

The first study using this task-oriented approach compared Boolean versus natural language searching in an online medical textbook (Hersh and Hickam 1995). There was no difference in ability to answer questions with one interface or the other. Most answers were found on the first search to the textbook. For the questions that were incorrectly answered, the document with the correct answer was actually retrieved by the user two-thirds of the time and viewed more than half the time.

Another study compared Boolean and natural language searching of MEDLINE with two commercial products, CD Plus (now Ovid) and Knowledge Finder representing Boolean and natural language searching respectively (Hersh et al. 1996). Sixteen medical students were recruited and randomized to one of the two systems and given three yes/no clinical questions to answer. The students were able to use each system successfully, answering 37.5% correctly before searching and 85.4% correctly after searching. There were no significant differences between the systems in time taken, relevant articles retrieved, or user satisfaction. This study demonstrated that both types of systems could be used equally well with minimal training.

A more comprehensive study looked at MEDLINE searching by medical and nurse practitioner (NP) students to answer clinical questions. A total of 66 medical and NP students searched five questions each (Hersh et al. 2002). This study used a multiple-choice format for answering questions that also included a judgment about the evidence for the answer. Subjects were asked to choose from one of three answers:

- Yes, with adequate evidence.
- Insufficient evidence to answer question.
- No, with adequate evidence.

Both groups achieved a presearching correctness on questions about equal to chance (32.3% for medical students and 31.7% for NP students). However, medical students improved their correctness with searching (to 51.6%), whereas NP students hardly did at all (to 34.7%).

This study also attempted to measure what factors might influence searching. A multitude of factors, such as age, gender, computer experience, and time taken to search, were not associated with successful answering of questions. Successful answering was, however, associated with answering the question correctly before searching, spatial visualization ability (measured by a validated instrument), searching experience, and EBM question type (prognosis questions easiest, harm questions most difficult). An analysis of recall and pre-

cision for each question searched demonstrated a complete lack of association with ability to answer these questions.

Two studies extended this approach in different ways. Westbook et al. assessed use of an online evidence systems and found that physicians answered 37% of questions correctly before use of the system and 50% afterwards, while nurse specialists answered 18% of questions correctly and also 50% afterwards (Westbrook et al. 2005). Those who had correct answers before searching had higher confidence in their answers, but those not initially knowing the answer had no difference in confidence whether their answer turned out to be right or wrong. McKibbon and Fridsma performed a comparable study of allowing physicians to seek answers to questions with resources they normally use (McKibbon and Fridsma 2006) employing the same questions as Hersh et al. (2002). This study found no difference in answer correctness before or after using the search system.

Pluye et al. (Pluye and Grad 2004) performed a qualitative study assessing impact of IR systems on physician practice. The study identified 4 themes mentioned by physicians:

- Recall—of forgotten knowledge
- Learning—new knowledge
- Confirmation—of existing knowledge
- Frustration—that system use not successful

The researchers also noted two additional themes:

- Reassurance—that system is available
- Practice improvement—of patient-physician relationship

More recent studies have focused on searchers using well-known modern IR systems. Kim et al. looked at the ability of internal medicine interns to answer questions starting from Google versus an evidence-based summary resource developed by a local medical library (Kim et al. 2014). Ten questions were given to each subject, with each participant randomized to start in either Google or the summary resource for half of questions. Answers were found for 82% of the questions administered, with no difference between groups in correct

answers (58–62% correct) or time taken (136–139 seconds). While those starting in the summary resource mostly found answers in resources that were part of the summary system 93% of the time, those starting with Google found answers in commercial medical portals (25.7%), hospital Web sites (12.6%), Wikipedia (12.0%), US government Web sites (9.4%), PubMed (9.4%), evidence-based summary resources (9.4%), and others (18%). Another study looked at medical students' short-term knowledge when randomized to answer questions in Wikipedia, UpToDate, and a digital textbook, finding the best short-term knowledge acquisition with Wikipedia (Scaffidi et al. 2017).

Koopman et al. assessed factors comprising effective queries and those making them (Koopman et al. 2017). They found that query formulation had more impact on retrieval effectiveness than the particular retrieval systems used. The most effective queries were short, ad-hoc keyword queries and queriers who inferred novel keywords most likely to appear in relevant documents.

Other users of IR systems have been studied beyond clinicians. One study used the TREC Genomics Track 2004 collection to assess the value of MeSH terms for different types of searchers (Liu and Wacholder 2017). The researchers recruited four types of searchers:

- Search Novice (SN) – undergraduates with no formal search training or advanced knowledge in biomedicine
- Domain Expert (DE) – biomedical graduate students
- Search Expert (SE) – library and information science graduate students
- Medical Librarian (ML)

The searchers used a digital library system to search on 20 topics from the original test collection. Searchers assigned to search with MeSH were provided access to a MeSH browser. As with other studies, recall (0.15–0.23) and precision (0.29–0.40) were relatively close across different groups. MeSH terms had little impact upon recall in the four groups, but they were found to substantially

increase precision in search novices (SN and DE) and decrease it in search experts (SE and ML) (recall and precision with MeSH; without MeSH). User characteristics that improved precision were number of undergraduate and graduate biology courses for SN and DE respectively. User characteristics associated with improved recall included having had online search courses and MeSH use experience. Other factors having no association with search results included gender, native language, age, or experience or frequency with database searching.

Another group of searchers that have been studied are consumers. A study from Mayo Clinic analyzed search queries submitted through general search engines but leading users into a consumer health information portal from computers and mobile devices (Jadhav et al. 2014). The most common types of searches were on symptoms (32–39%), causes of disease (19–20%), and treatments and drugs (14–16%). Health queries tended to be longer and more specific than general (non-health) queries. Health queries were somewhat more likely to come from mobile devices. Most searches used key words, although some were also phrased as questions (wh- or yes/no).

An additional study aimed to assess differences in searching between medical experts

and lay people (Palotti et al. 2016). This study found that medical experts were more persistent in their interaction with the search engine. They also noted that the main focus of users, both laypeople and professionals, was on disease rather than symptoms.

## 23.8 Research Directions

The above evaluation research shows that there is still plenty of room for IR systems to improve their abilities. In addition, there will be new challenges that arise from growing amounts of information, new devices, and other new technologies.

There are also other areas related to IR where research is ongoing in the larger quest to help all involved in biomedicine and health—including patients, clinicians and researchers—to better apply knowledge to improve health. ■ Figure 23.7 shows this author’s “funnel” by which the user searches all of the scientific literature using IR systems to obtain a set of possibly relevant literature. In the current state of the art, he/she reviews this literature by hand, selecting which articles are definitely relevant and may become “actionable knowledge” that can be acted upon to make better decisions.

Our ability to carry out the activities in the upper part of the funnel, i.e., IR, is much better than those in the lower part. These areas include:

- **Information extraction and text mining**—usually through the use of natural language processing (NLP, see ► Chap. 8) to extract facts and knowledge from text (K. Cohen and Demner-Fushman 2014). These techniques are often employed to extract information from the EHR, with a wide variety of accuracy as shown in a systematic review (Stanfill et al. 2010).
- **Summarization**—providing automated extracts or abstracts summarizing the content of longer documents (Fiszman et al. 2004; Mani 2001). In recent years, these methods have been applied to text and other data in the EHR (Pivovarov and Elhadad 2015).

■ **Fig. 23.7** Funnel of knowledge discovery, showing how an information need starts with a search (information retrieval) leading to a large possibly relevant set of literature that is winnowed down to a smaller definitely relevant set (usually by human inspection but with techniques like information extraction and text mining possibly automating the process in the future). Ultimately actionable knowledge is obtained that can be applied by a human or fashioned into, for example, rules for a computer-based decision support system

- **Question-answering**—going beyond retrieval of documents to providing actual answers to questions, as exemplified by IBM’s Watson system (Ferrucci et al. 2010). Watson has been evaluated for answering questions on medical board exams (Ferrucci et al. 2012) as well as making cancer treatment recommendations (Somashekhhar et al. 2018).

## 23.9 Digital Libraries

Discussion of IR “systems” thus far has focused on the provision of retrieval mechanisms to access online content. Even with the expansive coverage of some IR systems, such as Web search engines, they are often part of a larger collection of services or activities. An alternative perspective, especially when communities and/or proprietary collections are involved, is the **digital library**. Digital libraries share many characteristics with “brick and mortar” libraries, but also take on some additional challenges. Borgman (1999) noted that libraries of both types elicited different definitions of what they actually are, with researchers tending to view libraries as content collected for specific communities and librarians alternatively viewing them as institutions or services. Lindberg and Humphreys (2005) laid out a vision in 2005 for libraries 10 years hence, noting that while collections would be virtual and accessed in many diverse ways, other elements of science would stay intact, including journals and the peer review process.

This section provides an overview of key issues of digital libraries, with an orientation toward biomedical libraries.

### 23.9.1 Functions and Definitions of Libraries

The central function of libraries is to maintain collections of published literature. They may also store unpublished literature in archives, such as letters, notes, and other documents. The general focus on published literature has implications. One of these is that, for

the most part, quality control can be taken for granted. Until recently, most published literature came from commercial publishers and specialty societies that had processes such as peer review, which, although imperfect, allowed the library to devote minimal resources to assessing their quality. While libraries can still cede the judgment of quality to these information providers in the Internet era, they cannot ignore the myriad of information published only on the Internet, for which the quality cannot be presumed.

Other functions of libraries besides maintaining collections include cataloging and classification of items in those collections, being a place (even virtual) where individuals could go to get assistance with information seeking, and providing space for work or study, particularly in universities.

The paper-based nature of traditional libraries carried a number of assumptions that are challenged in the digital era. For example, items were produced in multiple copies, freeing the individual library from excessive worry that an item could not be replaced. In addition, items were fairly static, simplifying their cataloging. With digital libraries, this status quo is challenged. There is a great deal of concern about archiving of content and managing its change when fewer “copies” of it exist on the file servers of publishers and other organizations. A related problem for digital libraries is that they do not own the “artifact” of the paper journal, book, or other item. This is exacerbated by the fact that when a subscription to an electronic journal is terminated, access to the entire journal is lost; that is, the subscriber does not retain accumulated back issues, as was taken for granted with paper journals.

### 23.9.2 Access

Probably every Web user is familiar with clicking on a Web link and receiving an error message that a page cannot be found. Digital libraries and commercial publishing ventures need mechanisms to ensure that documents have persistent identifiers so that when the

document itself physically moves, it is still obtainable. The original architecture for the Web envisioned by the Internet Engineering Task Force was to have every **uniform resource locator (URL)**, the address entered into a Web browser or used in a Web hyper-link, linked to a **uniform resource name (URN)** that would be persistent (Sollins and Masinter 1994). The combination of a URN and a URL, a **uniform resource identifier (URI)**, would provide persistent access to digital objects. However, no publicly available resource for resolving URNs and URIs was ever implemented on a large scale.

One approach that has seen widespread adoption by publishers, especially scientific journal publishers, is the **digital object identifier (DOI)**<sup>66</sup> (Paskin 2006). The DOI has recently been given the status of a standard by the NISO with the designation Z39.84. The DOI itself is relatively simple, consisting of a prefix that is assigned by the International DOI Foundation (IDF) to the publishing entity and a suffix that is assigned and maintained by the entity. For example, the DOI for articles from the Journal of the American Medical Informatics Association have the prefix 10.1197 and the suffix jamia.M####, where #### is a number assigned by the journal editors. Publishers are encouraged to facilitate resolution by encoding the DOI into their URLs in a standard way, e.g., ► <https://doi.org/10.1197/jamia.M0996> for a paper cited earlier in the chapter (Hersh et al. 2002).

### 23.9.3 Interoperability

---

As noted throughout this chapter, metadata is a key component for accessing content in IR systems. It takes on an additional value in the digital library, where there is desire to allow access to diverse but not necessarily exhaustive resources. One key concern of digital libraries is **interoperability** (Besser 2002). That is, how can resources with heterogeneous metadata be accessed? Arms et al. note that

three levels of agreement must be achieved in digital libraries:

1. Technical agreements over formats, protocols, and security procedures
2. Content agreement over the data and the semantic interpretation of its metadata
3. Organizational agreements over ground rules for access, preservation, payment, authentication, and so forth

### 23.9.4 Intellectual Property

---

**Intellectual property** issues are a major concern in digital libraries. Intellectual property is difficult to protect in the digital environment because although the cost of production is not insubstantial, the cost of replication is near nothing. Furthermore, in circumstances such as academic publishing, the desire for protection is situational. For example, individual researchers may want the widest dissemination of their research papers, but each one may want to protect revenues realized from synthesis works or educational products that are developed. The global reach of the Internet has required that intellectual property issues be considered on a global scale. The World Intellectual Property Organization (WIPO)<sup>67</sup> is an agency of the United Nations devoted to developing worldwide policies, although understandably, there is considerable diversity about what such policies should be.

### 23.9.5 Preservation

---

Another function of libraries of all types is preservation of materials. In paper-based libraries, the goal of preservation was the survival of the physical object, i.e., the book, journal, image, etc. that could become lost, stolen, or deteriorated. Preservation issues in digital libraries are somewhat different. Digital libraries still do need to be concerned with physical survival of the information. Lesk compared the longevity of digital materials (Lesk 2005). He noted that the longev-

---

66 ► <http://www.doi.org/>

67 ► <http://www.wipo.int/portal/en/index.html>

ity for magnetic materials was the least, with the expected lifetime of magnetic tape being 5 to 10 years. Optical storage has somewhat better longevity, with an expected lifetime of 30 to 100 years depending on the specific type. Ironically, paper has a life expectancy well beyond all these digital media. Rothenberg noted that the Rosetta Stone, which provided help in interpreting ancient Egyptian hieroglyphics and has survived over 20 centuries (Rothenberg 1999). He reiterated Lesk's description of the reduced lifetime of digital media in comparison with traditional media, and to note another problem familiar to most long-time users of computers, namely, data can become obsolete not only owing to the medium, but also as a result of data format. Both authors noted that storage devices as well as computer applications, such as word processors, have seen their formats change significantly over the last couple of decades.

The US Library of Congress has devoted considerable effort to digital preservation, documenting its efforts on the Web site.<sup>68</sup> An early digital preservation effort in the US was National Digital Information Infrastructure Preservation Program (NDIIPP) of the Library of Congress, which has now become the National Digital Stewardship Alliance (NDSA)<sup>69</sup> and is housed by the Digital Library Federation (DLF), at the Council on Library and Information Resources (CLIR). Other digital preservation efforts include Portico,<sup>70</sup> a collaboration of publishers, libraries, and government agencies to preserve electronic scholarly content and LOCKSS (Lots of Copies Keep Stuff Safe),<sup>71</sup> which provides libraries with digital preservation tools and support.

### 23.10 Future Directions for IR Systems and Digital Libraries

There is no doubt that considerable progress has been made in IR and digital libraries. Seeking online information is now done routinely not only by clinicians and researchers, but also by patients and consumers. There are still considerable challenges to make this activity more fruitful to users. They include:

- How do we lower the effort it takes for clinicians to get to the information they need rapidly in the busy clinical setting?
- How can researchers extract new knowledge from the vast quantity that is available to them?
- How can consumers and patients find high-quality information that is appropriate to their understanding of health and disease?
- Can the value added by the publishing process be protected and remunerated while making information more available?
- How can the indexing process become more accurate and efficient?
- Can retrieval interfaces be made simpler without giving up flexibility and power?
- Can we develop standards for digital libraries that will facilitate interoperability but maintain ease of use, protection of intellectual property, and long-term preservation of the archive of science?

A vision for open science from the National Academies of Medicine, Science, and Engineering.

### ? Questions for Discussion

1. With the advent of full-text searching, should the National Library of Medicine abandon human indexing of citations in MEDLINE? Why or why not?
2. Explain why you think open-access publishing will succeed or not.
3. How would you aggregate the clinical evidence-based resources described in the chapter into the best digital library for clinicians?
4. Devise a curriculum for teaching clinicians and patients the most important points about searching for health-related information.
5. Find a consumer-oriented Web page and determine the quality of the information on it.
6. What are the limitations of recall and precision as evaluation measures and what alternatives would improve upon them?
7. Select a concept that appears in two or more clinical terminologies and demonstrate how it would be combined into a record in the UMLS Metathesaurus.
8. Describe how you might devise a system that achieves a happy medium between protection of intellectual property and barrier-free access to the archive of science.

### Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What are the key motivations for clinical decision support?
- What are typical design considerations when building a decision-support system?
- What are some ways in which developers of decision-support systems encode and represent clinical knowledge?
- What are some current standards in the HIT industry that facilitate the construction of decision-support applications?
- What are the current main areas of research and development in clinical decision-support systems?

In this chapter, we discuss information technology aimed at furnishing **clinical decision support** (CDS) – the process that “provides clinicians, staff, patients, or other individuals with knowledge and person-specific information, intelligently filtered or presented at appropriate times, to enhance health and health care” (Osheroff et al. 2007). CDS systems (often referred to as **CDSSs**) communicate information that takes into consideration the particular clinical context, offering situation-specific information and recommendations. Generally, we think of such systems as reasoning about the clinical situation and presenting their conclusions as recommendations to the user. **Information retrieval** systems that find relevant information from repositories of documents with high relevance to a specific patient and clinical context can also serve in this role, but do not themselves make patient-specific recommendations for care. CDS systems do not directly perform clinical decision making; they provide relevant knowledge and analyses that enable the ultimate decision makers—clinicians, patients, and health-care organizations—to develop more informed judgments; hence the importance of the word “support” in the term “CDS”. (Closed-loop systems such as in implantable cardioverter defibrillators and other devices

such as insulin pumps are exceptions to this model; decision support for these systems is not covered in this Chapter.) Ideally, CDSSs can be described in terms of the five *rights* that they aim to accomplish: “provide the right information, to the right person, in the right format, through the right channel, at the right point in workflow, to improve health and health-care decisions and outcomes” (Osheroff et al. 2012).

Systems that provide CDS may be considered in terms of three basic categories: (1) those that use information about the current clinical context to retrieve highly relevant online documents, as with so-called “**Infobuttons**” (introduced in ► Chap. 14); (2) those that are **intelligent systems** that provide patient-specific, situation-specific alerts, advice, reminders, physician order sets, or other recommendations for direct action; or (3) those that organize and present information in a way that facilitates problem solving and decision making, as in **dashboards**, graphical displays, documentation templates, structured reports, and order sets.

Systems that create order sets offer an ideal example of CDS, not only because they can facilitate decision making by providing an actionable set of recommendations such as a combination of orders, but also because they provide a mnemonic function by gathering together items that should be associated in a particular setting. Order sets also can enhance workflow by providing a means to select a group of relevant activities quickly. Not all CDS systems have the ability to optimize workflow, as we shall discuss. In fact, some CDS systems are subject to concern if they are poorly implemented, as they actually can impede workflow or usability.

This chapter provides a review of computer-based decision aids, emphasizing their role and adoption within the current health-care milieu of the United States while keeping an eye on global trends. It offers some thoughts on the nature of the decision-making process, then it provides a description of current implementation strategies and challenges, and it closes with a discussion of critical research questions

that must be addressed to ensure optimal effectiveness of CDS in clinical practice.

## 24.1 The Nature of Clinical Decision Making

If you ask lay people what the phrase “computers in medicine” means, they often describe a computer program that helps physicians to make diagnoses. Although computers play numerous important clinical roles, people have recognized, from the earliest days of computing, that computers might support health-care workers by helping these people to sift through the vast collections of possible diseases, findings, and treatments.

We can view nearly all the contents of this book as addressing clinical data and clinical decision making. In ► Chap. 2, we discussed the central role of accurate, complete, and relevant data in supporting the decisions that confront clinicians and other health-care workers. In ► Chap. 3, we described the nature of good decisions and the need for clinicians to understand the proper use of information if they are to be effective and efficient decision-makers. In ► Chap. 4 we introduced the cognitive issues that underlie clinical decision-making and that influence the design of systems for decision support. Subsequent chapters have mentioned many real or potential uses of computers to assist with such decision-making. Medical practice *is* medical decision-making, so most applications of computers in health care are intended to have a direct or indirect effect on the quality of health-care decisions. In this chapter, we bring together these themes by concentrating on methods and systems that have been developed specifically to assist health workers in making decisions.

By now, you are familiar with the range of clinical decisions. The classic problem of **diagnosis** (analyzing available data to determine the pathophysiologic explanation for a patient’s symptoms) is only one of these. Equally challenging, as emphasized in ► Chaps. 3 and 4, is the **diagnostic process**—deciding which questions to ask, tests to order, or procedures to

perform, and assessing the value of the results that can be obtained in relation to associated risks or financial costs. Thus, diagnosis involves deciding not only what is true about a patient, but also what data are needed to determine what is true. Even when the diagnosis is known, there often are challenging **management** decisions that test the physician’s knowledge and experience: Should I treat the patient or allow the process to resolve on its own? If treatment is indicated, what should it be? How should I use the patient’s response to therapy to guide me in determining whether an alternate approach should be tried or, in some cases, to question whether my initial diagnosis was incorrect after all? (In that sense, the response to treatment is also a type of diagnostic test.) Also, when a clinician and a patient are faced with alternative treatments, and they seek help to choose among them, the estimation of the chance for cure or the risk of death or of complications is an important decision-making activity. Lastly, many disease processes evolve over time, and evaluation and change in treatment must evolve with them, resulting in the need for guidelines for management that take into account the temporal aspects of prior states and activities in order to decide what to do next. Decision making also may involve integrating data from multiple providers, treatments, and responses to them, as well as increased use of personal sensors and apps to provide additional data, so that aspects of care coordination over time play an important role. This is beyond our scope, but the topic is addressed in part in ► Chaps. 21, 22 and 23.

Biomedicine is also replete with decision tasks that do not involve specific patients or their diseases. Consider, for example, the biomedical scientist who is using laboratory data to help with the design of her next experiment or the hospital administrator who uses management data to guide decisions about resource allocation in his hospital. In addition, new financial models for health-care payment or reimbursement based on value (roughly, patient outcomes and cost of care), rather than on fee-for-service calculations based on individual patient care activities, require that decisions be made on the basis of aggregate

data on outcomes for groups of patients to determine expected norms and to identify outliers. Although we focus on systems to assist with clinical decisions in this chapter, we emphasize that the concepts discussed generalize to many other problem areas as well. In ► Chap. 29, for example, we examine the need for formal decision techniques and tools in creating health policies. As we develop databases that can identify patients with specific diseases, with risks of complications, or in need of specific interventions such as screening tests or immunizations (see ► Chap. 18), **population management** can be used to provide a form of decision support for groups of patients. Some clinical decision support is also aimed directly at patients, in terms of alerts, reminders, or aids to interpretation of information, especially given increasing use of smartphone apps and connected sensors and devices; techniques for assessing prognosis and risk of alternative strategies should involve shared decision making between providers and patients, which is also an important area of activity.

In this chapter, we focus on decision aids for the provider in particular—the clinician seeing the patient at the point of care. The requirements for excellent decision-making fall into three principal categories: (1) accurate data, (2) pertinent knowledge, and (3) appropriate problem-solving, or clinical reasoning, skills.

The data about a patient must be adequate—both accurate and sufficiently comprehensive to include everything relevant for making an informed decision—but they must not be excessive (see ► Chap. 4). Indeed, a major challenge occurs when decision-makers are bombarded with so much information that they cannot process and synthesize the information intelligently and rapidly (see, for example, ► Chap. 21). Thus, it is important to know when additional data will confuse rather than clarify and when it is imperative to use tools (computational, visual, or otherwise) that permit data to be summarized for easier cognitive management (see ► Chap. 4). Operating rooms and intensive-care units are classic settings in which this problem arises; patients are monitored extensively, numerous

data are collected, and decisions often have to be made on an urgent basis.

Access to data from all relevant sources is required but difficult to achieve in practice. Patients may be seen in different venues, including a primary care office (perhaps via a telecare visit), a specialist office, an emergency room, a laboratory or imaging facility, a hospital, an extended care facility, or they may be monitoring themselves at home. Each venue may be using different and incompatible EHRs or data repositories, terminologies, and data representation models. Access to these data and interoperability across data repositories may be limited. Typically, the data available are only those within a health system and its EHR—which may include affiliated office practices, clinics, emergency rooms, and hospitals, or by interaction with an available **health information exchange** (HIE) (see ► Chap. 15).

Equally important is the quality of the available data to input to a CDSS. In ► Chap. 2, we discussed imprecision in terminology, illegibility and inaccessibility of records, and other opportunities for misinterpretation of data. Similarly, measurement instruments or recorded data may simply be erroneous; use of faulty data can have serious adverse effects on patient-care decisions. Thus, clinical data often need to be validated.

Even good data are useless if we do not have the knowledge necessary to apply them properly. Decision-makers must have broad knowledge of medicine, in-depth familiarity with their area of expertise, and access to pertinent additional information resources. Their knowledge must be accurate, with areas of controversy well understood and questions of personal choice well distinguished from those where a more prescriptive approach is appropriate. Their knowledge must also be current; in the rapidly changing world of medicine, facts decay just as certainly as dead tissue does.

Good data and an extensive factual knowledge base still do not guarantee a good decision; good problem-solving skills are equally important. Decision-makers must know how to set appropriate goals for a task, how to reason about each goal, and how to make explicit

the trade-offs between costs and benefits of diagnostic procedures or therapeutic maneuvers. Skilled clinicians draw extensively on personal experience, and new physicians soon realize that good clinical judgment is based as much on an the ability to reason effectively and appropriately about what to do as it is on formal knowledge of the field or access to high-quality patient data. Thus, clinicians must develop a strategic approach to the selection and interpretation of diagnostic tests, understand ideas of sensitivity and specificity, and be able to assess the urgency of a situation. Similar issues relating to test or treatment selection, in terms of costs, risks, and benefits, must be understood. Awareness of biases and of the ways that they can creep into problem-solving also are crucial (see ► Chap. 3). Also, as noted above, patient preferences and concerns must be adequately addressed as part of the decision-making process. Thus, good communication and interaction with the patient is essential. This brief review of issues central to clinical decision-making serves as a fitting introduction to the topic of computer-assisted decision-making: Precisely the same topics are pertinent when we develop a computational tool for CDS. The program must have access to good data, it must have extensive background knowledge encoded for the clinical domain in question, and it must embody an intelligent approach to problem-solving that is sensitive to requirements for proper analysis, appropriate cost–benefit trade-offs, and efficiency.

## 24.2 Motivation for Computer-Based CDS

---

Since the 1960s, workers in biomedical informatics have been interested in CDS systems because of a desire both to improve health care and to understand better the process of medical decision-making. Building a computer system that attempts to process clinical data to offer situation-specific advice can provide insight into the nature of medical problem solving and can enable the creation

of formal models of clinical reasoning. At the same time, construction of such systems offers obvious societal benefits if the computer programs can aid practitioners in their care of patients and can lead to better clinical outcomes. Although the more academic considerations have provided strong motivation for work in the area of computer-based decision aids over several decades, the recognition of the importance of CDSSs as practical tools has increased markedly in recent years as a result of the inexorable growth in health-care complexity and cost, as well as the introduction of new health-care legislation, regulatory initiatives, and payment incentives aimed at addressing these trends—which have all made the development and broad adoption of CDS technology a priority.

The twenty first century has seen changes in health-care practices that make the development of CDS technology particularly necessary. Computer-based CDS has taken on increasing urgency for four reasons: (1) increasing challenges related to knowledge and information management in clinical practice, thus increasing physician information needs, (2) the ubiquity of electronic medical records and the desire to enhance health care through the communication and integration of the relevant data, (3) the goal of delivering increasingly personalized health-care services—tailored to the patient’s preferences for care and to his or her individual genome, and (4) the growing evidence that CDS can not only improve the quality of care delivered but also reduce costs of care. We consider these four reasons in the sections that follow.

We note another factor that is shaping new directions for CDS which we will explore further at the end of this chapter—the trend toward use of personal devices and apps, as well as more portable, distributed laboratory or analytic procedures, to provide a growing range of sources of data to incorporate into decision making. These devices and apps also provide an ability to track, monitor, and intervene early whenever needed, both interacting with the user/patient directly, and also for those conditions warranting it, with the provider.

### 24.2.1 Physician Information Needs and Clinical Data Management

---

Modern health care is characterized by an ever-expanding knowledge base of clinical medicine, and by a growing clinical data base describing every patient characteristic from phenotype to genotype (Kohn et al. 2002). Despite the growing amounts of data and knowledge with which physicians need to work, health-care practitioners have seen the average time for a clinical encounter steadily curtailed, particularly in the United States, where the pressures of the prevalent fee-for-service reimbursement system and a concomitant rise in the amount of paperwork required for administrative management and billing continue to squeeze practitioners (Baron 2010). Studies of information needs among physicians in clinical practice have long revealed that unanswered clinical questions are common in ambulatory clinical encounters, with as many as one or two unanswered clinical questions about diagnosis, therapy, or administrative issues arising in every visit (Covell et al. 1985). Prior to the broad adoption of EHRs, in as many as 81% of clinical encounters in ambulatory care, clinicians were found to be missing critical information, with an average of four missing items per case (Tang et al. 1994, 1996). Currently, even with an EHR, providers may face major challenges in accessing relevant information, acquiring a complete picture of the patient's clinical state and history, and knowing what further testing or therapeutic actions are best to take. Prior to broad EHR adoption, studies suggested that as many as 18% of medical errors might be due to inadequate availability of patient information (Leape 1994). Today, conversely, the overabundance of information in the EHR can lead to 'information chaos' and may make it difficult for the clinician to find relevant information for clinical decision making (Melnick et al. 2019; Beasley et al. 2011). The demands for increased information management – in the setting of an ever-

expanding clinical knowledge base, and now as more data sources are available and use of EHRs is almost ubiquitous – are primary drivers for the adoption of CDS systems. (See ► Chap. 23 for a deeper discussion of physician information needs.)

### 24.2.2 EHR Adoption and Integration of CDS

---

The motivations for adoption of EHRs and CDS are affected by the way in which health care is financed and paid for, by the structure and organization of the health-care system of a nation or a region, and by political forces that can create constraints, regulations, and incentives. In this section, we use the United States as an example to demonstrate these influences.

Health-care safety and quality concerns, coupled with a seemingly inexorable rise in health-care costs, have led in the United States to a variety of cost-containment and quality-improvement strategies in recent years. Health-care delivery in the United States is in the midst of a profound transformation, in part due to Federal public policy efforts to encourage the adoption and use of health information technology (HIT). The American Recovery and Reinvestment Act (ARRA) of 2009, and the **HITECH regulations** within it, created incentives for the widespread adoption of health information technologies (Blumenthal 2009; see ► Chap. 29). These public policy efforts, while ultimately suffering some reversals for political reasons, are often viewed as a long-term adjunct to current health-care-payment reform efforts in the U.S., and a prelude to additional health-care-delivery redesign, payment reform, and cost containment. As recently as 2012, only 34.8% of physicians in ambulatory practice in the US used a basic or comprehensive electronic medical record (Decker et al. 2012), and only 26.6% of U.S. hospitals used health information technologies in inpatient care-delivery settings (DesRoches et al. 2012), although these numbers have had a rapid upward trajectory.

The ARRA and HITECH policies, and the resulting technology adoption, changed the practice of medicine and clinical care delivery in both beneficial and untoward ways (Sittig and Singh 2011).

To achieve meaningful and effective use of HIT, the software must be viewed as one component of a complex sociotechnical system, in which all elements must work effectively (Institute of Medicine 2011a). The movement toward value-based reimbursement, a more recent U.S. trend, encourages emphasis on wellness, prevention, and early intervention in disease processes, and requires a new level of connectivity, continuity, and coordination of care across multiple venues is gaining in acceptance. A prominent example is the advent of Accountable Care Organizations (ACOs; McClellan 2015), which require emphasis on not only integration of data from all sources (clinical and financial) but also aggregate, population-based data on outcomes, costs, and identification of outliers. These alternative payment models are distributing upside and downside financial risk based upon quality outcomes, patient experience, and costs, and thus call for CDSSs to support both payers and providers.

One of the principal motivations for EHR adoption is to provide an infrastructure with which to improve the quality, safety, and efficacy of health-care delivery. In the past decade, the U.S. government placed considerable emphasis on the adoption of quality measures and quality-reporting requirements as part of meaningful use of HIT (Clancy et al. 2009; Institute of Medicine 2011a). Quality measures, despite their ability to provide feedback that stimulates improved performance by the clinician, are only part of the process needed to make the desired improvements. Prospective, proactive clinical decision support must also be in place. The U.S. government's rules for **meaningful use** of HIT, which became progressively more demanding over a 4–6 year period, required only minimal CDS compliance in phase I and II, but Phase III of the meaningful use regulations in 2016 was intended to increase the mandate for CDS in EHR systems substantially by requiring APIs (application program interfaces) for access to

EHR data (Blumenthal and Tavenner 2010; Adler-Milstein et al. 2017). More recently, the Medicare Access and CHIP Reauthorization Act of 2015 (MACRA),<sup>1</sup> the Twenty-first Century Cures Act of 2016 in the United States,<sup>2</sup> and other initiatives have promoted a wide array of additional enhancements and improvements to the use of health information technology in clinical practice. Notably, the Twenty-first Century Cures Act removed from U.S. Food and Drug Administration (FDA) consideration as a medical device software devoted to performing the functions of an EHR, administrative tools, or providing clinical decision support. Significant push-back to the burden on both EHR vendors and on health-care organizations to comply with Meaningful Use Phase III resulted in relaxation of these constraints. Meaningful Use regulations have been superseded in the United States by the Cures Act, promoting more sweeping goals for interoperability and access to quality measures (Sinsky and Privitera 2018; see ► Chap. 29). More recently, political considerations regarding health-care financing in the United States have made the speed of adoption of such measures somewhat uncertain.

From a more worldwide perspective, interoperability of data and of CDS knowledge models are essential for wide adoption, as well as for improving the evidence base from which knowledge is derived.

### 24.2.3 Precision Medicine

The fundamental model for the practice of medicine has undergone dramatic change in the past century or so. The objectives of clini-

cal care have shifted radically from the archaic goal of correcting putative imbalances of bodily humors to the scientific understanding of pathophysiology, of mechanisms for eliminating pathogens, and of remedying biological aberrancies. The resulting view of medicine as the application of biological principles was at the core of the report produced by Abraham Flexner (1910) that upended medical education in the early twentieth century and that had led to the **reductionist biomedical model** that prevailed for the rest of that century. More recently, however, George Engel's **biopsychosocial model** (Engel 1977) brought to the fore of clinical care the need to address psychological and social factors in clinical treatment plans in addition to underlying biomedical problems. By the end of the twentieth century, it became increasingly accepted that CDS requires not only the rapid communication of appropriate scientific medical knowledge, but also the adaptation of that knowledge to reflect the psychological and social situation that would temper the application of the knowledge. Added to this complexity is the aging of the population, owing in part to advances in health and health care. The result has been a much higher burden of chronic diseases, multiple diseases, and multiple testing and treatment options, with both their positive and negative consequences that must be balanced—all contributing to the increasing intricacy of care. Indeed, the view of care is so complex for some patients that a major role of CDS is to integrate models of patient state and context (provider, setting, specialization, and activity) to provide selective visualization, analysis, and decision-making support for optimal care management (Greenes et al. 2018).

As a further extension of these trends, the genomic era in which we now live has further increased the need for clinical practice to reflect **precision medicine** and the need to tailor care to individual factors in ways that never before were imaginable (Ginsburg and Willard 2009). Precision medicine is characterized by decision making that may take into account patient personal history, family history, social and environmental factors, along with genomic data and patient preferences

regarding their own care (see ► Chap. 26). In this approach, clinical decision making is explicitly patient-centered in new ways, bringing the best evidence at the genetic level to bear on many clinical scenarios, while incorporating patient preferences for acquiring and applying genetic information (Fargher et al. 2007; Marcial et al. 2018). The increasing use of genomics in medicine (Chan and Ginsburg 2011) is generating data that outstrip the information and knowledge-processing capabilities of practitioners, and many clinicians feel threatened by the impending tsunami of additional knowledge that they will need to master (Baars et al. 2005). As precision medicine becomes the norm, primary-care and specialist practitioners alike will need to manage their patients by interpreting genomic tests along with myriad other data at the point of care. It is hard to imagine how clinicians will manage to perform such activities without substantial computer-based assistance. Informatics is well suited to support a personalized approach to clinical genomics (Ullman-Cullere and Mathew 2011).

As mentioned earlier, another related change is growing recognition of the importance of promoting optimal health and wellness, not just by treating disease but by encouraging healthy lifestyles, fostering compliance with health and health-care regimens, and carrying out periodic health-risk assessments. Key to prescriptive medicine are tools to support *prospective medicine* (Langheier and Snyderman 2004)—assisting the acquisition of a detailed family history, social history, and environmental history, using personal apps and sensors, providing health-risk assessments, and managing genomic information (Hoffman and Williams 2011; Overby et al. 2010).

#### 24.2.4 Savings Potential with Health IT and CDS

CDS has been shown to influence physician behavior (Colombet et al. 2004; Lindgren 2008; Schedlbauer et al. 2009), diagnostic test ordering and other care processes (Bates and Gawande 2003; Blumenthal and Glaser

2007), and the costs of care (Haynes et al. 2010), and it may have a modest impact on clinical outcomes (Bright et al. 2012). While there is enormous promise for HIT and CDS, their implementation is not without potential peril: HIT poorly designed or implemented, or misused, can generate unintended consequences (Ash et al. 2007; Harrison et al. 2007; Bloomrosen et al. 2011), and introduce new types of medical errors (Institute of Medicine 2011a).

Only a handful of studies have examined the **return on investment** (ROI) for HIT, and even fewer have investigated ROI for decision-support specifically. The value of CDS in terms of ROI is difficult to measure. Isolated studies of various hand-crafted systems in academic centers have shown value (Wang et al. 2003; Kaushal et al. 2006), but adoption elsewhere has often been problematic. Broad adoption has not occurred, for many reasons discussed later in this chapter, including the proprietary nature of systems for CDS and for representation of knowledge, the lack of interoperability of data and knowledge, the mismatch of CDS to workflow, and usability concerns.

Systematic reviews of the scientific literature, such as the one performed by Bright et al. (2012), have not been able to demonstrate an effect of CDS on patient outcomes except in the short term. This finding is not surprising, however, because the time point at which CDS occurs is often long before a final outcome, and many intervening factors may have a greater effect. In the case of CDS for many chronic diseases whose complications ensue over years or decades, it simply may be impractical to continue longitudinal studies of sufficiently long duration to be able to measure meaningful differences in outcome. Nevertheless, economic simulation studies of the potential effect of CDS on chronic diseases have demonstrated benefit in the long term (McClellan 2015; Bu et al. 2007; Adler-Milstein et al. 2007).

Historically, the adoption of CDS technology has been motivated by a virtuous desire to enhance the performance of clinicians when dealing with complex situations. The recent

advent of legal, regulatory, and financial drivers, as well as the increasing importance of personalizing medical decision making on the basis of genomic data, now make CDS an essential element of modern clinical practice.

### 24.3 Methods of CDS

As we have already noted, CDS systems (1) may use information about the current clinical context to retrieve pertinent online documents; or (2) they may provide patient-specific, situation-specific alerts, reminders, physician order sets, or other recommendations for direct action; or (3) they may organize information in ways that facilitate decision making and action. Category (2) largely consists of the various computer-based approaches (“classic” CDS based on the application of intelligent systems) that have been the substrate for work in informatics since the advent of applied work in probabilistic reasoning and artificial intelligence in the 1960s and 1970s. Such systems provide custom-tailored assessments or advice based on sets of patient-specific data. They may follow simple logics (such as algorithms), they may be based on decision theory and cost-benefit analysis, or they may use probabilistic approaches or derive their conclusions on the basis of machine learning from large amounts of data. Some diagnostic assistants (such as DXplain; Barnett et al. 1987) suggest differential diagnoses or indicate additional information that would help to narrow the range of etiologic possibilities. Other systems suggest a single best explanation for a patient’s symptomatology. Other systems interpret and summarize the patient’s record over time in a manner sensitive to the clinical context (Shahar and Musen 1996). Still other systems provide therapy advice rather than diagnostic assistance (Musen et al. 1996).

CDS systems can achieve their results using a wide variety of computational methods. These approaches include Bayesian probabilistic reasoning (see ► Chap. 3), the use of machine learning to make predictions based on large amounts of data (often

from the EHR), performing inference using IF–THEN rules, or by the identification of relevant templates for the clinician to fill in, such as knowledge-based groupings of physician orders (order sets), or some combination of these approaches (James et al. 2013). CDS systems may acquire the data on which they base their recommendations interactively from users or directly from a health information system (or some combination of these approaches). We now discuss the issues that drive CDS system design, and we highlight how these issues are manifest in current clinical decision aids.

### 24.3.1 Acquisition and Validation of Patient Data

---

As mentioned in the introduction to this chapter, a prerequisite to any decision-making process is having available all the data that are needed to perform the required actions. As emphasized in ► Chap. 2, few problems are more challenging than the development of effective techniques for capturing patient data accurately, completely, and efficiently. You have read in this book about a wide variety of techniques for data acquisition, ranging from keyboard entry, to speech input, to methods that separate the clinician from the computer (such as scannable forms, real-time data monitoring, and intermediaries who transcribe written or dictated data for use by computers).

The problems of data acquisition go beyond entry or extraction from the EHR, or from other repositories, of the data themselves, however. A primary obstacle is that we lack standardized ways of expressing most clinical situations in a form that computers can interpret. As discussed in detail in ► Chap. 7, there are several controlled medical terminologies that health-care workers use to specify precise diagnostic evaluations (e.g., the International Classification of Diseases and SNOMED CT), clinical procedures (e.g., Current Procedural Terminology and LOINC codes), drugs (e.g., RxNorm),

and so on. Still, there is no controlled terminology that can capture all the nuances of a patient’s history of present illness or findings on physical examination. There is no coding system that can reflect all the details of physicians’ or nurses’ progress notes. Given that much of the information in the medical record that we would like to use to drive decision support is not available in a structured, machine-understandable form, there are clear limitations on the data that can be used to assist clinician decision-making. The prose of progress notes, consultation notes, procedure or operation reports, discharge summaries, and other documents contains an enormous amount of information that never makes it to the coded part of the EHR. Nevertheless, even when computer-based patient records store substantial information only as free-text entries, the data that are also available in coded form (typically, diagnosis codes and prescription data) can be used to significant advantage (van der Lei et al. 1991).

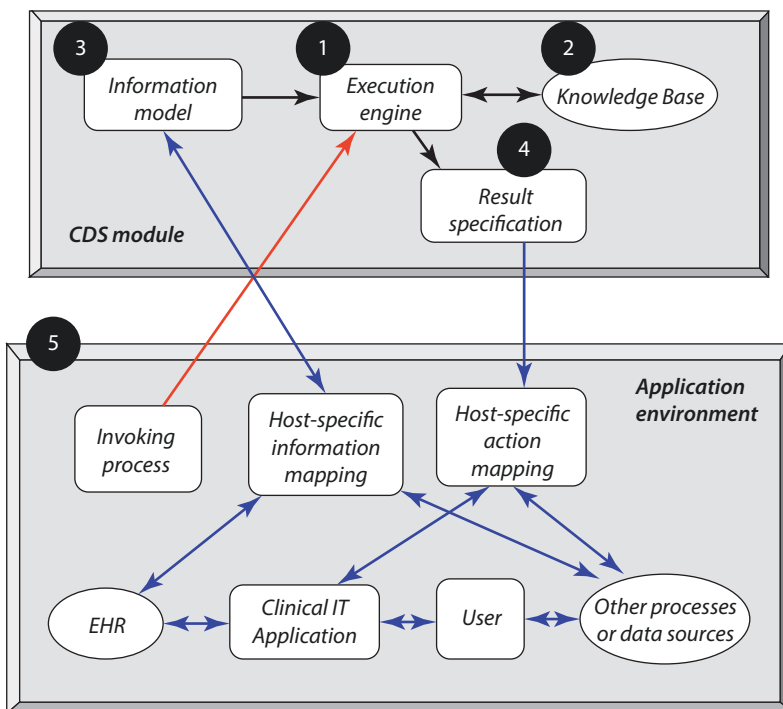

The desire to access information from the EHR that may be available only in text has been a topic of great interest to the CDS community. Some information systems provide options for **structured data entry**, asking clinicians to use fill-in-the-blanks forms or templates on the computer screen to enter patient-related information that otherwise would be entered as part of a prose note. In general, providers have resisted such human–computer interfaces, often finding it restrictive and cumbersome to make selections from predefined menus when they would much rather express themselves more freely in prose. In fact, structured templates or methods for collecting information about a particular problem or finding are themselves often regarded as a form of CDS, in that they provide an organized framework and a mnemonic function. Fortunately, work in **natural language processing** has made major advances in recent years, making it increasingly possible to mine the textual notes of EHRs to identify information that might bear on the CDS process (see ► Chap. 8).

### 24.3.2 Decision-Support Methodologies

24

When designing a CDS system, it is helpful to consider several aspects (■ Fig. 24.1). We consider these aspects as components interacting with one another, because each requires thought and effort to accomplish, and can be facilitated by developing standard, interoperable approaches for implementing them. Further, they can be independently enhanced over time, and are able to be shared and reused if engineered in a component-based manner. Much CDS can be accomplished by direct implementation and embedding into a clinical system, but the result is a set of one-off implementations that cannot be readily maintained, updated, or shared, especially of concern given that an organization may have hundreds, if not thousands, of CDSS artifacts in operation.

There are five aspects of CDS that, at least in principle, can be viewed as independent of each other, and that work together to produce CDS capability (Greenes 2014). These aspects include: (1) the method of computation or inferencing or, more generally, execution of the CDS function (e.g., targeted information retrieval, hard-coded algorithms, Bayesian estimation, neural-network classification, rule-logic evaluation); (2) the knowledge needed to carry out the function (e.g., prior and conditional probabilities, rule assertions, mathematical formulae, clinical guidelines); (3) the information model that governs how data are provided to the CDSS (i.e., the data needed and the method of encoding, such as specific FHIR data from the clinical setting, laboratory-test results encoded in LOINC, environmental data, or medical facts in specific coding schemes); (4) the type of recommendation to be provided (e.g., prediction,

■ **Fig. 24.1** A conceptual model of CDS components. There are five aspects of CDS that work together to produce CDS capability. The aspects are: (1) the method of computation or inferencing; (2) the knowledge needed to carry out the computation; (3) the information model for the data that drive decision making; (4) the type of

recommendation to be provided; and (5) how the process interacts with the application environment, including how it is invoked and how the data and recommendations are communicated. (Adapted from Greenes 2014)

action, classification, relevant citations); and (5) how the process interacts with the application environment, including how it is invoked (e.g., a process launched by an event monitor, by the user explicitly, or by being embedded in workflow) and how the data and recommendations are communicated (e.g., provided via a FHIR API or delivered as a popup alert). In this section, we focus primarily on the methods of computation required for CDS (Aspect 1 of  Fig. 24.1), and to a lesser extent on the knowledge needed during computation (Aspect 2). We consider the other elements in subsequent sections.

Aspect 1 was central to much of the early work on CDS development, beginning in the 1960s and largely led by academic centers, which focused on developing and exploring different computational models of CDS in the absence of any health IT infrastructure in which to embed the systems. In recent years, much of CDS has been built by vendors of proprietary systems, giving rise to a range of different approaches, often embedded in those systems, and with methods that are less able to be inspected, formalized, and shared. Some of the trends in health-care delivery that we cited in  Sect. 26.2 are hoped to give rise to increased interoperability and sharing in vendor-developed systems. Even if current commercial products may not manifest the different components of  Fig. 26.1 distinctly, we adopt this conceptual focus in our discussion of various strategies for CDS to clarify the underlying principles.

### 24.3.2.1 Context-Specific Information Retrieval

Early developers of CDS systems argued that decision support entails more than identifying relevant information that can help a clinician to solve a problem; it was believed that a CDS system has to suggest specifically how the problem should be solved. Thus, simply providing information for the user to read and digest was not considered “real” decision support. Nevertheless, as information-retrieval systems have improved over the years—with better performance characteristics—it is often hard to maintain that such systems do not offer decision support in a genuine sense.

Indeed, such systems are now ubiquitous in health care. ( Chap. 25 provides a comprehensive discussion of information-retrieval methods.)

The simplest, and perhaps most common, form of CDS uses contextual information from an EHR to perform information retrieval from a database of information about online documents. A person viewing data in an EHR may see selectable icons (**infobuttons**) next to the names of drugs, laboratory tests, patient problems, or other elements of the patient record, or the items themselves may be hyperlinked to an information retrieval engine. Clicking on an infobutton causes the clinical information system to perform a query on the database, providing the user with one or more immediately accessible resources that can offer more information about the item in question. Alternatively, the system may automatically query one or more of those external resources and return the results of the queries for display (Cimino et al. 2002). Clicking on an infobutton next to a drug, for example, might allow the user to access information about customary dosing, side effects, or alternative medications (see  Fig. 14.15 in  Chap. 14). The query that retrieves the links to the documents is tailored based on whatever is next to the infobutton icon on the screen. The query may also take into account contextual information, such as patient-related data, the activity in which the user is engaged, and the role of the user in the health-care enterprise (physician, nurse, patient, and so on).

An **infobutton manager** mediates the queries between the clinical information system and the available information resources. The standards development organization Health Level Seven has created a standard for “context-aware knowledge retrieval,” leading to infobutton managers that have been adopted by many commercial EHR vendors.<sup>3</sup>

3 HL7 International (2014). HL7 Version 3 Standard: Context Aware Knowledge Retrieval Application (“Infobutton”), Knowledge Request, Release 2. Retrieval February 19, 2020:  [https://www.hl7.org/implement/standards/product\\_brief.cfm?product\\_id=208](https://www.hl7.org/implement/standards/product_brief.cfm?product_id=208)

Infobutton managers need to anticipate how the clinical context might tailor the specific query performed by any given infobutton, so that the result of the query is highly precise and relevant to the situation at hand. Detailing specifically how contextual information might alter the queries performed by each infobutton type can be tedious, and the process requires developers to be adept at second-guessing all the reasons that might cause a user to click on a particular infobutton. Current research concentrates on the development of a Librarian Infobutton Tailoring Environment (LITE; Jing et al. 2015) that promises to aid the authoring of infobutton queries via “wizards” and other user-interface conveniences.

Although infobuttons are unquestionably important knowledge resources, many people would argue that they are not true CDS systems. Infobuttons retrieve relevant information for a user, but they do not explicitly address particular *decisions* that the user needs to make. The possible reasons that a user might click on an infobutton are folded into the query specification at the time that the infobutton is created; at runtime, of course, there is no way for the system to know exactly why the user selected the infobutton. Infobutton managers therefore require sophisticated query capabilities, but they do not need to reason from a clinical situation to a particular recommendation.

When the goal is to generate a situation-specific recommendation regarding diagnosis or therapy, developers need to turn to methods that can perform some kind of inference. The sophistication of the required technique is a function of the kind of inference that is necessary to render a result for the user.

#### 24.3.2.2 Organizing or Grouping Information as a CDS Method

As we have noted earlier, a valuable kind of CDS is to organize information to provide a ready collection of items that need to be considered together (e.g., order sets for particular clinical indications or settings, documentation templates for particular purposes, or structure

and formatting of reports). This capability serves not only as a convenience to the user, but also as a mnemonic function (i.e., offering a check list; Gawande 2009).

When patients are admitted to the hospital with a particular condition such as a suspected myocardial infarction or pneumonia, when hospital staff must prepare them for diagnostic procedures or surgery, or when they need to be transferred to another care team or to be discharged home, there often are stereotypical groups of medical orders that physicians tend to request. For example, patients with possible pneumonia often require a chest x-ray examination, the recording of vital signs at certain intervals, the administration of supplementary oxygen, cultures of their sputum or blood, and administration of antibiotics. When patients are admitted to a hospital with the diagnosis of pneumonia, the EHR can automatically suggest to the treating physicians that such a set of orders be considered. Systems that produce such order sets can use the clinical situation to tailor the recommended orders (e.g., the computer may not recommend a chest x-ray examination if the patient has just had one; knowledge that the patient has been placed on an artificial ventilator may trigger a separate set of associated orders for consideration).

Clinicians routinely face many other stereotypical tasks, such as describing the results of a diagnostic procedure such as an imaging study or reporting the sequence of events that took place during a surgical operation. Automated systems that recognize the clinical context can provide a tailored template for the clinician to fill in, helping to ensure that information is provided accurately and completely.

Throughout their professional activities, clinicians constantly must keep in mind large amounts of information when treating patients with even routine medical problems and reporting the results of their work. The use of simple mnemonics such as check lists can be remarkably effective in ensuring that care givers remember everything that they need to do or to report in a given context (Algaze et al. 2016; Alamri et al. 2016; Pageler

et al. 2014). Transforming such check lists into groups of orders to consider, groups of features to note in a diagnostic evaluation, or groups of steps that may have been followed when performing a surgical procedure can help clinicians to remember important details and to improve both the quality of medical care and what clinicians may report about it.

Computationally, systems that offer order sets or templates to clinicians typically assemble predefined information from collections of text strings or database entries. The HL7 organization has issued a standard for creating libraries of order sets. Systems that suggest specific order sets to users by making selections from such a library are generally embedded within the EHRs that call on their services, however. Thus, the specific methods that these systems use tend to be proprietary.

Researchers have experimented with the use of machine-learning techniques to create order sets on the fly based on empirical data. For example, Wang et al. (2018) have built a system that infers groups of orders for particular situations by examining a data warehouse for the individual orders that physicians have administered historically. The system then suggests that the groups of orders that it discerns from the database may be reasonable for clinicians to administer as an ensemble.

### 24.3.2.3 Hardcoding Clinical Algorithms

From a computational perspective, there is nothing simpler than encoding an algorithm directly in a computer program. In health care, there is generally nothing simpler than defining a decision process in terms of a flowchart. Numerous CDS systems thus have taken problem-specific flowcharts designed by clinicians and encoded them for use by a computer. Although such flowcharts have been useful for the purpose of triaging patients in urgent-care situations and as a didactic technique used in journals and books where an overview for a problem's management has been appropriate, computable interactive flowcharts have been largely rejected by physicians as too simplistic or generic for routine use (Grimm et al. 1975),

other than for particular kinds of computations such as drug dose calculations (e.g., for pediatric patients). In addition, the advantage of their implementation on computers has not been clear; the use of simple printed copies of the algorithms generally has proved adequate for clinical care (Komaroff et al. 1974). A noteworthy exception that gained enormous attention in the early 1970s was a computer program deployed in Boston at what was then the Beth Israel Hospital (Bleich 1972); it used detailed algorithmic logic to provide advice regarding the diagnosis and management of acid-base and electrolyte disorders. More recently, such branching-logic and other inference methods approaches have been widely adopted in the administrative information systems that third-party payers use to process requests to pre-certify payment for expensive services such as MRI studies and elective surgery (the HL7 Da Vinci Project is a notable body of work in this area).

Although representing clinical algorithms simply as computer code offers a very direct approach to implementing a CDSS, there are obvious challenges that occur when it becomes necessary to refine or update the program's behavior. Every modification requires reprogramming the system. It may not always be obvious how to reprogram the system to render the desired behavior and making the necessary changes in one part of the program may have unintended consequences when other parts of the program execute. Thus, although it may seem appealing simply to hardcode clinical algorithms, developers of decision support systems generally seek more flexible mechanisms to represent clinical knowledge and to reason about it. We discuss this matter further in ► Sect. 24.4.5, and we address future research directions in this area in the Conclusion.

### 24.3.2.4 Learning from Data

Considerable flexibility is achieved when the CDSS is largely data-driven. The advent of extraordinarily fast computers and the ability to process enormous amounts of data has led to an explosion of interest in the use of

large datasets to learn patterns in the data to support clinical decision making (James et al. 2013). The success of such data-driven methods has led to considerable excitement about the use of “big data” in health care. It is important to appreciate, however, that workers in biomedical informatics benefited from such approaches long before computers could manage the enormous datasets that they process today.

### Probabilistic Systems

Attempts to drive computer-based decision support from relationships inferred directly from data began during the earliest days of research in biomedical informatics. A seminal article in 1959 first introduced Bayes theorem and also value theory (later known as utility theory) into health-care decision making (Ledley and Lusted 1959). In the 1960s, workers in the field recognized that they could use computers to apply **Bayes’ rule** to determine the posterior probability of diseases based on observations of patient-specific parameters (see ► Chap. 3). Such calculations were based on the determination of appropriate probabilistic relationships between findings and diseases by analyzing available datasets. Large numbers of **Bayesian diagnosis programs** have been developed in the intervening years, many of which have been shown to be accurate in selecting among competing explanations of a patient’s disease state.

Among the most significant of the early experiments were those of F. T. de Dombal and his associates (1972) in England, who focused on the diagnosis of acute abdominal pain. De Dombal’s group used a **naïve Bayesian model** that assumed that there are no conditional dependencies among findings (i.e., a model that makes the inappropriate but convenient assumption that the presence of a finding such as upper abdominal pain never affects the likelihood of the presence of a finding such as lower abdominal pain). Using surgical or pathologic diagnoses as the gold standard, de Dombal’s group used sensitivity, specificity, and disease-prevalence data for various signs, symptoms, and test results to calculate, using Bayes’ theorem, the proba-

bility of seven possible explanations for acute abdominal pain (appendicitis, diverticulitis, perforated ulcer, cholecystitis, small-bowel obstruction, pancreatitis, and nonspecific abdominal pain). To keep the Bayesian computations manageable, the program made the “naïve” Bayesian assumptions of (1) conditional independence of the findings for the various diagnoses, (2) mutual exclusivity, and (3) exhaustiveness of the seven diagnoses (see ► Chap. 3).

In one system evaluation (de Dombal et al. 1972), physicians filled out data sheets summarizing clinical and laboratory findings for 304 patients who came to the emergency department with abdominal pain of sudden onset. The data from these sheets provided the attributes that were analyzed using Bayes’ rule. Thus, the Bayesian formulation assumed that each patient had one of the seven conditions and it selected the most likely one on the basis of the recorded observations.

In contrast to the clinicians’ diagnoses, which were correct in only 65–80% of the 304 cases (with accuracy depending on the individual clinician’s training and experience), the program’s diagnoses were correct in 92% of cases. Furthermore, in six of the seven disease categories, the computer was more likely to assign the patients to the correct disease category than was the senior clinician in charge of the case.

De Dombal’s system began to achieve widespread use—from emergency departments in other countries to the British submarine fleet. Surprisingly, however, the system never obtained the same degree of diagnostic accuracy in other settings that it did where it had initially been deployed—even when adjustments were made for differences in prior probabilities of disease. There are several reasons possible for this discrepancy, which are relevant for all Bayesian CDS systems. The most likely explanation is that there may be considerable variation in the way that clinicians interpret the data that must be entered into the computer. For example, physicians with different training or from different cultures may not agree on the criteria for identification of certain patient findings on physical

examination, such as “rebound tenderness.”<sup>4</sup> Another possible explanation is that there are different probabilistic relationships between findings and diagnoses in different patient populations.

Although a naïve Bayesian model may have limitations in accurately modeling a diagnostic problem, a major strength of this approach is computational efficiency. When the findings that bear on a hypothesis are assumed to be conditionally independent, then the order in which the findings are considered in the Bayesian analysis does not matter. The computer starts by considering a given finding, the prior probability of each possible diagnosis under consideration (generally the prevalence of each diagnosis in the population), and the conditional probabilities of the finding (or the absence of the finding) given each diagnosis (or the absence of the diagnosis)—the *sensitivity* and *specificity* of the finding (see the discussion of these concepts in ► Chap. 2). The computer then applies Bayes’ rule to calculate the posterior probability of each diagnosis given the value of the finding. The computer now is poised to update the probability of each diagnosis given the value of a second finding. The prior probability for each diagnosis in this case is not the prevalence of the diagnosis in the population, however. Having applied Bayes’ rule once, we have more information than we had at the start. We can treat the *posterior probability* of each diagnosis given the first finding as the *prior probability* of the diagnosis when we apply Bayes’ rule a second time. When it is time to consider a third finding, the posterior probability for each diagnosis after processing the second finding serves as the prior probability for the next application of Bayes rule. The process continues until the value of each finding has been considered. This **sequential Bayes** approach was explored as early as the 1960s for the diagnosis of congenital heart

disease (Gorry and Barnett 1968) and has been used in many CDS systems since.

In recent years, the use of naïve Bayesian models has been seriously challenged by the adoption of systems based on Bayesian **belief networks** (see below), which can take advantage of efficient algorithms that overcome the limiting assumptions of naïve Bayesian approaches—albeit at the cost involved in creating a more complex (and more nuanced) model of the underlying probabilistic relationships. In addition, systems that adopt the sequential Bayes approach lack the ability to choose the next test to be applied in a manner that can optimize reasoning. Bayesian systems that use more sophisticated reasoning strategies based on decision analysis (see ► Chap. 3) can use utility theory to identify the test that will provide the most useful information given the current state of reasoning. Considerations of cost, discomfort to the patient, and the availability of the test can influence the utility of the particular choice.

## Machine Learning

The availability of large biomedical datasets and computers and algorithms that can process huge amounts of data are revolutionizing health care and the life sciences. Machine learning is everywhere in health care, from interpreting radiographic images to predicting utilization of health care services to identifying potential adverse drug events. It is not surprising that decision-support based on machine-learning models is becoming increasingly common in clinical settings. Such systems have been in place for decades, but now they are assuming increasing prominence, given the new opportunities that the renaissance in machine learning is offering all of biomedicine in the era of “big data.”

There are a host of **supervised learning techniques** that can determine how data are associated with hypotheses (James et al. 2013), and that consequently can be trained on EHR data to infer conclusions based on some set of input data. For example, the decision-support capabilities of the patient monitoring systems discussed in ► Chap. 21 often apply statistical methods to the current data stream to

---

4 *Rebound tenderness* is pain that is exacerbated when the physician presses down on the abdomen and then suddenly releases, generating a “rebound” when the abdomen returns to its baseline position.

infer corresponding classifications to inform care providers of the patient's current state. Regression analysis or more sophisticated techniques, such as artificial neural networks and support vector machines, when applied to routinely collected patient data, have enabled investigators to develop venerable decision aids such as the APACHE system (Knaus et al. 1991; Zimmerman et al. 2006), which offers prediction models providing prognostic information regarding patients in the ICU (see ► Chap. 21).

Recent work demonstrates the value of applying data-driven techniques to a wide range of clinical problems for which clinicians may benefit from decision support, from assessing newborns in the ICU (Saria et al. 2010) to development of models that can suggest which patients might benefit most from palliative care (Avanti et al. 2018). Scores of start-up companies have emerged in recent years, each hoping that different large datasets and specialized machine-learning techniques will lead to new insights about particular clinical problems in an effort to enhance decision making.

From the beginning, such machine-learning approaches have been criticized when used as the basis for CDS, primarily because of the lack of transparency in how data-driven methods reach their conclusions (Shortliffe et al. 1979). Because the associations between findings and diagnoses are inferred as the system is trained on the data and are not readily available for inspection, such systems cannot offer guidance as to *why* they might reach particular conclusions. This inability to explain the basis for their recommendations is especially important when the recommendations of a system might be overly fitted to the peculiarities of a dataset drawn from a patient population different from the one to which the system is being applied (as may have been the case with de Dombal's system). Because the output of a CDSS based on a machine-learning algorithm must be accepted at face value, there is typically no way to know what biases may exist in the data that trained the system or what clinically relevant intermediary states may have led the system to reach

its final conclusion. There is currently intense interest in being able to develop new technologies powered by machine-learning methods that in some measure can explain the basis of their reasoning and that can allow users to assess the likelihood that particular recommendations are appropriate in their clinical setting (Ribeiro et al. 2016).

### 24.3.2.5 Declarative Representation of Knowledge

In simple Bayesian systems and in those CDSSs based on machine-learning algorithms, data are provided as input into the system, and the output is a classification of the data—often a diagnosis on which to act. Since the 1970s, however, workers in biomedical informatics have pursued the development of decision-support technologies that attempt to encode in a more explicit way how the inputs to the system relate to the outputs. The goal is to encode models—models of reasoning, models of pathophysiology, models of probabilistic relationships, models of the evidence in support of alternative treatment options, and other relevant models—in a way that forms the basis for a system's computation to derive an appropriate recommendation from the input data. Such systems are often built with the objective that the underlying models be examinable and explainable. Often, there is a desire to make those models editable, so that the models easily can be updated in light of new discoveries and new understanding. The unifying idea in this approach is that CDSSs are built with a computer-based representation of the knowledge that drives system behavior. There are many ways to represent knowledge in computers (Musen 2014), and each strategy has different strengths and weaknesses.

### Bayesian Belief Networks

Much of the early interest in the naïve, sequential Bayesian approach stemmed from a conviction that it simply was impractical to construct Bayesian systems in which the assumption of conditional independence was lifted: There would be too many probabilities to assess when building the system, and the necessary computation could be intractable.

Work on the use of **belief networks**, however, has demonstrated that it actually is realistic to develop more expressive Bayesian systems in which conditional dependencies are modeled explicitly—often by taking advantage of approximate algorithms for concluding the posterior probabilities that are computationally efficient in most cases. (Belief networks are described in detail in ► Chap. 3.) Currently, many modern CDS systems that make recommendations based on probabilistic relationships use belief networks as their primary representation of the underlying clinical situation, and then “solve” the belief network at runtime to calculate the posterior probabilities of the conditions represented in the graph. The use of belief networks is popular because the formalism makes probabilistic relationships perspicuous, overcomes the assumption of conditional independence, and enables the attendant probabilities to be learned from analysis of appropriate data sets (for example, EHR data). The approach has been demonstrated in numerous diagnostic systems, from belief networks that ascertain the status of newborns from data in the neonatal ICU (Saria et al. 2010), systems for differential diagnosis (Shwe et al. 1991; Middleton et al. 1991), to belief networks that offer interpretations of biomedical image data (Kahn et al. 1997).

Because making most decisions in medicine requires weighing the costs and benefits of actions that could be taken in diagnosing or managing a patient’s illness, researchers also have developed tools that draw on the methods of **decision analysis**. Decision analysis adds to Bayesian reasoning the idea of explicit decisions and of **utilities** associated with the various outcomes that could occur in response to those decisions (see ► Chap. 3). One class of programs for decision-analysis is designed for use by the analysts themselves; such programs are of little use to the average clinician or patient, however (Pauker and Kassirer 1981). A second class of programs uses decision-analysis concepts within systems designed to advise physicians who are not trained in these techniques. In such programs, the underlying decision models gener-

ally have been prespecified—either as decision trees that enumerate all possible decisions and all possible ramifications of those decisions or as belief networks in which explicit decision and utility nodes are added, called **influence diagrams** (Shachter 1986).

We say that belief networks and influence diagrams represent knowledge in a **declarative** manner, because a belief network provides an inspectable, editable model of the probabilistic relationships that are relevant to the decision problem under consideration. If a developer wants to designate a new relationship between two entities in the network, then she needs only to augment the model by adding a new edge to the graph that encodes the given network. The network thus provides a transparent mechanism to communicate what the system “knows” about the probabilistic relationships among the entities in the application domain, and changing the network intrinsically changes the behavior of the system when it reasons about those entities. This is different from the case of a hardcoded algorithm or a system based on machine learning, where the knowledge is not readily inspectable or editable in a direct manner.

### Rule-Based Approaches

Although belief networks provide a convenient mechanism to encode knowledge about the world in a declarative fashion, they are only one of several alternative frameworks that may be used to drive CDS based on explicit models of the application area. Since the 1970s, workers in medical AI have been exploring the use of methods that emphasize the modeling of rules that describe conclusions that can be reached about the decision problem and the variables that may predicate those conclusions. Often called **knowledge-based systems**, these programs reason about the clinical situation by examining a collection of rules of the form, “If some set of conditions is true, then conclude that something else is true” (► Fig. 24.2). Although these rules may be created through machine-learning approaches, they often are built by manually encoding relationships between clinical data and corresponding conclusions that are

Rule 507

IF:

- 1) The infection that requires therapy is meningitis
- 2) Organisms were not seen on the stain of the culture
- 3) The type of infection is bacterial
- 4) The patient does not have a head injury defect, AND
- 5) The age of the patient is between 15 years and 55 years

THEN

The organisms that might be causing the infection are  
Diplococcus-pneumoniae and Neisseria-meningitidis

■ **Fig. 24.2** A rule from a rule-based system. Rules are conditional statements that indicate what conclusions can be reached or actions taken if a specified set of conditions is found to be true. This rule, taken from the CDSS known as MYCIN, is able to conclude probable bacterial causes of infection if the five conditions in the premise are all found to be true for a specific patient

offered by experts in the field or by examination of evidence reported in the scientific literature. When a knowledge-based system is encoded using rules, it is referred to as a **rule-based system** (Buchanan and Shortliffe 1984).

Rule-based systems provide an important mechanism for developers to build CDS capabilities into modern information systems. From CDS systems that interpret ECG signals to those that recommend guideline-based therapy, rules provide an extremely convenient means to encode the necessary knowledge. Rule-based systems require a formal language for encoding the rules, plus an interpreter (sometimes called an **inference engine**) that operates on the rules to generate the necessary behavior.

Perhaps the best-known rule-based CDSS is one that was never put into clinical use, but that has served as a prototype for the many rule-based systems that have followed. The program, known as MYCIN, combined a diagnostic component with an advisor component that suggested appropriate management of patients who have infections (Shortliffe 1976). MYCIN's developers believed that straightforward algorithms or probabilistic approaches were inadequate for this clinical problem in which the underlying knowledge was poorly understood and even the experts often disagreed about how best to manage specific patients, especially before definitive bacterial culture results became available. As a result, the researchers were drawn to the

use of interacting rules to represent knowledge about organisms that might be causing a patient's infection and the antibiotics that might be used to treat it.

Knowledge of infectious diseases in MYCIN was represented as *production rules* (see ■ Fig. 24.2). A production rule is an IF–THEN conditional statement. The conclusions drawn by one production rule may be used to satisfy the premises of other rules when a system of rules is used for reasoning by an inference engine. MYCIN's power was derived from such rules in a variety of ways:

- The MYCIN program determined which rules to use and how to chain them together to make decisions about a specific case. The MYCIN reasoning program used an approach called **backward chaining**; whenever a rule was being considered and the system did not know whether the condition on the left-hand side of the rule (i.e., the premise) was true, MYCIN would look backward to see whether the knowledge base contained any other rules that, when evaluated, could conclude information that might inform the evaluation of the current rule's premise. (Nearly all contemporary rule-based systems, on the other hand, use an inference method known as **forward chaining**: Whenever a production rule “fires” and the conclusion of that rule is proven to be true, the system looks forward for other rules in the rule base that use the concluded information in their premise, and that therefore also might be able to fire now that the new conclusion is known to be true.)
- The rules often formed a coherent explanation of MYCIN's reasoning—those that applied to the current decision were displayed in response to a user's questions (■ Fig. 24.3). Although rules were stored in a machine-readable format, English translations could be displayed.

By removing, altering, or adding rules, system developers could modify the program's knowledge structures rapidly, without explicitly reprogramming or restructuring other parts of the knowledge base. The rule base

In this series, how many of the cultures were positive for E.coli  
(ORGANISM-1)?

*(typical system prompt)*

**\*\*WHY**

*(request from user to determine motivation for question)*

[i.e. WHY is it important to determine the number of cultures which were  
positive for the organism?]

*(system's rephrasing of the WHY  
question, and answer)*

[1.0] This will help to determine whether there is significant disease  
associated with this occurrence of the organism.

It has already been established that

[1.1] the culture was taken from a sterile source

[1.2] the number of cultures in the series is greater than 2

Therefore, if

[1.3] the number of cultures which were positive for ORGANISM-1  
is greater than 2

Then there is suggestive evidence (.5) that there is significant disease  
associated with this occurrence of the e.coli (ORGANISM-1).

[RULE049]

**\*\*WHY**

*(repeated WHY to determine relevance of previous explanation)*

[i.e. WHY is it important to determine if there is significant disease  
associated with this occurrence of the organism?]

[2.0] This will help to determine a diagnosis for which the infection should  
be treated.

It has already been established that

[2.1] the infection is not one of: primary bacteremia, meningitis

[2.2] for some current culture of the patient it is true that the site  
of the culture is blood

Therefore, if

[2.3] there is significant disease associated with this occurrence of  
the organism

Then

It is definite (1.0) that the diagnosis for which the infection should  
be treated is secondary-bacteremia

[RULE103]

**■ Fig. 24.3** Two examples of MYCIN's explanation capabilities. User input is shown in boldface capital letters and follows the double asterisks. The system

expands each ["WHY"] question (enclosed in square brackets) to ensure that the user is aware of its interpretation of the query

thus offered the kind of inspectability and editability that we discussed when considering belief-network representations of knowledge.

The developers evaluated MYCIN's performance on therapy selection for patients with blood-borne bacterial infections (Yu et al. 1979a), and for those with meningitis (Yu et al. 1979b). In the latter study, MYCIN gave advice that compared favorably with that offered by experts in infectious diseases—results that ushered in enormous excitement about the potential of rule-based systems to offer high-level clinical advice in real-world situations.

The developers of MYCIN had to construct their own syntax for encoding rules and had to program their own inference engine to evaluate the rules. However, now there are many open-source and proprietary **rule engines** that provide custom-tailored editors for writing rules and inference engines that can execute the rules at runtime. For example, JESS is a popular Java-based rule engine that can be licensed from Sandia National Laboratory and that currently is free for academic use. Drools is an open-source rule engine developed by the JBoss community that also has had substantial adoption.

Developers use JESS, Drools, and proprietary rule engines to create CDS systems that contain multiple rules that, as with MYCIN, can chain together to generate conclusions based on a sequence of inference steps. Decision support sometimes requires multiple rules to execute at runtime, together generating a final recommendation that derives from the consequences of the rules chaining off one another.

In most installed information systems, however, rule-based decision support is much simpler and also more limited. Most deployed CDS systems have rules that generally do not chain together, but that are triggered individually, each time that either there is a relevant change to the data in a patient database that should generate an alert, there is a time-related event that should trigger a reminder, or an action is performed (e.g., by a user, when the action is established in the workflow as a triggering event). Each rule examines the state of the database and generates a corresponding action, alert, or a reminder that is usually sent to a particular clinician or to members of the health-care team. Such rules are of the general form: Event – Condition – Action (ON Event, IF Condition, THEN Perform Action) and they are commonly referred to as **ECA rules**.

For example, **Arden Syntax** became an international standard for ECA rules known as **Medical Logic Modules** (MLMs), endorsed by HL7 and ANSI in 1999 (■ Fig. 24.4). Arden Syntax provides a standard mechanism for declaring the variables about whose values the system will perform its reasoning (values that derive from data in the clinical information system); the conditions that, if true, would predicate specific actions; the actions that should be taken, and the kinds of events that would invoke or trigger the rule. The standard was created with the hope that the informatics community would develop whole libraries of MLMs, all written in Arden Syntax, that could operate in any clinical environment where an information system could interpret the standard format.

A significant obstacle to the sharing of MLMs, however, is that Arden Syntax is, in fact, just a syntax. What is missing from the

standard is any notion of the *semantics* of the data on which the MLMs operate. When an MLM executes, the variables that are used in the logic of the rule are bound to values that derive from the patient database of the information system in which the MLMs operate. Arden Syntax specifies that the individual database queries needed to determine the values of the variables should appear within the “curly braces” of variable definitions in the portion of the MLM known as the “data slot” (see ■ Fig. 24.4). What a developer should include within the curly braces depends on the particular schema of the relevant patient database and mechanism for performing queries. EHR information models and the way in which elements are coded differ from system to system. Thus, all system-specific aspects of MLM integration need to be provided within the curly braces. To adapt an MLM for use in a new environment, a programmer needs to consider the variables on which the MLM operates, determine whether those variables have counterparts in the local patient database, and write an appropriate query that will execute at runtime.

The **curly braces problem** is compounded because there may be assumptions regarding the semantics of the variables themselves that may not be obvious to the local implementer: If the MLM refers to serum potassium, should the logic be executed if the original specimen was grossly hemolyzed?<sup>5</sup> If a serum potassium value is not available in the database, but there is a value for a whole-blood potassium, should the MLM be executed using that value instead?<sup>6</sup> If there is no serum potassium value available for today, but there is one from last night, should the logic execute using the most recent value? Decision rules cannot simply be dropped from one system into another and be shared effortlessly; rather, considerable thought, analysis, and computer skill needs to go into writing the appropriate database que-

5 If the red blood cells in a specimen *hemolyze* (burst), they release potassium, which can cause an inaccurate elevation in the measured potassium value.

6 The *serum* is the liquid that is left when the cells are removed from whole blood.

 if (Diabetes\_Present and exist Foot\_Exam and Foot\_Exam occurred not within past 12 months) then  
 conclude true ;  
 endif;  
 conclude false ; ;;  
 Action: write "Patient is a diabetic with no Diabetic Foot Exam in last 12 months. Please order or perform one.";;

**Fig. 24.4** This medical logic module (MLM), written in the Arden syntax, prints a warning for health-care workers whenever a patient who has diabetes is registered for a clinic visit and has not had a documented foot examination in the past year. The evoke slot defines a situation that causes the rule to be triggered; the logic slot encodes the decision logic of the rule; the action slot

defines the procedure to follow if the logic slot reaches a positive conclusion. The data slot defines the variables that are to be used by the MLM; the text between curly braces must be translated into queries on the local patient database when the MLM is deployed locally. (Courtesy of P. J. Haug, Intermountain Healthcare, with permission)

ries that go within the curly braces to make such rules operational.

In the case of Arden Syntax, developers write rules to deal with one clinical problem at a time. There may be one MLM to deal with the problem of administering a drug like penicillin to a patient with a history of penicillin allergy; another MLM may report that a patient has a dangerously low serum potassium value. Unlike the rules in MYCIN, MLMs are generally not intended to interact with one another or to be chained together to generate complex inferences. MLMs may be coerced to chain together when one MLM posts to the patient database a value that can trigger another MLM. This mechanism also allows one MLM to set up information in the database that might invoke another MLM in the case of some future event, thus enabling the recommendation of actions that unfold over time, as in the case of many clinical practice guidelines for chronic diseases. Although this approach allows developers to program complex problem-solving behavior, the technique has the same disadvantages that came to light with chaining rule-based systems such as MYCIN: When the rule base grows to a large size, interactions among rules may have unanticipated side effects. Furthermore, when rules are added to or deleted from a previously debugged knowledge base, there may be unexpected system behaviors that emerge as a result (Clancey 1983; Heckerman and Horvitz 1986).

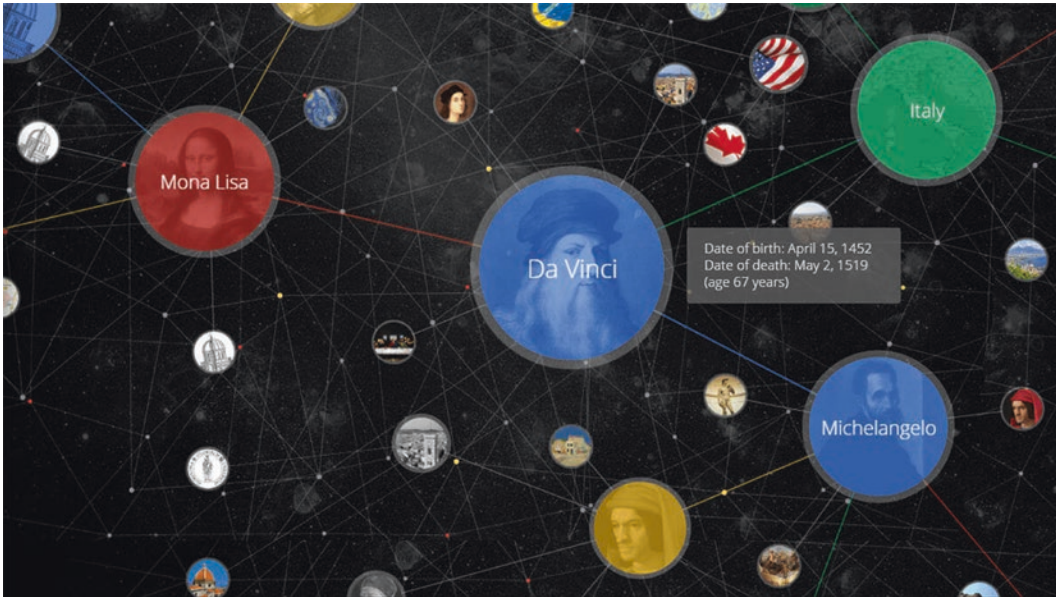

For MLMs to work well in practice, moreover, the rules need to be tailored to the particular clinical environment—triggered by appropriate workflow events, interacting with particular kinds of participants, customizing logic to account for various business and workflow processes, and notifying the user in setting-specific ways. To customize an MLM to account for such considerations requires that it become less portable. Much of the effort required to introduce CDS systems into the health-care enterprise involves precisely such adaptations. To accelerate portability, MLM developers must seek a balance between a generic specification of logic that is widely agreed upon, and site-specific customizations that will facilitate the use of that

logic. Achieving the right balance will always remain an elusive target (see also ▶ Sect. 24.5.4).

### More General Representations of Knowledge

The variety of approaches for building CDS systems that we have described so far suggests that each method has significant strengths and weaknesses. Hardcoded branching-logic systems can be very easy to build but difficult to update and maintain when the program code becomes complicated. Belief networks and influence diagrams offer precision in probabilistic reasoning when the goal is to make a classification of some clinical phenomena, but they offer limited capabilities if the goal is to generate a plan for medical therapy on the fly or to simulate some biomedical situation. Rule-based systems can help to decompose decision problems into tractable IF–THEN chunks, but they typically are limited in what these chunks can express about a clinical problem. All of these approaches are constrained in their inability to reason about clinical abstractions (e.g., knowing that elevated serum potassium is *a kind of* electrolyte abnormality) and by their inability to make inferences about situations that entail nuance or complexity.

In recent years, developers of CDS systems have become increasingly interested in the use of more general representations of clinical knowledge to provide more sophisticated capabilities for decision support. These interests have paralleled the surge of enthusiasm in the World Wide Web community for the notion of developing **knowledge graphs** that encode facts about the world in a lattice of nodes that represent the kinds of entities in the world and links between them that represent relationships among those entity types (Noy et al. 2019). Unlike belief networks, which typically contain dozens of nodes, knowledge graphs often contain hundreds or thousands or even millions of nodes—or more. Whereas belief networks store numeric, probabilistic relationships among the entities in the graph, knowledge graphs store symbolic, logical connections among the enti-

**Fig. 24.5** Google depicts its knowledge graph artistically as a vast collection of nodes representing entities in the world, linked to other entities in a rich network. The graph allows Google’s search engine to highlight attributes of entities for which users might search, to

expand searches by including synonyms, and to collect information about entities related to the subject of a search for presentation to the user. (Source: ► <https://searchengineland.com/laymans-visual-guide-googles-knowledge-graph-search-api-241935>)

ties in addition to various properties of each entity. There currently is no standard way of creating a knowledge graph and there is not even consensus on what features a knowledge graph should support. Nevertheless, virtually all well-known e-commerce sites—from Google to Facebook to Bing to eBay—use a graph-based representation of knowledge to provide key functionality for users hoping to perform a variety of tasks.

Google, for example, has a knowledge graph that comprises more than one billion classes of entities and instances of those entities, and more than 70 billion facts about those entries (► Fig. 24.5) (Noy et al. 2019). The graph makes it possible for Google to know that, when a user searches for some abstraction, such as “medications for diabetes,” the user may be interested in different *kinds of* medications for diabetes, such as insulin and hypoglycemic drugs. Thus, the knowledge graph causes the search engine to bring up links to related entities when a user performs a search, and the graph helps to disambiguate the user’s query when the objective of the search may not be clear.

Many commercial CDS systems are adopting knowledge-graph technology as a component of their software architecture. Because there is no standard knowledge-graph approach, these systems adopt different knowledge-graph formalisms and perform different tasks using their graphs. “IBM Watson,” for example, is a name that encompasses a family of CDS systems that have been deployed for a range of clinical domains in recent years. Although these IBM Watson systems have had a variety of capabilities and evolving computational architectures, a common theme has been their use of knowledge graphs to implement precise information retrieval and to assist with natural language understanding. Thus, a knowledge graph can allow an IBM Watson system to interpret a user’s natural language query and to locate a document or a fact that is itself stored in a knowledge graph to respond to that query. Indeed, the use of knowledge graphs in general search engines such as Google and Bing provides such technologies with capabilities that make them useful for decision support. When reporting search results, both

Google and Bing display the contents of their knowledge graphs for the indicated item in a “knowledge box” at the upper right of the page. These knowledge boxes often can be very effective in offering specific information to address user queries.

The simplest form of knowledge graph is one that encodes an enumeration of the kinds of entities in an application area and that places them in an abstraction hierarchy, indicating when elements of one entity form a subclass (or superclass) of another. This type of data structure is often referred to as an **ontology**. Ontologies are like **controlled terminologies** (see ► Chap. 7), in that they provide a standard means for referring to the types of entities that comprise a domain, but they organize those entities using a graph that makes explicit the semantics of the relationships among the entities. **SNOMED CT** and the **NCI Thesaurus** are examples of commonly used controlled terminologies that are represented using knowledge graphs in a manner that also makes them ontologies.

Ontologies are important in biomedical informatics for their explicit representation of abstraction relationships, thus facilitating interpretation of high-throughput experiments, aiding information retrieval and natural language processing, and indexing data (Bodenreider and Stevens 2006). CDS systems can use ontologies that encode knowledge about different application areas in a manner that aids reuse of that knowledge in new settings and that makes it easy for developers to update the knowledge as their understanding of the application area evolves. Such systems use ontologies (or knowledge graphs more generally) to encode clinical knowledge in a manner that may overcome some of the limitations of the more prevalent CDS architectures. These systems make an explicit distinction between the *static knowledge* of the clinical domain (e.g., knowledge of the specifications entailed by a clinical practice guideline) and the *problem-solving knowledge* needed to apply the static knowledge to a particular patient (e.g., the means to generate specific prescriptions for medications based on the general guideline recommendations and the particular clinical situation

that the patient is experiencing). This distinction makes it possible for system builders to address different elements of the knowledge needed to be represented in the computer using tailored approaches and tools (Musen 1998; deClerq et al. 2004).

The ATHENA-CDS system exemplifies this component-oriented approach (Goldstein et al. 2000). ATHENA-CDS is a computer system that is integrated with the HIS that has been used by the U.S. Department of Veterans Affairs (VA), known as VistA.<sup>7</sup> ATHENA-CDS has been installed at several VA medical centers and has remained in continuous use at the Palo Alto VA medical center since the 1990s. ATHENA-CDS offers advice regarding patients who have certain chronic diseases, whose physicians would like to treat those patients in accordance with recognized evidence-based clinical practice guidelines (■ Fig. 24.6). ATHENA-CDS draws on several electronic knowledge bases, each one constituting a knowledge graph that encodes the knowledge of a particular guideline (e.g., for hypertension, for hyperlipidemia, for diabetes, and so on). Each time that a patient with a relevant diagnosis (e.g., hypertension) is seen in the outpatient clinic, ATHENA-CDS takes as input the corresponding guideline knowledge base and patient-specific data from the VistA EHR and generates as output suggestions to the clinician for treating the patient to ensure that the treatment is consistent with the care that the guideline would recommend. Because the standard documents that define clinical practice guidelines can be long and complicated, it is extremely helpful for the computer to focus the clinician’s attention on precisely which interventions should be considered to guarantee that the patient’s care is consonant with the medical evidence captured by a given guideline (■ Fig. 24.7).

ATHENA-CDS was engineered using an approach that separates out static knowledge about the clinical application area from knowledge about problem solving (i.e., knowledge about generating a situation-specific clin-

7 The VA is in the process of replacing VistA with a commercial HIS offered by Cerner.

The screenshot displays the ATHENA Hypertension Advisory interface. At the top, it shows the patient's name (redacted) and a link to view the patient summary. The main content area is divided into several sections:

- Recommendations:** A prominent red alert states "Blood Pressure apparently not under control: Based on last measurement of 145/92 taken 87 days ago on mm/dd/yyyy". Below this, it indicates a "CARDIO RISK FACTOR 23% High" and provides an "Explain" link. The recommendations list:
  - Consider intensifying drug treatment: BP Elevated based on most recent available BP.
  - There appears to be a Strong Contraindication to a currently prescribed drug, evaluate clinical significance.
  - Bronchospasm is a Strong Contraindication or use of beta adrenergic receptor antagonists, although many patients tolerate and therefore benefit from this drug therapy.
- Therapeutic Possibilities:** A table with three columns: Indications, Contraindications, and Therapeutic Possibilities.
 

Indications	Contraindications	Therapeutic Possibilities
Heart Failure <i>evidence</i>	Brochospastic disease	Discontinue <i>atenolol</i>
CKD <i>evidence</i>		AND start one of the following drugs
		ACE Inhibitors ( <i>lisinopril</i> )
		(non-DHP) Calcium Channel Blocker ( <i>diltiazem</i> )
	Heart Failure	Add one or more of the following drugs
		ACE Inhibitors ( <i>lisinopril</i> )
		(non-DHP) Calcium Channel Blocker ( <i>diltiazem</i> )
	Heart Failure	Increase dosage of hydrochlorothiazide
- Blood Pressure and Prescription History:** A line graph showing blood pressure trends from January 2005 to July 2006. A specific point is highlighted: "142/90 on [redacted]". Below the graph, a medication history bar chart shows the use of Lisinopril (80 MG), Med 2 (5 MG), Med 3 (100 MG), Med 4 (60 MG), Med 5 (80 MG), Med 6 (5 MG), and Med 7 (100 MG).

At the bottom, there is a feedback form and an "Exit" button.

Fig. 24.6 An example of the ATHENA-CDS system interface. ATHENA-CDS provides decision-support for the management of hypertension and several other chronic diseases by using a declarative knowledge base created as an instantiation on a generic guideline ontology. In the screen capture, the provider has entered

the patient's most recent blood pressure, and is offered advice about possible alterations in therapy based on the relevant clinical-practice guideline. The screen image depicts only simulated patient data (Courtesy of M. K. Goldstein, VA Palo Alto Healthcare System)

ical recommendation; Musen et al. 1996). To construct ATHENA-CDS, it was necessary first to define an ontology of clinical practice guidelines (Fig. 24.8). The guideline ontology makes it clear that all guidelines must include *eligibility criteria* that indicate which patients should be treated in accordance with the guideline, a *clinical algorithm* that specifies the sequence of treatments recommended by the guideline, and *guideline drugs* that represent all the medications that patients might be given when their provider follows the guideline. Because the guideline ontology is general, the graph does not contain information about any *particular* clinical algorithm, any *particular* eligibility criteria, and so on. The ontology merely states that all guidelines for management of chronic diseases have such characteristics.

Developers of ATHENA-CDS used the Protégé ontology-development system (Musen 2015) to create the ontology of clinical practice guidelines, which constitutes a knowledge graph. The developers then used Protégé to create subgraphs that represent distinct knowledge bases that define how to manage patients in accordance with particular guidelines. The developers created a knowledge base for management of hypertension reflecting the guideline that is used by the VA and the Department of Defense (DOD), supplemented with recommendations from the Joint National Commission on Hypertension (National High Blood Pressure Education Program 2004; Fig. 24.9). They instantiated the ATHENA-CDS guideline ontology to build a knowledge base for management of congestive heart failure based on the guideline

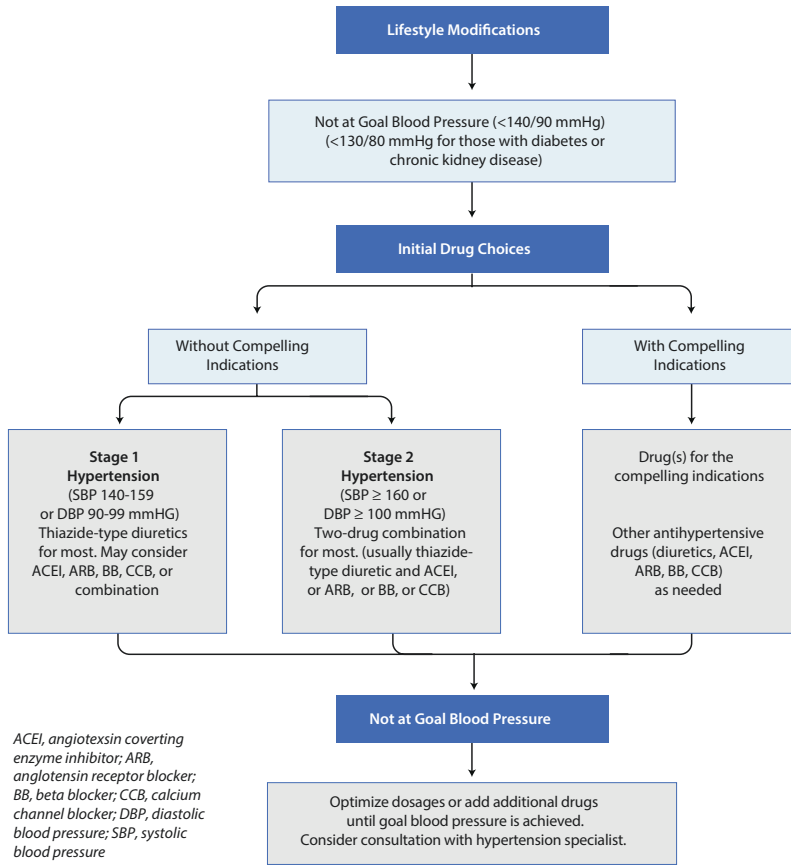

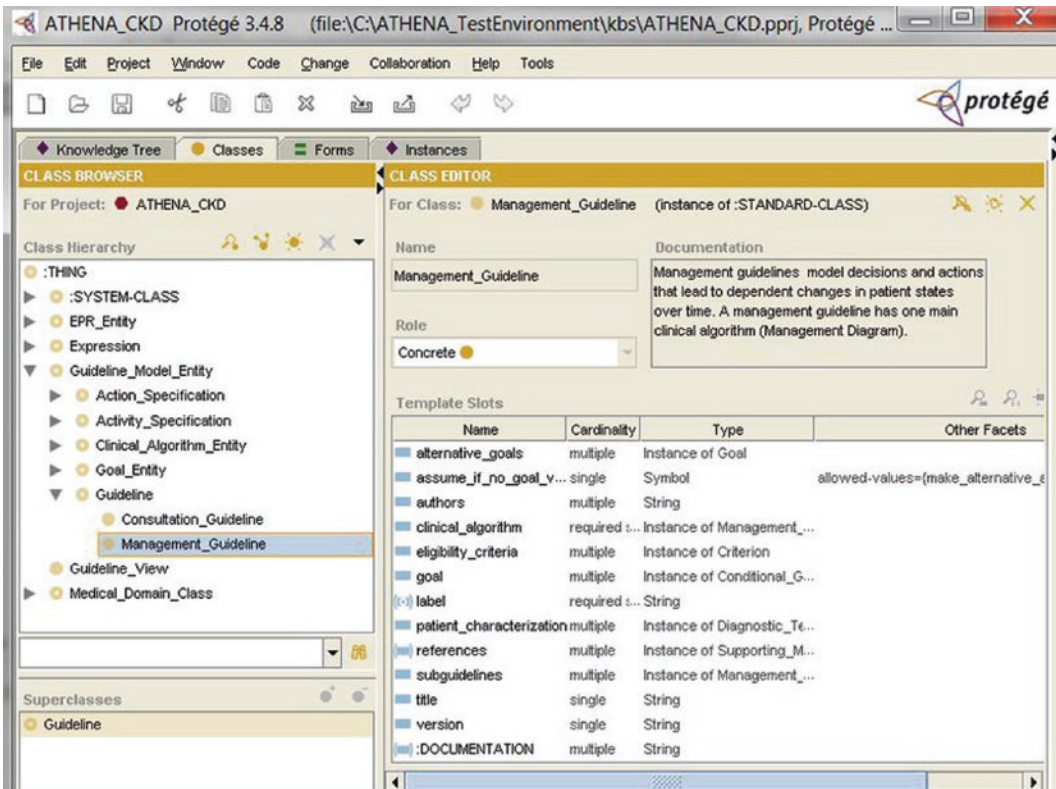

Fig. 24.7 Professional societies, health-care practices, private foundations, and other organizations are all working to capture “best practices” for managing patients in accordance with scientific evidence in terms of clinical practice guidelines. Unfortunately, nearly all these guidelines are published initially as large paper

documents. Here is a high-level, paper-based flowchart from the guideline developed by Joint National Commission on Hypertension. The flowchart summarizes detailed recommendations that the guideline document specifies in many pages of text

developed by the American Heart Association and the American College of Cardiology. The developers built a knowledge base for management of chronic pain, based on the guideline promoted by the VA and the DOD (Trafton et al. 2010). Other knowledge bases for guideline-based care of diabetes, hyperlipidemia, and chronic kidney disease were created in a similar manner.

The ontology-driven approach makes it possible to start with a particular ontology (in this case, one for clinical practice guidelines for management of chronic disease) to create multiple knowledge bases, each one instanti-

ating the ontology to specify the knowledge required for particular guidelines. Similarly, the different knowledge bases can be mapped to different problem-solving programs, such that each problem solver automates a different task associated with guideline-based care (therapy planning, eligibility determination, and so on). The ability to “mix and match” knowledge bases and problem solvers offers considerable flexibility, and it enables developers to reuse elements of previous solutions to address new CDS problems that require different domain knowledge or different problem-solving procedures.

■ **Fig. 24.8** A small portion of the ontology of clinical guidelines used by ATHENA-CDS as entered into the Protégé ontology-editing system. The hierarchy of entries on the left includes entities that constitute building blocks for constructing guideline descriptions. The panel on the right shows the attributes of whatever entity is highlighted on the left. Here, *goal*, *eligibility\_criteria*, and *clinical\_algorithm*, for example, are attri-

butes of the entity known as *Management\_Guideline*. The ontology entered into Protégé reflects concepts believed to be common to all guidelines, but does not include specifications for any guidelines in particular. The complete domain model is used to generate automatically a graphical knowledge-acquisition tool, such as the one shown in ■ Fig. 24.7

### 24.3.3 Coda

There is no standard way to build a decision-support system. Developers need to make choices, based on the nature of the decision task to be performed, the data and knowledge that are available, and the software tools with which they are most familiar. There are a variety of approaches from which to choose, and each one entails different kinds of trade-offs. A CDSS for providing advice about something potentially as complicated as a clinical practice guideline can be hardcoded in software, implemented as a rule-based system, or driven by knowl-

edge-graph technology. In cases when there is no appropriate evidence-based guideline, a CDSS can use probabilistic approaches or machine learning to suggest reasonable treatment decisions. Although interoperability standards such as SMART-on-FHIR are offering the opportunity to embed custom-tailored CDS technology within proprietary Health IT systems (see ► Chap. 7), the monolithic nature of most installed systems makes it challenging to achieve this kind of flexibility in the real world. Nevertheless, new IT standards are improving the landscape considerably, as we discuss in the next section.

**Identifier**  
VA/JNC-VII Hypertension Guideline

**Title**  
The clinical information from this system is advisory only and is intended to supplement the knowledge of health care professionals regarding the management of hypertension. It is not intended to replace sound clinical judgment or individualized patient care in delivery of healthcare services.

**Authors**  
NIH NHLBI Joint National Committee  
Mary Goldstein, MD  
Brian Hoffman, MD  
Susana Martins, MD MSc

**Version**  
February, 2009

**Eligibility Criteria**  

- presence of diagnosis of hypertension
- absence of renovascular disease
- no diagnosis of pregnancy
- Absence of Secondary Hypertension
- absence of spinal cord injury

**Clinical Algorithm**  
hypertension management diagram

**Goal**  

- BP target patient with diabetes mellitus
- BP target for patient without diabetes mellitus

**Patient Characterization**  

- Risk\_Group\_A
- Risk\_Group\_B
- Risk\_Group\_C
- Home\_BP

**Drug Usages**  

- ACE\_Inhibitors
- Alpha\_beta\_blockers
- Alpha\_blockers
- Angiotensin\_II\_receptor\_blockers
- Beta-Blockers-Cardioselective
- Beta-Blockers-non-cardioselective

■ **Fig. 24.9** A screen from a Protégé-generated knowledge-acquisition tool for entry of clinical-practice guidelines. The tool is generated automatically from a domain ontology, part of which appears in ■ Fig. 24.7.

The entries into the tool specify the knowledge required to treat patients in accordance with the guideline for chronic hypertension adopted by the Department of Veterans Affairs

## 24.4 Translating CDS to the Clinical Enterprise

Over the past several decades, advanced CDS systems have been developed and deployed in a number of academic medical centers. The technology has subsequently diffused into commercial EHR systems and into routine practice (Chaudhry et al. 2006). The uptake has been greater in medium-to-large hospitals and in medical-center-based networks, including affiliated practices, and has been much less in smaller hospitals, clinics, and independent practices. Although these trends had been sluggish, the “meaningful use” regulations for HIT and other regulatory and incentive-based approaches in the United States as well as elsewhere accelerated the adoption of CDS

technology (Blumenthal and Tavenner 2010; Blumenthal 2010).

In general, the CDS systems deployed to date in vendor EHR systems are quite varied, and relatively limited in scope, and their capabilities in knowledge management are also varied (Wright et al. 2009). The greatest uptake has been in the form of simple alerts and reminders, standard physician order sets, CPOE-based prescription templates with dose checks, allergy checks, identification of drug–lab and drug–drug interactions, and some use of info-buttons or access to context-specific knowledge resources. In some specific settings, rule-based systems have been used to drive the intelligent collection of clinical information in a comprehensive, structured clinical documentation form (Schnipper et al. 2008).

A few vendors have been successful at distributing knowledge resources, making available shareable clinical knowledge in the form of drug-interaction databases, order sets for common indications, rule-based knowledge, documentation templates, and information resources for infobutton-based queries (Middleton et al. 1998). More recent research has examined opportunities for creating knowledge repositories to make these resources more readily available in both the public and private sector (Osheroff et al. 2007; Kawamoto et al. 2013).

Despite growing demand, many years of research and development, and the broad adoption of EHRs in recent years, CDS has had relatively limited adoption to date. There are several reasons for the slow uptake of CDS (Wright et al. 2009), which need to be addressed by approaches such as those enumerated in the sections that follow.

#### 24.4.1 Standard Patient Information Model

---

CDS rules and other problem-solving approaches need to operate on specific patient data with a clear understanding of the patient data model and semantics of the terms. If those data are stored in a proprietary format and with non-standard encodings, then a set of rules needs to be customized to use data in that form, or the data need to be translated to the information model of the CDS rules, quality measure, or other uses. The customization of rules for each EHR (or EHR implantation) has been the prevailing mode, typified by the “curly braces problem” of Arden Syntax rules, described previously. As a result, vendor EHR systems tend to have libraries of rules that operate only in their own systems, using their proprietary data dictionaries and data models. Knowledge sharing across platforms and systems has been limited, and considerable work is required to integrate vendor HIT products with external CDS systems.

One approach is to develop a canonical information model that both the knowledge source systems, and the knowledge artifacts

can use. This strategy can facilitate a common understanding of semantics in the data and the semantics of the knowledge artifact, and it alleviates mapping CDSS variables to local data or developing a set of custom rules to access the local data in each and every setting. This approach does not eliminate what some describe as an “irreducible mapping problem” in Health IT, but it does distribute it in an effective manner such that, as data representation evolves more toward a canonical form, we can approach **iso-semantic mappings** of data from data source to knowledge artifact—that is, where the semantics of the source data are identical to the semantics of the data expected in the CDS analytic. This approach has been pursued in the very successful Observational Health Data Sciences and Informatics (OHDSI) project in research informatics (Hripscak et al. 2015), which adopts a Common Data Model for source systems to map to, and for analytics (and federated queries) to run against (Jiang et al. 2017a, b).

As discussed below in ► Sect. 26.4.2, in 2012, a **virtual medical record (vMR)** based on the HL7 version 3.0 **Reference Information Model (RIM)** was an initial effort to arrive at the notion of a canonical information model. It was approved by HL7 as a draft standard for trial use for linking dynamically at runtime the arbitrary data elements available in the patient database of an EHR to CDS systems that assume the standard vMR data model for data encoding (Kawamoto et al. 2010). The vMR was designed to serve as an intermediary data model—a canonical form—between proprietary database formats and standards-based CDS systems that developers might plug into any EHR that can make its data available in a vMR-compliant manner. HL7 supported work to map the vMR to standard terminologies and clinical data element definitions. So, for example, data elements in an ECA rule could be referred to in an interoperable manner, rather than, say, the individual mapping of data elements to access methods inside the curly braces of Arden Syntax MLMs (see Rule-Based Systems in ► Sect. 26.3.2).

Newer work focuses on the development of the **Quality Data Model (QDM)** to represent clinical data and concepts used in specifying quality measures, and ultimately clinical decision support logic. The QDM is an information model that describes the relationships between patients and clinical concepts in standardized formats. QDM allows the definition of a clinical concept used in a specification to measure quality of patient care via defined data elements, and it provides the vocabulary needed to relate concepts to each other. For example, QDM, at the highest level of abstraction, defines categories such as Medication, Procedure, Condition, and so on. Within a category, the Datatype definition gives the context of the clinical care process being assessed such as “medication - active,” or “medication - administered.” Further Datatype details are defined with Attributes that can further define the Datatype, or define the expected source for the data. For example, a diagnosis of “Diabetes Mellitus Type I” is an *active diagnosis* datatype, a “Metformin prescription” is a *medication prescribed*, and a “Hemoglobin A1c value” is a *laboratory result*. Each of these elements can be related to terms in controlled terminologies via specification of corresponding code sets. By relating attributes between data elements, the QDM provides a method to construct complex clinical representations both for electronic clinical quality measures and for clinical decision-support logic. Because of this ability to share common logic elements (expressions, value sets, terminology) between quality measure and CDS specifications, QDM has become popular for specifying quality measures among a wide variety of measure developers and CDS implementers (Pathak et al. 2013; Hong et al. 2016).

More recently, the **Fast Healthcare Interoperability Resource (FHIR)** standard from HL7 has emerged from a multi-vendor collaboration in the Argonaut Project (HealthMgt 2015). FHIR is designed specifically for the Web and provides resources and foundations based on common methods and technologies used in the Web (XML, JSON, HTTP, and OAuth) (Bender and Sartipi

2013). FHIR resources are accessed through what is known as a **RESTful API**, which can be defined as one that uses HTTP requests to GET, PUT, POST and DELETE data. FHIR frameworks are built around the concept of resources—basic units of interoperability and modular components that can be assembled into working systems to try to resolve clinical, administrative and infrastructural problems in health care. This capability has partially addressed the heterogeneity of different systems, and it has dramatically improved interoperability between systems.

#### 24.4.2 Adoption of Standard Knowledge-Representation Models

Although Arden Syntax has been an HL7 and ANSI standard since 1999, only a few vendor systems manage their libraries of decision rules using Arden Syntax. Even doing so, of course, the rules still need to be customized for use with vendor-specific patient databases on a tedious, rule-by-rule basis to overcome the curly-braces problem described in ► Sect. 24.3.2. HL7 has pursued the development of more interoperable models not only for data query but also for defining elements of ECA rules. A succession of efforts led to a specification for a query language called GELLO (Sordo et al. 2004), and then the Health eDecisions rule formalism,<sup>8</sup> and more recently the Clinical Query Language, discussed below.

##### 24.4.2.1 Standards for Encoding Clinical Guideline Models

Particularly challenging in the standards-development world is creation of a standardized, shared model for representing clinical practice guidelines in a form suitable for execution at run time. The **Guideline Element Model (GEM; Shiffman et al. 2000)**

<sup>8</sup> HL7 International (2014). Health eDecisions. Retrieval February 19, 2020: ► [https://wiki.hl7.org/index.php?title=Health\\_eDecisions](https://wiki.hl7.org/index.php?title=Health_eDecisions)

is an XML mark-up specification that is an American National Standards Institute (ANSI) standard, now in its third revision, that guideline authors can use to annotate their narrative guidelines to identify key elements for both quality assessment and execution. GEM allows authors to demarcate the text that identifies guideline actions or eligibility criteria, and thus can serve an intermediary purpose in work to transform a prose guideline into a computable specification, but the standard does not itself provide a mechanism to translate a marked-up guideline document into a structure that a computer can interpret and execute. Such systems may be criticized as not explicitly representing the underlying ontology of the guideline components to be used at run time.

Other efforts have focused on creation of a guideline ontology, such as the one adopted by ATHENA-CDS (see ■ Fig. 24.8), that can inform the creation of computer-understandable knowledge bases that are able to capture knowledge about specific guidelines. Such knowledge bases then could allow a CDS system to use knowledge about the guideline, data from the EHR, and information concerning patient preferences and available resources to offer situation-specific, guideline-directed advice. As we have noted, an underlying infrastructure known as EON (Musen et al. 1996) drives the ATHENA-CDS system. Other ontology-based approaches have appeared over the years, including GLIF, GUIDE, PRODIGY, Asbru, and GLARE. Peleg and colleagues (2003) compared many of these guideline models, and they showed significant commonalities among them. Despite the large degree of agreement, however, work in this area has not yet led to anything near a standard that is widely adopted. Part of the problem is that there is wide variation in the structure, granularity, and specificity of existing clinical practice guidelines, making it difficult to develop a single comprehensive and yet readily applicable guideline model. Analysis of the use of guidelines also indicates that guidelines themselves are rarely “executed” without considerable adaptation or localization, except in situations such as protocol-driven care (for example, in clinical trials

or in very specific procedures such as renal dialysis). ATHENA-CDS thus dispenses with offering specific guideline-based recommendations, and instead suggests to the clinicians when certain treatment options might be “compellingly indicated” or “relatively contraindicated.” In highly regimented settings such as the administration of chemotherapy for cancer, however, a CDS system generally would need to be much more “prescriptive” in offering recommendations to clinicians.

#### 24.4.2.2 Standards for Encoding ECA Rules

As we have noted, the ability to share decision rules is hindered in the absence of standards to encode both the logic of the rules (how the IF and the THEN components are to be evaluated) and the clinical data on which the rules depend. Recently, the **Clinical Quality Language (CQL)** has emerged as an expression language that addresses these challenges. CQL is intended to characterize both quality-measure logic and decision-support logic and the data that such logic processes (Odigie et al. 2019). For example, CQL expressions define the expected input data model, library resources that may be called, parameters, value sets, and code sets used in definitions of patient conditions, and additional concepts needed to specify and encode the clinical logic and data types used in a clinical quality measure—or in a CDS rule (Jiang et al. 2015).

Expression languages are commonly used to represent the logic to be used at the presentation layer of an application, and the methods that may be used to interact with standard data models. CQL grew out of prior efforts such as GELLO and the Health eDecisions framework, from work in the U.S. Office of the National Coordinator’s Clinical Quality Framework Initiative. It was focused on identifying, defining, and harmonizing standards and specifications that promote integration and reuse between clinical decision support and clinical quality measurement (CQM) knowledge-representation formalisms. It strives to be more clinician friendly and accessible to subject-matter experts. However, the standards used for the electronic representation of CDS and CQM artifacts have not been

developed in consideration of each other, and the domains use different approaches to the representation of patient data and computable expression logic. Harmonization of these approaches now is focused on clearly identifying the various components involved in the specification of quality artifacts, and then establishing as a principle the notion that they should be treated independently (separation of concerns). Broadly, the components of a CQL artifact involve specifying:

- Metadata – Information about the knowledge artifact (whether CQM or CDS) such as its identifier and version, what health topics it covers, supporting evidence, related artifacts, dependencies, etc.
- Clinical Quality Information – The structure and content of the clinical data (data model) involved in the artifact
- Expression Logic – The actual knowledge and reasoning being communicated by the artifact

The CQL specification is an approved HL7 standard endorsed by the U.S. Centers for Medicare and Medicaid Services, the U.S. Centers for Disease Control and Prevention, and others for the representation of either CDS or CQM knowledge artifacts. It is part of the Clinical Quality Framework effort supported by the Standards and Interoperability Framework of the U.S. Office of the National Coordinator for Health IT. As such, it aims to promote the interoperability of knowledge artifacts through standardization of the data models, logic statements, and controlled medical terminology (including value sets). Because CQL is also fully specified in a machine-readable way, it may be programmatically converted into what HL7 calls an *expression logical model* (ELM), which can then be interpreted in an execution environment.

The convergence of a common formalism that accommodates the use of standardized data models, facilitates clinical query and computation through a library of methods, and which is machine interpretable dramatically improves the portability of clinical knowledge artifacts. In addition, this specification

is designed to be data model-independent, meaning that CQL has no explicit dependencies on any aspect of any particular data model. Rather, the specification allows for any data model to be used, so long as a suitable description of that data model is supplied.

Current efforts now focus on further standardization of input data models, as well as alignment with the FHIR API standard. For example, the QUICK specification and the Quality Improvement Core (QICore) are being developed concurrently with the CQL specification to ensure that the two specifications interoperate effectively. QUICK is a logical model consisting of clinical objects, attributes, and relationships. QUICK provides a uniform way for clinical decision support and quality measures to refer to clinical data. This initiative began in 2013 with the creation of the Quality Improvement Domain Analysis Model (QIDAM), which drew on the vMR and QDM as sources of requirements. Originally, the QUICK data model was developed entirely independently of FHIR. However, recognizing the broader community focus on FHIR, QUICK was aligned, structurally and semantically, as closely as possible to FHIR. This alignment not only creates a common model for quality and interoperability, but also it will make it easier in the future to leverage other FHIR-related efforts, such as Clinical Document Architecture (CDA) on FHIR, or CQL on FHIR. Authors of future quality measures and clinical decision support artifacts may use QUICK, together with the Clinical Quality Language (CQL), to create interoperable and executable knowledge artifacts, thus dramatically the ability to share computable biomedical knowledge artifacts.

### 24.4.3 Modes of Deployment of CDS

---

Even with the emergence of shareable, computable, biomedical knowledge artifacts, one of the key impediments to widespread adoption of CDS, particularly the use of rules

and alerts, is clinician annoyance with pop-ups, messages, emails, and other notifications that interrupt workflow. Ideally CDS systems should be integrated into the organization and presentation of information to facilitate workflow and decision making, by anticipating what information is needed for a decision, pre-fetching it, displaying it in ways that support visualization of trends or relationships, and tying these analyses to care plans or actions that can be offered immediately and quickly selected by the user. Order sets, as stated in the beginning of this chapter, form a good example of use of CDS both to suggest appropriate actions in a given setting and to make it easy to accomplish those actions, by immediately enabling the orders in the set to be entered automatically into the EHR, perhaps with modification.

There is much ongoing research to develop methods for managing the processes of data capture, data presentation, data visualization, and selection of actions, but this work is usually being done outside of vendor EHRs. Given limited interoperability and access to the internals of proprietary systems, this kind of experimentation is now tending to take place in the form of apps and services that operate on externally extracted data (Mandl and Kohane 2012). There is growing support for the notion of SMART apps—Substitutable Medical Applications and Reusable Technologies—that use standard API methods to access electronic health record data, perform clinical inferences external to the EHR, and return insights in a standardized container (whether iFrame, Web page, or free-standing application; Mandel et al. 2016).

#### 24.4.4 Workflow and Setting-Specific Factors

As noted in ► Sect. 24.3.2, applications based on single-step situation–action rules are among the most prevalent and useful types of CDS systems. Such systems can be invoked in many contexts to provide either recommenda-

tions in real time or reminders or alerts that are processed in batch, based on time-oriented triggers or data-evaluation events. Rules can invoke other knowledge resources—providing new information content, triggering other rules, or offering order sets.

Rule content is ideally based on analysis of clinical evidence, such as recommendations or guidelines emanating from the U.S. Preventive Services Task Force, or from professional-society studies of best practices for specific diseases. The job of formalizing these recommendations into executable logic requires that they be expressed in a specified way, but even having done so, such rules are not typically ready to execute in a particular environment, even if they are expressed in a rule execution language “understood” by an EHR system, and if they refer to the data elements in the EHR in their expected format. The reason the rules are not readily executable is also the reason that rules that work well in one environment are often not able to be successfully deployed elsewhere without substantial modification (even if in the same representation format and if using the same data model).

The reason for the failure is lack of adaptation to what we refer to as *setting-specific factors* (SSFs; Greenes et al. 2010). To work effectively, rules need to integrate well with the clinical setting, workflow, users, application environment, and other factors. These requirements are reflected in how and when the rule should be triggered—on various events such as examination of some element of the EHR, on login to the system, or on the availability of laboratory test results. Rules may also be developed in the form of reminders that are triggered when the CDSS evaluates on a batch basis a practice’s list of patients to be seen on a given day, the patients who have a birthday in a given month, the passage of a specific interval of time since a previous comparison event, and so on. The rules additionally may vary based on the practice setting (e.g., the emergency department, an office practice, or an inpatient unit); particular inclusion or exclusion criteria or threshold

modifications that may be site-specific; how the recommendation should be transmitted (e.g., via electronic mail, popup windows, or sidebar messages); whether the recommendation requires acknowledgment by the recipient; whether it can be overridden; whether the alert should be escalated to supervising clinicians, and so on. Rules that have been custom tailored in such ways by means of executable code naturally are less sharable than are generic rules. Failure to capture the kinds of customizations that are needed, however, makes it time consuming for individual sites to adapt generic medical recommendations to their particular requirements or to capitalize on the experiences of others. What is needed is a way to represent useful experience in terms of SSF combinations that work, without needing to do so at the level of detailed code that is difficult for users to visualize and modify.

#### 24.4.5 Sharing of Best-Practice Knowledge for CDS

---

The methods described above for sharing computable biomedical knowledge are now gaining momentum (viz., SMART, CQL, FHIR). Historically, it generally has fallen on each health-care organization, user group, or other entity to undertake its own process of identifying and managing the best-practice knowledge it wants to deploy in its CDS systems. Most institutions lack the expertise, or the resources, to accomplish this task. Even having a national or international repository of such knowledge would not preclude the need for customization, but it would certainly make it easier for each health-care entity to start with a trusted source. Over the past decade, the U.S. Agency for Healthcare Quality and Research has funded efforts to create such a public repository, known as CDS Connect (Lomatan et al. 2019). In CDS Connect's repository, the goal is to archive knowledge artifacts represented in the CQL formalism to promote sharing and interoperability. Where such a repository should be hosted, how it might integrate public and pri-

vate knowledge sources, who would have oversight over it, how its knowledge would be peer reviewed and quality-rated, and how it would be sustained are among the many questions that have not yet been answered, but this is an area of intense research and development. While many health-care organizations continue to perform this kind of knowledge-curation work for their own constituencies, several initiatives show a clear pathway to becoming viable alternatives for knowledge aggregation and dissemination.

### 24.5 Future Research and Development for CDS

---

Workers in biomedical informatics have studied problems in assisting with complex decision making for more than half a century. It seems that it is only now, with the very recent adoption of HIT on a widespread basis, that the foundations are finally in place for the rapid advance of CDS technology in clinical settings. Although considerable logistical problems still must be surmounted as outlined in ► Sect. 24.4, this is an exciting time in which to study CDS and its translation from the laboratory to the point of care.

#### 24.5.1 Standards Harmonization for Knowledge Sharing and Implementation

---

Many implementation challenges remain for the broad adoption and effective use of CDS in EHR systems. As mentioned above, one of the most active areas of current research focuses on development of standard approaches to knowledge sharing for CDS. Knowledge sharing may take the form of human-readable artifacts, machine-interpretable artifacts, or executable Web services (Osheroff et al. 2007; Goldberg et al. 2014; Dixon et al. 2013; Kawamoto et al. 2013). A capability for CDS sharing, as well as CDS functionality itself, would be substantially facilitated by the continued develop-

ment and use of common standards designed to serve CDS needs in health care.

As noted, several standards currently exist that are aimed at specific areas of CDS and types of CDS artifacts, or that could be leveraged to benefit CDS. For example, the Clinical Decision Support Consortium, a large collaborative research and development group supported by the U.S. Agency for Healthcare Research and Quality, adopted an enhanced version of the Continuity of Care Document (CCD) to serve as the foundation for input data for multi-institutional trials of CDS technology (Middleton 2009). When taking advantage of the most current standards such as CQL and FHIR, systems developers tend to adopt not only the standards but also arrive at more common implementation approaches or patterns, that promote knowledge sharing and reuse, and which may decrease the implementation burden if EHR vendors accommodate the standardized API and interaction models, as well as the data model expectations of the standards.

### 24.5.2 Context-based Knowledge Selection

---

Much of the above effort is aimed at overcoming the non-portability of event-condition-action (ECA) rules, such as alerts and reminders, because of the need to localize and adapt triggering conditions, modes of interaction, and specific workflow processes of sites (Setting-specific factors, or SSFs, as discussed in ► Sect. 24.4.4), leading to many variations that must be laboriously designed and tracked.

One of the possible modes for reducing this need for customization and localization is to use the context, state, and activity (CSA) of a CDSS user to automatically identify appropriate knowledge artifacts to be made available. The idea relies on maintaining patient state, user role, expertise, setting, and specific tasks being performed to determine when the knowledge might be pertinent. The latter also requires a rich multi-axial set of metadata for the knowledge artifact repository that allow selection based on user CSA.

Other ways in which context could be used might be to create specialized views or filters of available data, based on CSA. For example, selection of data to be viewed could be based on a user's role and domain expertise. Associations (and, ideally, typed relations) among data items could be highlighted—for example, among problems, findings, and actions. Such relations could also potentially be used to anticipate assessment and plan entries in notes based on data items present or being focused on. Such approaches undoubtedly will only be scalable in generalized web-services implementations. For example, infobutton managers already use context such as user type, app/function being performed, and specific item being evaluated to identify retrieval keys for external knowledge resources. The idea behind the expansion of context as a mode for invocation of CDS more generally is to create a more detailed and continually updated model of context, state, and activity. Such efforts are just getting underway.

### 24.5.3 Representation Models

---

To date, standards and related efforts addressing CDS have heavily emphasized specific CDS execution methods and the representation of the clinical context of the patient. For example, as we have noted previously, a variety of frameworks for working with rules, including Arden Syntax, Drools, JESS, CQL, along with several proprietary formats, have worked their way into vendor offerings. This diversity has inhibited the exchange of best-practice knowledge to date, but progress toward more effective knowledge interchange is being made with CQL in particular. The current situation is that both public and private knowledge repositories of knowledge artifacts that address specific pieces of the CDS problem exist (e.g., NLM Value sets, CMS eCQMs, standardized data models, professional society clinical pathways, vendor implementations of algorithms and analytics, and SMART applications) and we see growing adoption given the increased pressures on clinical reasoning and operations in practice.

In addition to reducing unwarranted clinical variability in practice, future work needs to establish a canonical patient information model with a formal ontology, an event model for triggering conditions, an action model for CDS intervention recommendations, a workflow model for appropriately inserting CDS interventions into the routines of clinical practice, a knowledge-representation schema with a standard regular expression language, and, ideally, a measurement standard to assess CDS performance in use.

#### 24.5.4 Externalizing CDS

Standardization of methods for externalized CDS (CDS performed outside of the EHR, in the cloud) is becoming more commonplace due to emerging standards described above (CQL, CQM, QUICK, FHIR). Prior research and development efforts have demonstrated the feasibility of accessing clinical data from the electronic health record via standards-based (viz., FHIR) and proprietary RESTful APIs, and running executable knowledge artifacts – both quality measures, and clinical decision support – on the data in the secure cloud environment and returning insights into the app being used in the clinical workflow (Wright et al. 2015; Dixon et al. 2013). Current work is focused on representing all of the requisite knowledge artifacts required to create a computable practice guideline fully represented in CQL, and on running those knowledge artifacts via FHIR data-access methods. Use of services enables considerable flexibility and breadth of kinds of CDS that can be made available widely, and ongoing work with FHIR resource specifications is improving the ability to gather the data needed and deliver it, and to integrate with clinical workflow processes more smoothly.

We have described the many efforts underway to standardize data models for information exchange, CQL for knowledge representation, and functional integration with EHR workflows using SMART, and FHIR. A deeper functional integration model between externalized services and EHR work-

flow is provided by **CDS Hooks**. CDS Hooks (Dolin et al. 2018) is a method for enabling an event in the host system to determine when an app (such as provided by SMART-on-FHIR) should be launched programmatically, thus complementing the need to launch apps directly by users. The EHR detects an event such as a physician beginning to write an order, and it then can invoke an external decision-support service. That service can determine what task is being performed and return information in the form of a “card” (a phrase or text snippet containing an inference or assessment, or suggested action) that will be displayed within the EHR. CDS Hooks may also provide a link to an external app. The main downside of these approaches to CDS is that, although they have formal methods for launching apps, they basically have no constraints on what happens within the apps, or support for linking to the intrinsic functionality and workflows of a host EHR. Thus, the methods can result in a proliferation of SMART apps and CDS Hooks modules in an organization’s library, with a number of them that may be of limited utility. This situation could cause significant challenges for an enterprise seeking to manage and update its CDS capabilities on a regular basis.

#### 24.5.5 Usability Research and CDS

The use of CDS within EHRs, and health IT in general, have been identified as double-edged swords: technology may provide benefit, but it also may cause considerable harm. Clinician error when using information systems that may result in untoward outcomes and unintended consequences (Karsh et al. 2010; Sittig and Singh 2009) may be an emerging property that is demonstrated only after system implementation or widespread use. Medical errors related to use of Health IT are problematic, not only for clinical and quality of care reasons, but technically, since they may represent a mismatch between the user’s model of the task being performed and the model used in a computation (National Research Council (U.S.) Committee on Engaging the Computer

Science Research Community in Health Care Informatics et al. 2009), a mismatch between the application's intended functionality and the resulting action or event (Harrison et al. 2007), or a latent health IT-related error yet to happen (Ash et al. 2007). Excessive alert fatigue can undermine the efficacy of clinical decision support in CPOE (Isaac et al. 2009; Strom et al. 2010), and in other IT functions (Chused et al. 2008), and result in very high user override rates (Shah et al. 2006; van der Sijs et al. 2006; Weingart et al. 2003). Critical research questions need to focus on the potential mismatch between the user's mental model or intent and the application design, use case, or workflow model (Zhang and Walji 2011; Patel et al. 2010). Further attention needs to be given to basic principles of human-factors engineering, such as the use of colors and layout within the application interface. Additional questions remain regarding the ideal design of methods and controls with which a user might interact to choose a medication from a long list, or identify and encode patient problems. More advanced research will enable visualization and decision making by matching problems with care plans, and facilitation of continuity and coordination of care based on underlying CDS rules and guideline-based workflows. Especially challenging is addressing the need for structured data to support clinical decision support and quality reporting, in a manner that is efficient for the end-user. This goal might be achieved by combining structured documentation during data entry, and natural language processing for data abstraction from the clinical narrative. Most important, however, are methods to direct CDS to the right user, at the right time, in the right workflow, with the right level of alerting or intervention, and the right information (Osheroff et al. 2012).

### 24.5.6 Data-Driven CDS

---

As we have discussed, a major area of research in informatics concerns methods for deriving knowledge from large data sets using a variety of techniques. With the adoption of health IT broadly, investigators are drawing on large-

scale data-mining methods to provide CDS for population monitoring, public health surveillance, and even to offer patient-specific recommendations based on cohort data when there is no specific evidence that could otherwise guide therapy. With the increasing availability of data from diverse sources relevant to patient care, large data sets may be created and used for both discovery of previously unknown associations, and novel clinical predictions (Frankovich et al. 2011; Longhurst et al. 2014). Critical research questions here will include how to define like cohorts of patients, how to structure and frame the index decision, what methods to use to assess the likelihood of alternate prediction scenarios, and how to model and elicit the patient's preferences for each scenario. The Institute of Medicine (2011b) articulated a long-term vision for a Learning Health System, in which clinical and administrative data of all kinds will begin to inform and enhance clinical practice on a national level in a wide variety of ways.

## 24.6 Conclusions

---

The future of CDS systems inherently depends on progress in developing useful computer programs and in reducing logistical barriers to implementation. Although ubiquitous computer-based decision aids that routinely assist clinicians in most aspects of their practice are currently the stuff of science fiction, progress has been real and the potential remains inspiring. Early predictions about the effects that such innovations would have on medical education and practice have not yet come to pass (Schwartz 1970), but growing successes support an optimistic view of what technology will eventually do to assist practitioners with the processing of complex data and knowledge. The research challenges have been identified much more clearly, legislative mandates are creating not only new financial incentives but also the practical substrate of increased EHR adoption and convergence toward data interoperability, and the implications for health-science education are much better understood. The basic com-

puter literacy of health professional students can be generally assumed, but health-science educators now must teach the conceptual foundations of biomedical informatics if their graduates are to be prepared for the technologically sophisticated world that lies ahead.

Equally important, we have learned much about what is not likely to happen. The more that investigators understand the complex and changing nature of medical knowledge, the clearer it becomes that trained practitioners of biomedical informatics will always be required as participants in fostering a cooperative relationship between physicians and computer-based decision tools. There is no evidence that machine capabilities will ever equal the human's ability to deal with unexpected situations, to integrate visual and auditory data that reveal subtleties of a patient's problem, to work with patients to incorporate their values and priorities in care plans, or to deal with social and ethical issues that are often key determinants of proper medical decisions. Considerations such as these will always be important to the humane practice of medicine, and practitioners will always have access to information that is meaningless to the machine. Such observations argue cogently for the discretion of health-care workers in the proper use of decision-support tools.

### Suggested Readings

Bright, T. J., Wong, A., Dhurjati, R., Bristow, E., Bastian, L., Coeytaux, R. R., Samsa, G., Hasselblad, V., Williams, J. W., Musty, M. D., Wing, L., Kendrick, A. S., Sanders, G. D., & Lobach, D. (2012). Effect of clinical decision-support systems: A systematic review. *Annals of Internal Medicine*, 157(1), 29–43 This thorough analysis of studies of CDS systems demonstrates that there is good evidence that CDS technology can alter clinician behavior in positive ways, but that evidence that CDS systems can improve long-term patient outcomes is still inconclusive. The paper is also useful for its comprehensive bibliography.

Greenes, R. A. (Ed.). (2014). *Clinical Decision Support*, 2nd Edition: The Road to Broad

Adoption. New York: Elsevier This book offers a comprehensive discussion of the nature of medical knowledge and of information technology to assist with medical decision making. It provides detailed discussions of the computational, organizational, and strategic challenges in the design, development, and deployment of CDS systems.

Institute of Medicine. (2011). *Digital infrastructure for the learning health system: The foundation for continuous improvement in health and healthcare*. Workshop Series Summary. Washington, DC: The National Academies Press. This monograph summarizes the vision for a national Learning Health System and offers the perspective of a wide range of thought leaders on the work required to achieve that vision.

Ledley, R., & Lusted, L. (1959). Reasoning foundations of medical diagnosis. *Science*, 130, 9–21 This is the paper that started it all. This classic article provided the first influential description of how computers might be used to assist with the process of diagnosis. The flurry of activity applying Bayesian methods to computer-assisted diagnosis in the 1960s was largely inspired by this provocative paper.

Sittig, D. F., Wright, A., Osheroff, J. A., Middleton, B., Teich, J. M., Ash, J. A., Campbell, E., & Bates, D. W. (2008). Grand challenges in clinical decision support. *Journal of Biomedical Informatics*, 41(2), 387–392 A rank-ordered list of some of the principal challenges for CDS technology development and implementation, intended “to educate and inspire researchers, developers, funders, and policy makers”.

### Questions for Discussion

1. Some researchers in medical AI have argued that CDS systems should reason from clinical data in a way that closely matches the reasoning strategies of the very best clinical experts, as such experts are the most clever diagnosticians and the most experienced treatment specialists that there are. Other researchers maintain that expert reasoning, no matter how excellent, is

- at some level inherently flawed, and that CDS systems must be driven from the mining of large amounts of solid data. How do you account for the apparent difference between these views? Which view is valid? Explain your answer.
2. Transitioning CDS systems from one clinical setting to another has always been problematic. The Leeds Abdominal Pain System was installed in several major clinical settings, and yet the system never performed as well elsewhere as it had done in Leeds. The Arden Syntax, created expressly to facilitate knowledge sharing across institutions, failed to meet this goal to a significant degree. Why kinds of setting-specific factors make it difficult to transplant decision-support technology from one environment to another? What kinds of research might lead to better methods for knowledge sharing in the future?
  3. In one early evaluation study, the decision-support system ONCOCIN provided advice concerning cancer therapy that was approved by experts in only 79% of cases (Hickam et al. 1985). In another study, the HyperCritic CDS system for the management of hypertension offered the same comments that were generated by a panel of experts in only 45% of cases (Van der Lei et al. 1991). Even today, such system performance is fairly typical for computer programs that suggest patient therapy. Do you believe that this performance is adequate for a computational tool that is designed to help physicians to make decisions regarding patient care? What problems might CDS systems encounter as their developers attempt to make the systems more comprehensive in the advice that they offer? Why might it be more difficult for computer systems to offer acceptable recommendations for patient therapy than seems to be the case for diagnosis? What safeguards, if any, would you suggest to ensure the proper use of such systems? Would you be willing to visit a particular physician if you knew in advance that she made decisions regarding treatment that were approved by expert colleagues less than 80% of the time? If you would not, what level of performance would you consider adequate? Justify your answers.
  4. A large international organization once proposed to establish an independent laboratory—much like Underwriters Laboratory in the United States—that would test CDS systems from all vendors and research laboratories, certifying the effectiveness and accuracy of those systems before they might be put into clinical use. What are the possible dimensions along which such a laboratory might evaluate decision-support systems? What kinds of problems might such a laboratory encounter in attempting to institute such a certification process? In the absence of such a credentialing system for CDS systems, how can health-care workers feel confident in using a clinical decision aid?
  5. There is considerable untapped potential for CDS to help in managing patients with multiple complex conditions. What are the challenges in dealing with such patients, and how can CDS be helpful? What are the features required of an algorithm that might integrate recommendations from the multiple clinical-practice guidelines that a CDS system could apply?
  6. CDS is often implemented poorly, resulting in dissatisfaction, if not outright annoyance. What are the human factors that need to be taken into consideration in implementing CDS effectively? Discuss issues and approaches to enhancing usability. What are situations in which graphics and visualization might be used? How can CDS be used to enhance rather than to impede workflow? What are strategies to help avoid unintended consequences of poorly implemented CDS?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- How can computers improve the delivery of in-class and self-learning, as well as in-practice learning?
- How can different approaches to learning be implemented using computers?
- How can simulations supplement students' exposure to clinical practice?
- What are the issues to be considered when developing computer-based educational programs?
- What are the significant barriers to widespread integration of computer-aided instruction into the medical curriculum?

## 25.1 Introduction

---

The application of digital technology to health science education is a sub-field of biomedical informatics. It includes the application of all aspects of information and computer technology to the content and delivery of education, as well as to research on the improvement and efficacy of education. Healthcare requires constant learning, with its practice in a multidisciplinary team environment in an information-rich world. Digital technology offers new approaches to learning that:

- increase engagement and retention of knowledge,
- allow personalization of knowledge delivery,
- enhance collaboration through connectivity,
- support learning any time and anywhere,
- make available the increasing volume of knowledge,
- support learning of evidence-based clinical practice, and
- enhance research through collection and analysis of large volumes of learner data.

In this chapter, we first discuss approaches to teaching and learning with digital technology. That section includes material about theories

of learning, digital technologies for learning environments, and an overview of learner audiences. We then transition to digital learning systems, which includes learning management systems, learning content creation systems, **just-in-time learning** systems and performance support, usability and accessibility, interoperability standards, digital content and assessment of learning. Finally, we discuss future directions and challenges for the application of digital technology in health science education.

## 25.2 Approaches to Teaching and Learning with Digital Technology

---

The continual rapid increase in health sciences knowledge requires a shift in learning methods both by the health sciences student as well as the health professional. Decades earlier, memorization and recall of facts were a primary, and sufficient, learning goal. Current learning approaches require learning the basic concepts and methods of a discipline but, in addition, emphasize the ability to integrate knowledge and to solve problems in the context of everyday healthcare.

### 25.2.1 Theories of Learning

---

Understanding how digital technology can support learning in the health sciences begins with an appreciation of how people learn. This understanding provides a foundation for thinking about the learning process and how it is shaped by context, purpose, goals, complexity, and the diversity of learners.

At its most basic, learning involves a change in how a learner perceives and understands some part of their world. The term schema is commonly used, in **cognitive science**, to describe the cognitive frameworks the people use to organize the information they have and their beliefs about a particular concept, activity, or experience. Schemas help us quickly assess a situation and act

appropriately. When individuals encounter new information, they try to incorporate it into their existing schema to enhance their understanding.

If new information contradicts the learner's existing knowledge or beliefs, the learner adjusts in one of two ways. They may accept the new information as valid, and modify their schema accordingly. Alternatively, they judge the new information as invalid, unimportant, or irrelevant, and they do not adapt their schema to account for this new information. When strong existing schemas keep individuals from accounting for new, valid information it can be very difficult for them to make changes such as altering unsafe procedures or adopting new safety protocols. To encourage such knowledge and behavioral change, it is important to explicitly address existing misconceptions and support learner motivation to change.

Changes in schema presume that individuals actively construct their own meaning through the interactions they have with information, other people, and the environment around them. This **constructivist** approach argues that individuals are not blank slates and bring their own history and experience to every learning situation. It is also important to recognize that this construction is an inherently social and situated process. Often learners are learning together in classes, groups, or teams. The conversations and shared experiences with others provide interpersonal cognitive and affective context for the learning process, and can shape the direction and scope of knowledge construction.

Digital technology can support a variety of approaches to learning. A common approach is didactic teaching, a one-way transfer of information through lectures, presented online via technologies such as recorded digital video. This approach has the advantage that new, as well as remedial, material can be made available, with additional links to in-depth content. A considerable amount of the available digital content is didactic, though it is usually enhanced with various activities for active learning. Active learning approaches, on the other hand, focus on engaging learners in the learning process by having them interact with

the content, with each other, and in reflection on what and how they are learning. Research has shown that instructional approaches that promote active learning consistently outperform transmission-only approaches at a statistically significant level (Freeman et al. 2014).

Flipping classes is a relatively recent strategy for encouraging active learning. Instructors flip the class when they provide the instruction, traditionally delivered through in-class lecture, online and the class time is devoted to active learning which replaces the majority of traditional homework. The homework becomes doing what needs to be done to prepare for the in-person class. Flipped classes are similar to hybrid or blended classes where the seat time that would be used for lecture is focused on active learning instead. Faculty engage with learners through case discussions, problem solving, and deep dives to further understand the content learned outside the classroom.

### 25.2.2 Digital Technologies for Learning Environments

Much, if not most, of today's learning content is delivered digitally. This is evident in the tools that are used within and outside of the classroom, for on-the-job training, in specialized learning facilities and elsewhere. In the classroom, learning content such as PowerPoint slides, Prezi presentations, websites, **simulations**, games and other digital media are often projected using digital projectors or delivered directly to the devices of learners, such as smartphones, tablets and laptops. Audience interaction methods, such as Web-based surveys, shared digital whiteboards or student/audience response systems, can help learners interact with the learning content, the instructor(s) or fellow learners.

The **classroom technologies** and device ecology accessible to teachers and learners can extend the learning experience seamlessly beyond the classroom. For instance, videoconferencing allows individuals to attend lectures remotely, raise their hand and ask a question. Depending on the teaching style, this remote participation may approximate face-to-face attendance fairly closely or fall

■ **Fig. 25.1** A life-size reconstruction of a digital human is viewed in a horizontal computer screen or “digital table”. With finger gestures, learners can identify structures, remove layers of tissue to make vessels, nerves and bones visible, or rotate the body. Additional functions at the edges of the table allow further viewing and measurement functions. Clinical cases, with anatomy reconstructed from radiologic images, such as CT and MRI, allow study of actual cases. (Courtesy of Anatomage Inc., with permission)

far short of it. Collaborative technologies, such as instant messaging, group **chats** or collaborative editing tools, can help bridge physical separation, and enable efficient and effective virtual group work.

Such collaborative work can also happen asynchronously and provide flexibility (within limits) to learner schedules. **Discussion lists**, **messaging boards** and collaboration sites enable episodic, time-independent contributions from and interactions with learners.

Some time ago, using advanced technologies, such as simulations, virtual reality and augmented reality, required a trip to a specialized facility, such as a **simulation center** or “virtual reality cave.” However, with devices such as Oculus or HTC Vive, such experiences are now available almost anywhere.

Last, social media such as Facebook, Google Hangouts, Twitter, Snapchat and Instagram have found important uses in education, ranging from real-time updates on projects to sharing experiences on a field-trip.

## 25.3 Overview of Learner Audiences

As discussed above, education in medicine, nursing, pharmacy, dentistry and other health professions is shifting from a focus on knowledge acquisition to competency-based education (Englander et al. 2013). Educational technologies are well positioned to support this

transition, but only if they take the specific context of learners and their goals into account. We therefore discuss learner audiences and their particular needs in the following sections.

### 25.3.1 Undergraduate and Graduate Health Care Professions Students

Basic science programs in medical schools were among the first to implement technology-supported learning. Visually rich content in anatomy, neuroanatomy and pathology was much more accessible on the computer than through the microscope or via the cadaver dissection room (■ Fig. 25.1). Excellent 3D learning programs for anatomy are available, such as Netter 3D Anatomy, Primal Pictures, VH Dissector, Anatomage Table,<sup>1</sup> and other products, providing ever more accurate visualization of the human in three dimensions. The use of microscopes in fields such as histology and pathology education has virtually disappeared. Interestingly, in many schools, the use of cadavers has seen a resurgence, both as an important learning tool and as a rite of passage into the health care profession.

1 Netter 3D Anatomy: ► <http://netter3danatomy.com>; Primal Pictures: ► <https://primalpictures.com>; VH Dissector: ► <https://www.toltech.net>; Anatomage: ► <https://www.anatomage.com>

Nursing schools have moved quickly to expand their use of technology in education. For instance, digitally-enhanced physical **mannequins** for simulation of realistic nursing **scenarios** are widely-used learning tools. Many nursing schools that used to share a simulation center with a medical school have found their own demand high enough to require building their own simulation centers.

Dental schools often share a part of their curriculum with medical schools, and as a result use the same or similar learning content. However, they also need specialized anatomical and simulation content for dental and craniofacial topics. 3D software for dental anatomy is used widely in pre-doctoral dentistry. Historically, simulation of dental procedures was practiced using physical objects such as chalk or plastic teeth, a practice that is still widespread. More recently, high fidelity digital simulators have been developed.

For many years, teaching hospitals had patients with interesting diagnostic problems such as “unexplained weight loss” or “fever of unknown origin”. This environment allowed for thoughtful “visit rounds,” at which the attending physician could tutor the students and house staff, who could then go to the library to research the subject. A patient stayed in the hospital for weeks as testing was pursued and the illness evolved. In the modern era of restricted insurance payments, managed care, and reduced length-of-stay, this opportunity for learning in the hospital environment, has vanished for most junior students. The typical patient in today’s teaching hospital is multi-morbid, usually elderly, and commonly acutely ill. The emphasis is on short stays, with diagnostic problems handled on an **outpatient** basis, and diseases evolving at home or in chronic care facilities. Thus, the medical student is faced with fewer diagnostic challenges suited to their level of knowledge, and has little opportunity to see the evolution of a patient’s illness over time.

One response of medical educators has been to try to move teaching to the outpatient setting; another has been to use **problem-based learning** and computer-simulated **virtual patients**. *Problem-based learning (PBL)* is a pedagogical approach where each small

group of students is given a clinical problem and they engage in discussion to develop an understanding of the problem, identify relevant knowledge, seek required knowledge using online and library research, discuss and challenge each other’s interpretations, and settle on a solution to the problem. PBL is widely used in undergraduate clinical learning, teaching students self-directed learning, reflection, and teamwork. An interesting analysis of PBL by a student is available at Chang (2016).

*Computer-simulated patients* allow a full range of diseases to be presented and allow the learner to follow the course of an illness over any appropriate time period. Faculty can decide what clinical material must be seen and can use the computer to ensure that this core curriculum is delivered. Moreover, with the use of an “indestructible patient,” the learner can take full responsibility for decision making, without concern over harming an actual patient by making mistakes. These simulated patients may be fully virtual, or may be computer-enhanced physical mannequins.

### 25.3.2 Practicing Health Care Providers

---

Health Sciences education does not stop after the completion of formal training. The science of medicine advances at such a rapid rate that much of what is taught rapidly becomes obsolete, and it has become obligatory for health professionals to be lifelong learners, both for their own satisfaction and, increasingly, as a formal requirement to maintain their professional certification. Therefore, online courses and online certification examinations have become increasingly common for maintenance of certification. An additional advantage of online certification is the automatic tracking of learner performance, and the accompanying automatic generation of certificates and institutional compliance reports.

Health professionals are also required to demonstrate clinical competence through their performance in simulated clinical scenarios. **Advanced Trauma Life Support** and **Advanced Cardiac Life Support** are some of the areas in which clinical competence is dem-

■ **Fig. 25.2** A screenshot of the SimSTAT simulation used for Maintenance of Certification by the American Society of Anesthesiologists. In a simulation of an operating room, the anesthesiologist ventilates the patient who is lying on the operating table. The simulation is viewed by the learner on a computer screen while the learner plays the role of the anesthesiologist. The learner guides the on-screen anesthesiologist to care for the unconscious patient by clicking on desired interactions,

such as the equipment in the room or the icons at the bottom of the screen. Through these interactions, the learner can control the level of sedation, give medications, fluids, and gases, and monitor the patient's physiologic status. The inset screen on the top left is a monitor for the patient's vital signs. The inset screen on the top right is the display from the anesthesia machine. (Courtesy of CAE Healthcare, Inc., with permission)

onstrated through actual participation in on-site scenarios. Online simulation of these and other scenarios can be used as preparation for testing in a live, crisis scenario. Some specialties, such as anesthesiology, have developed sufficiently rich online simulations in their specialty, with real time assessment, that they can reduce the requirement for use of live scenarios (■ Fig. 25.2).

### 25.3.3 Patients, Caregivers, and the Public

For those outside the health science professions, there is no systematic way to learn how to be a knowledgeable patient or home-based caregiver, or how to effectively communicate with a health care provider. For the provider interacting with the patient, the need to understand the patient accompanies the need to problem-solve. These changes in health care

delivery are occurring slowly, and technology, particularly simulation and role playing, will be part of this change (Zaharias 2018).

Meanwhile, healthcare information is widely available to the general public, with the most reliable information being on web sites affiliated with federal library resources such as **Medline Plus**, academic organizations, professional societies or federal health agencies. Online courses, both free and paid, are also available, many from traditional universities or other online education organizations. Interactive learning applications, however, are not widely available to the public though they are able to provide more engaging learning.<sup>2</sup>

2 ▶ <https://www.nih.gov/health-information>; ▶ <https://medlineplus.gov>; ▶ <https://www.cdc.gov>; ▶ <https://www.medscape.com>; ▶ <http://www.diabetes.org>; ▶ <https://www.heart.org/en/health-topics>; ▶ <https://my.clevelandclinic.org/health>; ▶ <https://www.mayoclinic.org>

Improving the patient's health literacy has become an important approach to providing higher quality health care. Failure to comply with medication regimes, exercise plans, or hospital discharge instructions are a major cause of return visits to the hospital or clinic. Patient and family caregiver education, leading to better understanding of clinical instructions, could result in a more effective partnership between the patient and the healthcare provider (Nelson 2016) (see ► Chap. 11). Online learning resources are one approach to alleviating the compliance problem.

In the next section, we take a close look at how digital learning content is created and delivered.

## 25.4 Digital Learning Systems

### 25.4.1 Learning Content Management Systems

A **Learning Content Management System (LCMS)** is a software platform that allows learning content creators, such as faculty, to create, manage, host and track changes in digital learning content. Prior to the development of LCMSs, educational content creators had to assemble several separate and disparate items to create rich, engaging learning content. LCMSs, on the other hand, are one-stop platforms that integrate a wide variety of tools for content creation. They overlap with Learning Management Systems (LMS, described below) in that both support content hosting and delivery. However, LCMSs specialize in tools to create, manage and update content.

Personally created course content may be a web site or a blog, created by a faculty member on any of a range of web site or blog creation tools. Other personal content creation tools include tools for quiz item development, capturing video lectures or demonstrations, and creation of interactive animations or games. The only requirement is that the content files be compatible with the LMS, so that the content can be uploaded to the LMS and

deployed to all learners without any need for special integration programming.

Collaborative content creation can be another powerful approach to learning. As opposed to structured content that is created by faculty or a similar creator, collaborative, learner-generated content is informal and created on the fly, for instance in a discussion forum. Structured discussion groups which encourage students to provide their thinking on the discussion questions, and to comment on content from other learners, are useful tools to support learning through active participation, argument, and reflection. Video conferencing tools, such as Zoom and Skype, support real-time discussion and collaboration, and can be content creation tools if there is a repository of the content.

When the content to be created is sufficiently complicated, requires strict adherence to organizational policy, or requires a range of skill sets and significant expense, it becomes necessary to approach it at the level of the enterprise. For example, the **American Heart Association** has developed courses for cardiac life support that are required training in the United States and many other countries.<sup>3</sup> These programs are created by teams, with each person providing a different skill, such as graphic design, programming, or content knowledge, rather than by an informal collaboration of learners with similar skills.

### 25.4.2 Learning Management Systems

A **Learning Management System (LMS)** is a repository of learning content, an interface for delivering courses and content to learners, and a platform for the course creator or administrator to track learner engagement and performance. From the learner's viewpoint, the LMS provides a single login access to all courses that they may need. Once within

<sup>3</sup> American Heart Association's ACLS, BLS, and PALS courses: ► <https://elearning.heart.org/courses>

a course, the learner can access content, such as text, videos, quizzes, games, handouts and assignments. The LMS may include administration features for the learner to select courses, register or join a wait list, pay for each course, and track their grades. It may also include resource sharing and collaboration between learners. From the faculty's point of view, the LMS allows uploading and modification of course content, as well as a dashboard for viewing the performance of learners, groups and classes as a whole. LMS features may include various statistics, such as usage of course components or the performance of the class on individual test items.

Higher education institutions provide a relatively structured curriculum to well-defined learner populations. Their needs typically are served by educational LMS applications such as Blackboard Learn, D2L Brightspace, Moodle, or Canvas (Dahlstrom et al. 2014). Medical centers and corporations often use LMSs that are more suited to corporate needs. Typically, the most important requirement of such an LMS is tracking learner compliance with required training, and export of reports for regulatory and accreditation purposes. There are numerous enterprise-oriented LMSs. Some common ones are Captivate Prime, TalentLMS, and Totara, but market leadership of LMSs changes continually.

### 25.4.3 Just-in-Time Learning Systems and Performance Support

Learning also occurs outside of formal learning contexts. This “just-in-time learning” happens on demand, for instance when learners need instant information at a critical moment, or something goes wrong and they need to know what to do next. Instant information can provide immediate help, or *performance support*, but can also be considered a learning opportunity. A particularly powerful approach is to make these tools accessible when and where they are likely needed, for instance in online help areas of electronic medical records.

Examples of performance support or just-in-time learning tools include:

- job aids, such as check lists, quick reference cards, and handouts;
- protocols and templates, such as the SBAR (Situation, Background, Assessment, Recommendation and Request) technique for communicating critical information;
- resource or policy documents;
- video and audio recordings, such as brief demonstrations of care procedures, particularly helpful for home-based care providers; and
- animations, simulations, and learning modules that include brief instructions, demonstrations, or explanations.

### 25.4.4 Interoperability Standards

The education enterprise process includes many parts, such as content, curriculum, LMSs, learner profiles, assessment, certification, and others. These parts are often supported by different tools and platforms that need to work together seamlessly. To enable this seamless environment, tools and platforms need to be interoperable, without the need for custom programming for integration. In this chapter, we discuss some of the interoperability standards in education (see ► Chap. 7).

Historically, the commonly used standard for such learning object interoperability was the Shareable Content Object Reference Model (SCORM).<sup>4</sup> It defines how a content object (a course) should be packaged and described, how it should be launched, and how data should be communicated between the LMS and the content package. A SCORM-compatible content object can be published to and played back from any SCORM-compatible LMS. SCORM can report on course completion and time spent. SCORM was last updated in 2009 and, as a standard, has not kept up with changing technology. However, it is still one of the most widely used standards for learning object interoperability.

4 SCORM: ► <https://scorm.com/>

The newer **xAPI** standard (aka TinCan API)<sup>5</sup> is much more robust in terms of analytics and mobile deployment. The drawback to xAPI is that it does not integrate with older LMSs and tends to be costly to deploy, often requiring professional development assistance.

With the rapid growth in the use of learning management systems in higher and continuing education and workplace learning, it has become critical to have interoperability standards that provide integration of web-based learning objects and applications. Learning Tools Interoperability (LTI)<sup>6</sup> is a standard developed by the IMS Global Learning Consortium to provide a means for seamless and secure pass-through of student credentials and grades between the LMS and the external application. LTI tools are usually web-based applications written in a server-side language which can serve a variety of purposes. These include, but are not limited to, hosting and serving video with quizzing, providing access to interactive learning materials from textbook publishers, allowing learners to create media, use specialized programs, and collaborate in integrated development environments (IDE), whiteboarding and mind mapping applications, or videoconferencing.

Other interoperability standards address various education services. For example, the **Medbiquitous**<sup>7</sup> organization has developed a Curriculum Inventory Data Exchange Standard that is being used by the Association of American Medical Colleges to collect and collate curriculum data from all its medical schools and map these curricula to competency requirements. Other Medbiquitous standards include the Educational Achievement Standard to document learner competency used by numerous medical certification organizations, and the Virtual Patient Standard to enable exchange of virtual patient simulations across institutions.

There has also been an interest in the exchange of education components, specifically learning content modules, between institutions. A number of content collections have been developed, with the most well-known being MERLOT. Standardized descriptions of learning objects, known as Learning Object Metadata, were developed, but exchanging and repurposing individual learning objects did not become commonplace. However, an interesting by-product was a standardized way to describe items in a content collection, to manage a library of learning objects and to track learner use of those objects. Another example of a repository of shared learning resources is the AAMC's MedEdPORTAL<sup>8</sup>, which is peer-reviewed and contains both patient cases and clinical scenarios.

#### 25.4.5 Usability and Access

Usability and access are important considerations in developing educational software (see ► Chap. 5). About 1 in 50 adults have some form of vision or hearing disability, and need alternate or augmented access to digital learning content. Two standards, Section 508 of federal law (508)<sup>9</sup> and the World Wide Web's Web Content Accessibility Guidelines (WCAG),<sup>10</sup> address use of digital content by people with disabilities.

Section 508 specifies that digital information provided by or to the government must be accessible if there is "no undue burden". In practice, designing accessible online content requires use of techniques available in current web design, such as the "Alt Text" tag for graphics, and indications to make the user interface more visible or audible. Adherence to Section 508 becomes more difficult in more complicated applications, such as 3D **immersive environments** and dynamic simulations,

5 xAPI: ► <https://xapi.com/overview/>

6 LTI: ► <https://www.imsglobal.org/activity/learning-tools-interoperability>

7 Medbiquitous standards: ► <https://medbiq.org/standards>

8 AAMC's MedEdPORTAL: ► <https://www.mededportal.org>

9 Section 508: ► <https://www.section508.gov/manage/laws-and-policies>

10 WCAG: ► <https://www.w3.org/WAI/standards-guidelines/wcag/>

requiring creative solutions to presentation and interface requirements.

WCAG is a set of formal guidelines on how to develop accessible web content. It does not address non-web digital content.

## 25.5 Digital Content

Digital content, unlike a typical textbook or lecture, can be interactive. Three levels of interactivity are typically possible:

- Level 1: The content includes text, graphics and video but interaction is primarily through clicking to move to the next chunk of content. This level may include simple quizzes such as multiple choice or true/false questions. Much of digital learning content consists of web pages or applications that incorporate this style of expository material.
- Level 2: The content includes multimedia such as audio, video and animations. The interactivity supports simple puzzles and games, like sorting and matching. The cost of development is higher than for Level 1, but the content is more engaging.
- Level 3: The content presented is very rich, including realistic three-dimensional environments and characters, or even immersive virtual reality (▶ Fig. 25.3).

▶ **Fig. 25.3** A screenshot of a Level 3 interactive application, BattleCare. The learner can select tools from the medical kit on the right, and drag them onto the simulated patient to clean and compress the wound or to listen to heart and lung sounds. (Courtesy of Innovation in Learning, Inc., with permission)

Interaction happens through games or simulations, with the content evolving based on the choices and decisions made by the learner.

### 25.5.1 Text/Image/Video Content

Much of digital learning content consists of web pages or applications that incorporate expository material, using text, graphics and video, and Level 1 interaction. Although much of the focus of computer-based teaching is on the more innovative uses of technology to expand the range of available teaching modalities, computers can be employed usefully to deliver didactic material, with the advantage of the removal of time and space limitations. For example, a professor can choose to record a lecture and to store the digitized video of the lecture as well as related slides and other teaching material, and upload this content to the institution's learning management system (see Section on LMSs.) This approach has the advantage that relevant background or remedial material can also be made available through links at specific points in the lecture. The ease of creating online video lectures has led numerous universities and corporations to provide libraries of recorded lectures for study by learners at their own convenience.

Many refinements have been developed that use technology to optimize the delivery of didactic or expository content. *Microlearning* is the presentation of brief segments of content, typically ranging from 5 to 15 minutes in duration. *Spaced repetition* is the repeated presentation of select content to optimize its retention. *Mastery learning* is a process of testing the learner for competence in a segment of content before they are allowed to progress to the next. The Khan Academy,<sup>11</sup> which includes healthcare content in its catalog, uses brief videos to teach single or small groups of concepts. In this micro-learning approach, the learner can select and complete

<sup>11</sup> Khan Academy, Health and Medicine: ▶ <https://www.khanacademy.org/science/health-and-medicine>

topics with a limited investment of time, and can demonstrate mastery.

**Massively Online Open Courses** (MOOCs) bring free-to-view, world-class university courses to a global audience. The first major MOOC, Introduction to **Artificial Intelligence**, launched with an astonishing 160,000 subscribers. The structure of the first courses was similar to a typical university course, with lectures released at the same time as they would be taught to an in-person class on campus, along with assignments and final examinations that needed to be turned in on time. Course support was provided by peer support through student discussion groups. Some MOOCs now require fees for certification of completion of courses. Private companies have sprung up providing support to students around selected MOOC, an indication of the ecosystems that develop around interesting technologies. EdX is a MOOC delivery platform launched by the Massachusetts Institute of Technology and Stanford University. Coursera, Udacity and FutureLearn are major private MOOC platforms.<sup>12</sup>

### 25.5.2 Interactive Content

Teaching programs differ in the degree to which they impose structure on a teaching session. In general, drill-and-practice systems are highly structured. The system's responses to students' choices are specified in advance; students cannot control the course of an interaction directly. In contrast, other programs create an exploratory environment in which students can experiment without guidance or interference. For example, a neuroanatomy teaching program may provide a student

with a fixed series of images and lessons on the brainstem, or it may allow a student to select a brain structure of interest, such as a tract, and to follow the structure up and down the brainstem, moving from image to image, observing how the location and size of the structure changes.

Each of these approaches has advantages and disadvantages. Fixed path learning programs ensure that no important fact or concept is missed, but they do not allow students to deviate from the prescribed course or to explore areas of special interest. Conversely, programs that provide an exploratory environment and allow students to choose any actions in any order encourage experimentation and self-discovery. Without structure or guidance, however, students may waste time following unproductive paths and may fail to learn important material, resulting in inefficient learning.

An example is the Tooth Atlas, used in dentistry. Understanding the three-dimensional structure of teeth is important for clinical dentistry. The key instructional objective of the program is to help students learn the complex external and internal anatomy of the variety of teeth in three dimensions. The rich, interactive 3D visualizations show teeth as they would be visually perceived as well as through very high resolution computed tomography scans, radiographs and physical cross-sections. The learners can rotate and section the computed models, and can control the transparency of each structure so as to study inter-relationships. While the visualization is highly exploratory, the embedded pedagogy is very structured, consisting of detailed textual quizzes with multiple-choice answers.

### 25.5.3 Games

A learning game places learning content within a digital video game. The game play experience engages and entertains the learner

12 Mulgan G, Joshi R. Clicks and mortarboards: how can higher education make the most of digital technology? November 2016. ► [https://media.nesta.org.uk/documents/higher\\_education\\_and\\_technology\\_nov16\\_.pdf](https://media.nesta.org.uk/documents/higher_education_and_technology_nov16_.pdf)

while certain steps in the game instill desired content knowledge. In a learning game, the learning content is embedded in the game. Gamification, on the other hand, has elements such as a score, achievement badges, or a “leader board”, to add excitement to an otherwise routine learning experience.<sup>13</sup>

A game has the following components: a goal, such as finding the best treatment for a patient; a setting, such as a three-dimensional rendition of an emergency department; game play, such as the information, tests, procedures, and medications available; and game mechanics, such as accessing game play elements by drawing up medication in a syringe or selecting a medication dosage from a menu. Successful resolution of a clinical problem can give the same satisfaction as an enjoyable game. However, to be considered a game, there need to be challenges, such as conquering “enemies” or accomplishing “quests”, evolving clinical problems, or a restricted availability of supplies and personnel, that must be overcome, as well as a clear criterion of success. To be a learning game, actions during game play should result in learning, either by exposure of a nugget of information, by **feedback** from a mentor embedded in the game, or by trying alternative medical approaches to find an effective treatment.

Numerous learning games have been developed for all aspects of healthcare education but the evidence for their efficacy is not clear (Gorbanev et al. 2018). Funding for efficacy research is limited, and is one reason for the paucity of rigorous studies (Reed et al. 2007). Game development that has a clear learning goal, and has been informed by research during the design stage as well as during development of the game play, has been shown to be both engaging and an effective learning tool (Kato et al. 2008) (▣ Box 25.1 and ▣ Fig. 25.4a and b).

### 25.5.4 Cases, Scenarios and Problem-Based Learning

The learner is presented with a story that includes a clinical problem. The presentation may be only in text, with text and graphics, in a near-realistic three-dimensional environment, or even in an immersive virtual environment, with correspondingly varying levels of interactivity. The learner’s role may be constrained such that the learner knows who they represent, what resources are available, and what problem must be solved. Alternatively, the learner may be required to investigate the situation (examine the patient), define the problem, find any supporting resources (what imaging and laboratory tests are available or what learning resources are at hand) and guide the scenario to an end goal. As the learner proceeds, the scenario evolves on the computer, based on the actions taken and the progress of time.

Prognosis is a case-based program with over 500 cases covering most specialties (▣ Fig. 25.5). Each case begins with a brief story of the clinical presentation. The learner must choose among available tests, diagnoses and treatments, and then receives feedback on the choices made, as well as the preferred or optimal choices. The presentation and interactivity are very simple, and the cases brief, but the engagement provided by the clinical puzzle has made this a popular program among medical students and residents.

An approach that combines the benefits of exploration with the constraint of a linear path through the material is one that breaks the evolving scenario into a series of short vignettes. A situation is presented, information and action options are available, and a decision must be made. Each decision triggers the presentation of the next vignette. This could lead to a branching story line but, usually, the next vignette presents the result of the best actions from the previous vignette. A scenario about a virtual patient could have vignettes that lead the learner through the steps of diagnosis, tests, and the course of treatment. This approach is commonly used in computer-based testing of

13 A leader board is a list of players with the highest scores. Players compete to be among the high scorers.

### Box 25.1 “Re-Mission: Fighting Cancer with Video Games” (► <http://www.re-mission2.org/>)

Re-Mission 2 games help kids and young adults with cancer take on the fight of their lives. Based on scientific research, the games provide cancer support by giving players a sense of power and control, and encouraging treatment adherence. Each game puts players inside the human body to fight cancer with an arsenal of weapons and super-powers, like chemotherapy, antibiotics and the body’s natural defenses. The game play parallels real-world strategies used to successfully destroy cancer and win.

Re-Mission 2 games are designed to:

- Motivate young cancer patients to stick to their treatments by boosting self-efficacy, fostering positive emotions and shifting attitudes about chemotherapy. These factors were key drivers of the positive health behavior seen with the original Re-Mission game
- Appeal to a broad audience by offering a variety of gameplay styles; and
- Tap into the popularity of casual games, playable in short bursts or at length, to provide cancer treatment support through fun, engaging play.

The games incorporate key insights from years of scientific studies and qualitative user research with adolescent and young adult cancer patients. An outcomes study showed that the original Re-Mission game improved treatment adherence and boosted self-efficacy in young cancer patients. The *Re-Mission Attitudes Study in the Brain* used fMRI technology to show how interactive gameplay impacts the brain to motivate positive behavior change (Kato et al. 2008).

■ **Fig. 25.4** Screenshots from opening screens of Re: Mission 2. **a** In “Nanobot’s Revenge,” players use an ever-increasing arsenal of powerful chemo attacks to crush the cancerous forces of the Nuclear Tyrant, firing targeted treatments on a growing tumor to pre-

vent cancer from escaping into the blood stream. **b** In “Nano Dropbot”, the player continues to kill cancer cells but also learns to recruit healthy cells in the fight

clinical knowledge where assessment of learner performance would be extremely difficult if the interactions were completely unconstrained.

The ability of the computer to track and store the learner’s actions allows post-processing and analysis of the tracked data. An interesting analytic capability is one that compares the performance of novice learners and experts to detect features that define expert information gathering or action sequences. Stevens et al. (1996) compared the information gathering and the conclusions of

novices and experts on a set of immunological cases. Using neural nets to process the tracking data, they detected consistent differences in the problem solving approach of novices compared to experts. In particular, novices exhibited considerably more searching and lack of recognition of relevant information, while experts converged rapidly on a common set of information items. The potential of using such expert patterns of performance to educate novice learners has not been widely explored in the health sciences.

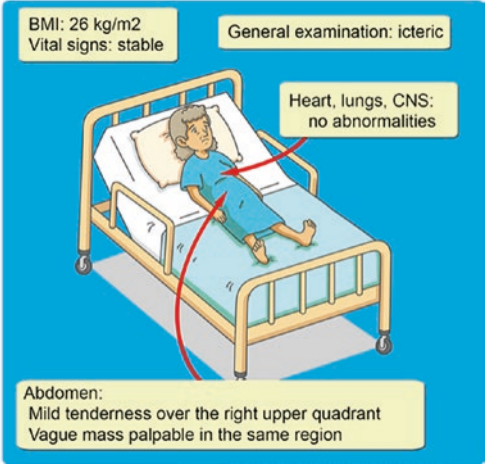

## Yellow 2

● Clinicals
● Investigations
● Management
● Finish

A 60-year-old woman presents with persistent jaundice, pruritus, and dark urine for two weeks, in a background of nausea, vomiting, and intermittent upper abdominal pain for four weeks, and a 15kg weight loss over three months.

Her medical, surgical, allergic, and family histories are unremarkable. She only drinks socially, does not smoke, and has never used recreational drugs. There is no history of recent foreign travel.

A complete blood count is found to be within normal parameters.

**BMI:** 26 kg/m2  
**Vital signs:** stable

**General examination:** icteric

**Heart, lungs, CNS:** no abnormalities

**Abdomen:**  
Mild tenderness over the right upper quadrant  
Vague mass palpable in the same region

■ **Fig. 25.5** Screenshot from the case-based program, Prognosis. The learner is presented with a summary of the case. The simple graphic presents physical examination information in a similar format for each case. The following screen offers options for laboratory, imaging and other investigation options. The learner selects the

management plan and receives summary feedback on the success or failure of the plan. The case ends with a review of the disease background and optimal management, including relevant references. (Courtesy of Medical Joyworks, LLC, with permission)

### 25.5.5 Simulations – Virtual Patients

Clinical training has been shown to benefit from the use of simulations to engage the learner (Gaba 2004; Aebersold 2018; Jeffries 2005). Learning is most effective when the learner is engaged and actively involved in decision making. The use of a simulated patient presented by the computer can approximate the real-world experience of patient care and focuses the learner's attention on the subject being presented (Huang et al. 2007). The Association of American Medical Colleges has prepared an informational summary of the value of and the issues around issues of using simulation for education.<sup>14</sup>

Talbot et al. (2012) present an analysis of the range of presentation and interactivity avail-

able in Virtual Patients. These simulations may be either **static** or **dynamic**. Under the static simulation model, each case presents a patient who has a predefined problem and set of characteristics. At any point in the interaction, the student can interrupt data collection to ask the computer-consultant to display the differential diagnosis (given the information that has been collected so far) or to recommend a data collection strategy. The underlying case, however, remains static. Dynamic simulation programs, in contrast, simulate changes in patient state over time in response to students' diagnostic or therapeutic decisions. Thus, unlike in static simulations, the clinical manifestations of the dynamic simulation can be programmed to evolve as the student works through them. These programs help students to understand the relationships between actions (or inactions), and patients' clinical outcomes. To simulate a patient's response to intervention, the programs may explicitly model underlying physiological processes and use math-

■ **Fig. 25.6** Screenshot from Timeout Training, a mobile training application. This illustrates a time-out dialog between the learner (a resident) and the nurse, prior to initiating a thoracentesis intervention. The learner selects from one of the presented dialog options. Careful design of dialog options can help in learning nuances of dialog possibilities as well in proper sequencing of a dialog. (Courtesy of Innovation in Learning, Inc., with permission)

emational models. An example of a dynamic simulation of a virtual patient is SimSTAT (see ■ Fig. 25.2), an operating room simulation that is used by the American Society of Anesthesiologists to train practicing anesthesiologists in the diagnosis and management of crises in the operating room.

Virtual Patients can be as simple as Prognosis, described above, or can be richly complex, simulating a complete encounter with a patient in a clinic or hospital room. Simulation of a conversational interaction with the patient or another character can be an important aspect of learning using a virtual patient (■ Fig. 25.6).

### 25.5.6 Simulations – Procedures and Surgery

**Procedure trainers** or part task trainers have emerged as a new method of teaching, particularly in the teaching of surgical skills. This technology is still under development, and it is extremely demanding of computer and graphic performance. Early examples have focused on endoscopic surgery and laparoscopic surgery in which the surgeon manipulates tools and a camera inserted into the patient through a small incision. In the simulated environment, the surgeon manipulates the same tool controls, but these tools control

simulated instruments that act on computer-graphic renderings of the operative field. Feedback systems inside the tools return pressure and other **haptic sensations** to the surgeon's hands, further increasing the realism of the surgical experience.

Commercially available trainers are now in use for many surgical procedures. For example, the 3D Systems company provides a line of Symbionix simulators for training in laparoscopy, endoscopy, and hysteroscopy.<sup>15</sup> Other simulators are now available for all levels of surgery, beginning with training in the basic operations of incision and suturing, and going all the way to robotic surgery.

### 25.5.7 Simulations – Mannequins

Physical simulations of a patient, in an authentic environment such as an operating room, have evolved into sophisticated learning environments. The patient is simulated by an artificial mannequin with internal mechanisms that produce the effect of a breathing human with a pulse, respiration, and other vital signs (■ Fig. 25.7). In high-end simulators, the mannequin can be given blood trans-

15 ► <https://www.3dsystems.com/healthcare/medical-simulators>

fusions or medication, and its physiological response changes based on these treatments. These human patient simulators are now used around the world both for skills training and for cognitive training such as crisis management or leadership in a team environment

**Fig. 25.7** This plastic mannequin simulates many of the functions of a living patient, including eye opening and closing, breathing, heart rate and other vital signs. Gases, medications, and fluids can be administered to this mannequin, with resulting changes to its simulated vital signs. (Courtesy of Parvati Dev, with permission)

(**Fig. 25.8**). The environment can represent an operating room, a neonatal intensive care unit, a trauma center, or a physician's office. Teams of learners play roles such as surgeon, anesthetist, or nurse, and practice teamwork, crisis management, leadership, and other cognitive exercises.

A seminal study by Hayden et al. (2014) showed that 50% of nurse clinical training, in the Bachelor's program, could be replaced by training on mannequin simulators. This is particularly important both because of the range of cases that can be presented on the simulator, and because of the difficulty in obtaining clinical training time in hospitals.

### 25.5.8 Virtual Worlds

An extension of the physical human patient simulator is the **virtual world** simulation, with a virtual patient in a virtual operating room or emergency room. Learners are also present virtually, logging in from remote sites, to form a team to manage the virtual patient. Products such as 3DiTeams and Health TeamSpaces are

**Fig. 25.8** Three-dimensional computer-generated virtual medical environments are used to present clinical scenarios to a team of learners. Each learner controls a character in the scenario and, through it, interacts with devices, the patient, and the other characters. Learning

goals may include medical goals such as stabilization of the patient, communication goals such as learning to point out a problem to senior personnel, or team goals of leadership and delegation. (Courtesy of Innovation in Learning, Inc. with permission)

■ **Fig. 25.9** A combined image depicting a learner wearing virtual reality glasses, and the scene visible to the learner. The learner feels she is inside the operating room, viewing the procedure. (Courtesy of SimTabs, LLC., with permission)

being used to construct and deliver team training in such virtual medical environments.<sup>16</sup>

### 25.5.9 Virtual Reality

The use of **virtual reality** glasses, along with spatially accurate sound and virtual hands, creates an immersive experience that surpasses the experience of a three-dimensional world as seen on a computer screen on the learner's desk. The learner feels truly “inside” the experience. The resulting immediacy is so real that it manifests itself through physiologic changes such as a speeding of the learner's pulse and a total lack of awareness of the actual physical surroundings (■ Fig. 25.9).

There are two types of virtual reality in use at present. One is reality as represented by a completely synthetic three-dimensional environment, within which the learner navigates and acts. The other is represented as a 360° video of a real environment within which the clinical action has been recorded. The video virtual reality is useful for didactic training about procedures, such as new surgical methods, where the learner has a front row view as though they were actually present in the operating room.

Examples of simulations using virtual reality have been demonstrated by many universities and organizations. VR simulations of surgery (<https://ossovr.com>) and patient examination (<https://oxfordmedicalsimulation.com>) are in use in medical and nursing curricula. There are a few studies examining the learning efficacy of VR simulations (Kyaw et al. 2019). It is likely that the realism of virtual reality, its “face validity”, will result in its use in education even if rigorous efficacy studies are not available.

### 25.5.10 Augmented Reality

**Augmented reality** (AR) differs from virtual reality in that a real world is seen through the AR glasses while other information is overlaid on the world by the glasses. Information can be textual, such as heart rate and blood pressure data when looking at a physical mannequin. It can be graphic, such as an open wound seen overlaid on a person on a bed, simulating an injured patient. The AR overlay information changes depending on what is being viewed, creating a world of information on top of the real visible world.

Learning possibilities using AR are endless. A new nurse can walk into an empty operating room and “see” the contents of closets and drawers, thus being trained on the location of OR supplies. A nursing student can see a “pressure sore” evolve on the heel

16 ► [https://anesthesiology.duke.edu/?page\\_id=825623](https://anesthesiology.duke.edu/?page_id=825623), ► <https://healthteamspace.simtabs.com>

of a real person because of pressure on the heel in the bed. A medical student can “scroll” through the electronic medical record as they talk with a simulated patient.

AR in medical education is in its infancy but its applications are expected to be wide-ranging.

### 25.5.11 3D Printed Physical Models

**Three dimensional (3D) printing** is a novel application of printing. Slice data from an object, such as a CT image of a bone, is used to print a layer of solid material, such as plastic. Subsequent image slices are used for printing a cumulative stack of plastic slices until the entire object has been printed. The advantage of sequential printing of slices, instead of carving the shape from a solid block of plastic, is that hollow portions of the original object can be printed as holes in the slice data. A second advantage is that very complex objects can be printed using this technology.

3D models are beginning to be used for learning. For undergraduate students, **cadaver** dissection, **plastinated** specimens, and dried bone have provided the physical specimens. 3D models add a new option. For healthcare practitioners, patient-specific 3D models help in planning procedures, but they also help in educating the patient about their upcoming surgery. In a recent systematic review on surgical planning for congenital heart disease, the authors found that 25% of the studies showed 3D printed models were useful in medical education for healthcare professionals, patients, caregivers, and medical students (Lau and Sun 2018).

## 25.6 Assessment of Learning

Assessment of student learning compares educational performance with educational goals. Ideally, the content used for assessment resides within a curriculum and an educational program that has a clear set of educational goals. Therefore, student learning is measured (assessed) against these overall goals as well

as against the goals of the specific learning module. Without these goals, any assessment is without direction and its purpose may be a mystery to the learner.<sup>17</sup>

Assessment maybe **formative** (guiding future learning and promoting reflection) or **summative** (making a judgment about competence or qualification before being allowed to advance to the next level of study). Assessment can also be used by instructors and education program designers to identify whether the learning content can be improved, and brought closer to the identified learning goals (Epstein 2007).

Digital technology supports rich assessment both because of its ability to present many types of assessment tools, and because of its ability to track learner actions in great detail. Selected assessment methods are presented below.

### 25.6.1 Quizzes, Multiple Choice Questions, Flash Cards, Polls

Quizzes test the learner’s knowledge and, depending on the quiz format, the learner’s ability to solve problems. Quizzes can be presented as questions with single or multiple correct answers, or may require sorting and matching two sets of items. Digital technology simplifies the process of preparing, presenting and scoring quizzes, and can make them engaging and fun by adding imagery, animations and game-like success states.

Flash cards that present the question on one side of the card and the answer on the other can also be simulated using technology. The learner types their answer. Through simple word or phrase matching, the learner’s answer is matched to the expected answer, and scored based on the level of match achieved. For more complex answers, some level of natural language processing is required.

Polls are particularly useful for an instructor to assess, in real time, the current status of

<sup>17</sup> AAHE, ► <https://www.oxy.edu/sites/default/files/assets/AAHE9Principles.pdf>

learner understanding in the classroom. The poll question, and multiple answers, are displayed on the classroom screen. Each learner selects an answer on a smartphone or on a polling device. The poll responses are immediately collated and presented as a bar graph. If all or most of the learners select the correct answer, the instructor can assume that the topic has been understood. If the responses are distributed over two or more answers, then the instructor can pause to review the topic and clear up learner misconceptions or lack of understanding.

### 25.6.2 Branching Scenarios

---

A branching scenario is a structured approach to assessment using simulation. A mini-scenario or a choice of data resources (such as laboratory tests) is presented at each branch point, and the learner chooses one out of a set of available decisions or responses. One or more of the decisions may be correct. Based on each consecutive decision, the learner moves through a branched scenario and achieves a final outcome to the scenario. The learner can be assessed on each decision or on the final outcome. If the same material is presented in a learning mode, the learner may receive feedback about each decision.

### 25.6.3 Simulations

---

Simulations for assessment may use standardized patients (actors trained to represent patients), realistic interactive mannequins, on-screen simulations, or simulations presented in virtual reality. In all cases, technology can be used to track learner actions and to assess their performance (Ryall et al. 2016). In all except standardized patients, this tracking is built into the simulation, and can be extracted and analyzed for performance reporting. These more complex, scenario-based simulations, differ from branching

simulations in that a large number of decision choices are available to the learner at every moment. Thus the simulation is a more realistic representation of a clinical situation but is also correspondingly more difficult to score for assessment (Dillon et al. 2002).

### 25.6.4 Intelligent Tutoring, Guidance, Feedback

---

*Intelligent Tutoring Systems (ITS)* differ from other technology-based learning systems in that they offer individualization of the learning experience based on the learner's performance while using the system (VanLehn 2011). Because of their architecture, continuous assessment of the learner is essential to the operation of ITSs, with **guidance** provided as needed, placing ITSs in the domain of formative assessment. Typically, an ITS is built to replicate one-on-one, personalized tutoring.

Modern ITSs use natural language for dialog between the learner and the tutor (■ Fig. 25.10). Conversational dialog is more likely to uncover learner misconceptions or gaps in knowledge. As the student responds to the tutor's questions, the response is compared to the expected response using statistical methods that compare the conceptual similarity of the two pieces of text. An example of a conversational tutoring system is Autotutor (Graesser et al. 2004), which has been used for learning domains ranging from physics and mathematics to training nurses for mass casualty triage (Shubeck et al. 2016).

### 25.6.5 Analytics

---

Understanding and improving the process and outcome of education requires applying metrics into many facets of the educational process. With digital technology, measurement and resulting data availability has increased steadily. At the same time, educational institutions and businesses are beginning to develop

**Fig. 25.10** Screenshot of a conversation with an intelligent simulated tutor. The learner, a first responder, converses with a tutor who uses natural language to guide a student to give detailed answers using their own words. (Courtesy of Innovation in Learning, Inc., with permission)

methods to unlock potential uses of this vast amount of data.

A particularly desirable outcome is personalizing learning to each learner's needs. The many assessment methods described above can be applied to generate a profile of the learner's current knowledge state and to create a detailed list of topics to be learned. To implement such an adaptive system, the content itself must be itemized and tagged so that the learner's state can be mapped to the desired learning goal state, and content items can be delivered in an appropriate sequence to achieve optimal learning.

Data analytics can also be applied to individual courses, to identify topics most sought by students, and areas in which testing shows that students consistently fail. Such failure may indicate students' lack of knowledge, but it could also provide a clue to areas in which teaching could be improved.

At the institutional level, analytics is used extensively to match community and business needs to the design of degree and certificate programs by universities. Businesses also use similar analytic approaches to discover knowledge gaps among their workers, and to design programs to develop or upgrade worker skills as changes occur in their industries.

## 25.7 Future Directions and Challenges

As this chapter has shown, computers have played, and will continue to play, an increasingly important role in health sciences education. How will the rapid change and fluid nature of innovation influence how we use technology in education in the future? As we increasingly "digitize" almost all aspects of our lives, we can expect information technology to continue to weave itself more and more into the essential fabric of how we teach and learn.

How can digital technology help *advance* teaching and learning? Most faculty have embraced, or at least accepted, technology's growing role in education. Students often have higher expectations of technology use than most health sciences schools can fulfill. How computers can help improve education is a key question of interest to faculty and students alike. Faculty members are keenly interested in finding out how technology can help them become better teachers. Students want to know how computers can help them learn more efficiently and effectively. Current trends in digital learning indicate how some of these questions will be answered (Adams

Becker 2017).<sup>18</sup> The following are examples of some of the challenges that we can expect to encounter.

- *Digital content production and verification* remains an ongoing challenge. Digital learning content can range from inexpensive recording and streaming the video of a single lecture to very expensive and time-consuming creation of a rich and dynamic simulation of a disease process. Effective curation and distribution of high-quality content remains a challenge, with some healthcare faculty being reluctant to use content developed at other universities. An emerging trend that may increase use of existing content is to apply the methods of the “flipped classroom” to MOOC-based online courses. In this method, selected online content, from MOOCs or other sources, is assigned for study at home, and group time is used for instructor-led content discussion and problem solving. Such approaches can combine the best of online content with the strengths of classroom teaching by faculty, and it is possible that such hybrid or blended classes will become increasingly common.
- *Learning analytics* is a direct outcome of digital learning content and learning management systems. An immediate challenge is to utilize the available data to improve the healthcare education process at the level of the individual, the course, the curricula, and the institution, and to match this education process to the needs of today’s healthcare. A more far-reaching challenge is to use data as evidence to understand what works and why. In particular, we need to understand the best approaches to blended online and face-to-face learning, the uses of collaborative and project-based learning, and the role of simulations and experiential learning.
- *Real-time feedback*. Significant portions of pre-clinical training in healthcare require use of simulators. With embedded sensing and compute capability, and internet access, these simulators will become capable of real-time monitoring of learner performance. Display of this data on a performance dashboard will allow both learner and teacher to observe flaws in performance and for the teacher to provide appropriate guidance at the time it is needed. With the addition of intelligent tutors that are built into the simulator, the learner can receive needed feedback by using the simulator at any time of the day. Similarly, we can challenge ourselves to understand and implement intelligent, real-time feedback into all aspects of healthcare learning.
- *Artificial intelligence and adaptive learning*. Understanding and engaging with each student’s success at the course level is the domain of the individual faculty, and remains a challenge for the application of appropriate digital technology. Implementation of adaptive learning, that is, adapting the presentation of learning content in response to continuous assessment of learner performance, will be an essential next step. We can expect student performance to be tracked, and personalized exercises and assessments presented, so that they can understand their strengths and weaknesses, and can request digital or in-person help they need for success.
- *Learning Management Systems* will see significant evolution. Currently they are narrowly focused on the administration aspects of learning, ensuring that learners are aware of courses needed for their program, delivering course material with the appropriate sequence and timing, and checking when these courses have been completed. In the future, the challenge will be for LMSs to go beyond administration, and to support student learning. In particular, for healthcare education, LMSs will be required to support mastery- and competency-based education, with detailed tracking of concept and skill acquisition.

---

18 Adams Becker S, Cummins, M, Davis A, Freeman A, Hall Giesinger C, and Ananthanarayanan V. (2017). NMC Horizon Report: 2017 Higher Education Edition. Austin, Texas: The New Media Consortium. ► <http://cdn.nmc.org/media/2017-nmc-horizon-report-he-EN.pdf>

The topics presented above are only a small selection of the interesting challenges in future healthcare education. Journals such as “Academic Medicine” and “Computers and Education”, and websites such as Educause.edu, periodically discuss these and other challenges in more depth.

## 25.8 Conclusion

Digital learning is widespread in healthcare education and has proven to be both effective and engaging. Digital content ranges from basic web pages to highly immersive interactive 3D virtual spaces. Digital support of learning uses learner tracking to assess performance and to advise and guide the learner towards optimal learning outcomes. Artificial intelligence and adaptive learning methods have the potential to personalize learning, and to provide the institution with detailed understanding of how to support each learner as well as how to align educational approaches with institutional goals. Simulators, for hands-on procedures and for diagnosis and communication, will provide a learning environment that parallels the student’s progress through the real clinical environment, providing safe, realistic practice before learners must use that knowledge on real patients. Virtual and augmented reality will make these simulated environments and tools appear and feel realistic, while providing the content scaffolding and mentoring that may not be available in the real clinical environment. Next generation learning management systems will provide the administrative infrastructure to support the student as they progress through their educational program, deliver personalized learning to each student, and offer detailed dashboard information to both faculty and institutional administration.

To realize the full potential of digital learning, there must be significant investment in further development of digital learning technology and content. There must also be effort to develop faculty and staff so that they move beyond simply using technology to understanding how to make each technology elicit the desired learning outcome.

This is an exciting time in digital learning capabilities. It is an even more exciting time to solve the many challenges ahead so as to move towards high performance learning systems.

Sorting out the virtual patient: How to exploit artificial intelligence, game technology and sound educational practices to create engaging role-playing simulations. *International Journal of Gaming and Computer-Mediated Simulations*, 4(3), 1–19. This paper is a good overview and analysis of the many methods of simulating a patient.

### Questions for Discussion

1. In developing effective educational interventions, you are often faced with a choice of instructional methods. Which of the instructional methods listed below would best match the instructional goals listed? Please justify your selection. Note: For some instructional goals, more than one instructional method might be appropriate.

#### Instructional Goal

1. Be able to intubate an unconscious patient
2. Memorize the terminology used in neuroanatomy

3. Recognize the symptoms of a patient with probable mental illness
4. Describe the pathophysiological process of hypertension
5. Detect histopathologic variations on histology slides

#### Instructional Method

1. Case-based scenarios that include video
  2. Physical simulation with computer-based feedback
  3. Didactic material that includes text, images and illustrations
  4. Intelligent tutoring system
  5. Drill-and-practice program
2. You are developing a software application for interprofessional education to teach participants about managing patients with advanced Type 2 Diabetes. Your audience includes students representative of the clinicians who are typically involved in the care of such patients: primary care physicians, specialists such as ophthalmologists and podiatrists, and nurses. Your software application is focused on the care of individual patients, and you have put together a set of clinical case studies as a basis. How could you leverage current collaborative technologies to help the team manage each case in a way that resembles what they would do in real life?
  3. Select a topic in physiology with which you are familiar, such as arterial blood–gas exchange or filtration in the kidney, and construct a representation of the domain in terms of the concepts and sub-concepts that should be taught for that topic. Using this representation, design a teaching program using one of the following methods: (1) a didactic approach, (2) a simulation approach, or (3) a game approach.
  4. You are a junior faculty member at a major medical center and you just were appointed director for a course on clinical patient examinations. You decide to

check out several sharing sites for curricular material, such as MedEdPORTAL, to try to find relevant teaching materials. What kind of issues/problems would you expect in integrating material from those sites in your course?

5. As Chief of Quality Improvement at the Veterans Administration, you are attempting to improve fairly poor outcomes of patients with Post-traumatic Stress Disorder (PTSD). You would like to develop a computer-based educational tool for patients and caregivers to help them cope with PTSD. Most of the patients and caregivers are quite unfamiliar with the disorder, and health literacy varies widely in your target audience. In conceptualizing your approach, you are focused on the following questions:
  - (a) What are the instructional goals of the program?
  - (b) What kind of digital content should you use?
  - (c) How do you assess baseline knowledge of patients and caregivers about PTSD, and how do you measure knowledge gains after they have used the program?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- How does translational bioinformatics differ from the more general field of bioinformatics?
- What do T1 and T2 refer to in the context of translational research?
- What is a biomarker, and why is it important in medicine?
- What is precision medicine, and how does it differ from traditional medical practice?
- What is the difference between pharmacokinetics and pharmacodynamics?
- What is the difference between statistical significance and clinical significance?
- How are genomic data being used today in research, clinical care, and consumer health?
- What are some ethical issues surrounding genomic medicine?
- How are ontologies useful in translational bioinformatics?

## 26.1 What Is Translational Bioinformatics?

► Chapter 9 described the field of bioinformatics, or the study of how information from biological systems is represented and analyzed. **Translational Bioinformatics (TBI)** is bioinformatics applied to human health and disease. It uses and extends the concepts and methods from bioinformatics to facilitate the translation of biological (“bench”) discoveries into actual impact on clinical care (“bedside”) and ultimately on population health (► Fig. 26.1). Translational bioinformatics lies at the intersection of bioinformatics and clinical informatics, applying informatics methods to increasingly voluminous **omics** data (genomics, transcriptomics, epigenomics, metabolomics, and proteomics data) to improve clinical care and health outcomes through the advancement and practice of **precision medicine** (see ► Chap. 28). In this chap-

► **Fig. 26.1** TBI bridges the gap between bioinformatics on the “bench” side of the T1 barrier and health informatics on the “bedside” end of the spectrum. Novel methods for storage, analysis, and interpretation span the spectrum from data to knowledge. (Adapted from Sarkar et al. (2011). Creative Commons CC BY-ND License)

ter, we describe key concepts and methods in TBI, summarize TBI data-related resources, and introduce the concept of precision medicine, which is enabled by TBI and covered in greater depth in ► Chap. 28. We conclude with a discussion of challenges and future directions for the field.

### 26.1.1 Differences from “Traditional” Bioinformatics

TBI differs from the larger field of bioinformatics in a number of key ways. As described above, the focus of TBI is human health. As such, the discipline centers primarily, though not exclusively, around human data. This fact has a number of implications from an informatics perspective. First, one encounters a range of data management, regulatory, and privacy issues that do not arise in handling data from model organisms such as mice, yeast, or *Escherichia coli*. Laws such as the Health Information Portability and Accountability Act (HIPAA)<sup>1</sup> (see ► Chap. 12) dictate how

<sup>1</sup> ► <http://aspe.hhs.gov/admsimp/pl104191.htm> (Accessed 30/11/2012).

patient data must be handled and safeguarded to protect patient privacy. Title 21 of the Code of Federal Regulations Part 11 (21 CFR part 11)<sup>2</sup> mandates how data must be managed if they are to be included as part of a submission to the Food and Drug Administration. In addition, institutional review boards (IRBs) typically require measures to ensure safety and confidentiality of human subjects before they will approve a research protocol. Making complete datasets publicly accessible for a mouse experiment is good scientific citizenship. Making the same type of data accessible for a human study, without approval, could be a serious violation of privacy and confidentiality.

Another difference is that while experimental perturbation through small molecule agonists or antagonists, siRNA, or knock-out genes are straightforward and common in yeast or *E. coli*, such approaches would be neither feasible nor ethical in human subjects. This has significant implications for data generation and collection in translational research. **Phase I clinical trials** are the notable exception to this rule, but they are performed only on ostensibly therapeutic agents. They also require a number of preliminary steps, are very expensive, and are performed in a very small number of subjects. Other factors that differentiate research with human subjects include genetic and environmental heterogeneity, which can be controlled in model organisms. Instead, much translational data from human beings comes from *in vitro* experiments on cell lines and observational inquiries regarding factors such as genotype, environmental factors, and outcomes. With so much inherent noise, very large sample sizes are typically required for new discoveries. Novel approaches to data integration, mining, and re-use are thus particularly important in translational research.

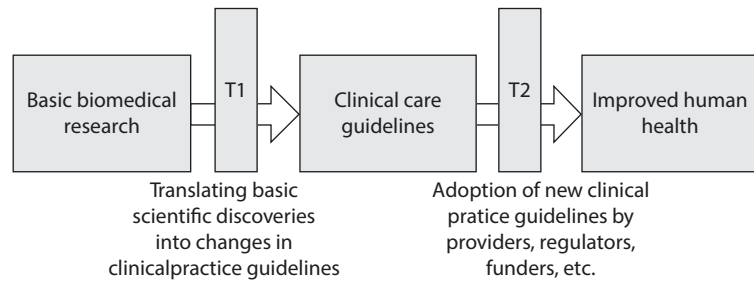

## 26.2 The Rise of Translational Bioinformatics

### 26.2.1 Promise of the Human Genome Project

In January of 2000, two different groups announced that they had fully sequenced the human genome (see ► Chap. 9). The public project, published in *Nature*, was based on multiple individuals (Lander et al. 2001). The other genome, published in *Science*, was a private venture, performed on the DNA of biologist and entrepreneur Craig Venter (Venter et al. 2001). The vision for the human genome was that once all the genes were identified, they could be assigned functional annotations, and we would thus be able to understand what goes wrong when human beings succumb to disease. Additionally, this knowledge would help us to understand exactly which pathways and molecules needed to be targeted in order to prevent or cure disease. Of course, biological reality is not quite so straightforward. To begin with, the “central dogma” of biology (Crick 1970)—DNA is transcribed into mRNA, which is then translated into protein—is overly simplistic. Variations in regulatory regions can affect when the gene is turned on, and to what degree. Most genes have a number of different splice variants, producing a number of different proteins. In addition, proteins undergo post-translational modifications, which impact their structure and function. Finally, additional complexity is added through **epigenetics**, or heritable traits that are not coded for through DNA sequencing alone. An example is methylation of the DNA molecule, which has been shown to affect transcription (Cedar 1988). Despite this, the sequencing of the complete human genome marked a decisive turning point in biomedical research. The parts list had been assembled and researchers could move on to the more interesting aspects of the genome—what each part does, how the parts differ among individuals, and what it all means. The impact

2 ► <http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/cfrsearch.cfm?cfrpart=11> (Accessed 30/11/2012).

**Fig. 26.2** Translational roadblocks along the continuum of biomedical research from scientific discoveries to changes in clinical practice and improvement of human health

this would have on the field of medical informatics was recognized immediately, reflected in the theme for the 2002 AMIA<sup>3</sup> Annual Symposium: “Bio\*Medical Informatics: One Discipline” (Tarczy-Hornoch 2007).

### 26.2.2 What Is Translational Research?

In the early 2000s, there was growing acknowledgement that the population at large, and patients in particular, were not reaping the full benefits of the considerable amount of research money being devoted to scientific discovery. It was recognized that researchers do not do a good job translating their discoveries “from bench to bedside,” i.e. bridging biological discoveries in the lab and clinical application of the findings (Lenfant 2003). Two significant roadblocks were initially identified (Fig. 26.2)—one in translating discoveries into clinical care guidelines (dubbed T1 translation), and the other in translating clinical care guidelines into actual practice (T2 translation) (Sung et al. 2003). Additional “T’s” have been devised more recently, and definitions refined to be more granular, e.g. splitting out early and late phase trials and knowledge dissemination vs. knowledge application (Waldman and Terzic 2010). In 2004, the National Institutes of Health (NIH) launched the Roadmap for Medical Research, aimed at

transforming life science research in the twenty-first century. Biomedical informatics plays a strong role across all three of the major Roadmap themes: New Pathways to Discovery, Research Teams of the Future, and Reengineering the Clinical Research Enterprise (Zerhouni 2006). As part of this Roadmap, the NIH embarked on a major initiative to break down translational barriers through a new funding mechanism known as the Clinical and Translational Science Award (CTSA). This award was aimed at major academic medical centers and their partners with the goal of improving translational research to get treatments to patients quickly.

It was in this context, with newfound attention to translational research, that Butte and Chen coined the term “translational bioinformatics” at the AMIA annual symposium in 2006 in a paper entitled “Finding Disease-Related Genomic Experiments Within an International Repository: First Steps in Translational Bioinformatics” (Butte and Chen 2006). AMIA added TBI as one of its key supported domains and in 2008 held its first annual Summit on Translational Bioinformatics. Later that year, the *Journal of the American Medical Informatics Association* (JAMIA) published a perspective on TBI’s “Coming of Age” that enumerated several reasons why the time was right for TBI to come into its own as a field (Butte 2008). In 2009, the editors of the *Journal of Biomedical Informatics* published an explicit Editorial to announce a change in the journal’s editorial policy to “focus its bioinformatics attention on innovations in the area of *translational bioinformatics*” (Shortliffe et al. 2009).

<sup>3</sup> AMIA is the American Medical Informatics Association, Bethesda, MD: ► <http://www.amia.org>

### 26.2.3 Precision Medicine as a Driving Force

Precision medicine (and its cousins: personalized medicine, genomic medicine, stratified medicine, individualized medicine, etc.) is health care that is based on an individual's unique clinical, genetic, omic, and environmental profile, in addition to his or her specific values and preferences. In 2004, Lee Hood coined the term “P4 medicine”: predictive, personalized, preventive, and participatory (Weston and Hood 2004). Based on an individual's specific risk factors, interventions or changes in lifestyle could be adopted *before* the person falls ill, improving quality of life *and* saving significant costs in health care spending. Armed with this individualized knowledge, patients would be empowered to play an active role in their own health and medical care. Quality medical care has never been one-size-fits-all; precision medicine acknowledges this fact and seeks to change the practice of clinical care accordingly. Precision Medicine is discussed further in ► Chap. 28.

## 26.3 Key Concepts for Translational Bioinformatics

As noted in the definition above, TBI involves the development of novel methods for the storage, analysis, and interpretation of molecular data to guide clinical care. In this section we elaborate on these different levels of informatics methodologies which can be framed as falling along a spectrum from data to knowledge (■ Fig. 26.1). *Data* represent specific values; at the simplest level, they can be reduced to ones and zeros. In the middle of the spectrum is *information*—ascribing new meaning to the data at hand through analysis. Finally, we arrive at *knowledge*—the ability to interpret information in a specific context, and for that interpretation to guide actions and behavior.

### 26.3.1 Data Storage and Management

Data are stored at a number of different levels corresponding to different stages along the translational pipeline. At the “bench” end of bench-to-bedside, there is the need to store massive files of raw data generated through omics technologies (Stein 2010). In the case of genome sequencing, these files can be so large that it has been suggested (though not necessarily concluded) that for easily regenerated samples, it might be more cost-effective to discard the raw data and, if necessary, resequence at a later time (Hsi-Yang Fritz et al. 2011). For each raw data file type, one can generally choose among several different processing tools or algorithms. Thus, in addition to the raw data, a researcher or core facility may want to store one or more versions of processed data files, still frequently very large in size. In addition to the actual data, experimental **metadata** are needed in order to understand how the data were generated and how they were processed or analyzed. Annotation facilitates both comprehension and data provenance. Unfortunately, that information is rarely standardized, and frequently stored only in the researcher's head, paper notes, or hard drive. Standards and tools such as the Ontology of Biomedical Investigations (OBI) (Brinkman et al. 2010), Minimum Information lists (Taylor et al. 2008) and the Investigation/Study/Assay (ISA) infrastructure (Rocca-Serra et al. 2010) (see ► Chap. 9), have been developed to address this issue. Guidelines and best practices were formalized in the “FAIR” framework—making data Findable, Accessible, Interoperable, and Reusable (Wilkinson et al. 2016). A website called ► [biosharing.org](https://biosharing.org), which had evolved out of the MIBBI initiative (Minimum Information for Biological and Biomedical Investigations), further evolved into ► [FAIRsharing.org](https://fairsharing.org).<sup>4</sup>

4 ► <https://fairsharing.org/> (Accessed 10/22/2018).

This online resource contains a manually curated collection of data and metadata standards, data repositories, and data sharing policies, as well as the relationships between these entities. For example, it includes a page for the ArrayExpress data repository, with a link to the page for the MINSEQE (Minimal Information about a high throughput SEQuencing Experiment) data standard it adopts, which links to the page for the Journal of Clinical Investigation by which that standard is endorsed.

For translational research purposes, there is also an increasing need to store information related to participant consent. As DNA **Biobanks** (described below) become more common, researchers will have greater access to tissue samples of participants who they did not themselves recruit. It will no longer suffice to have consent information stored on a paper form, locked away in a file drawer. Researchers and biobank administrators will need the ability to know to what each participant has consented, and to perform electronic queries to determine consent status on demand. May John Doe's tissue be used for research beyond the study for which he was enrolled? May the blood collected as a byproduct of care be used for **Genome-Wide Association Studies (GWAS)**? May Jane Doe be contacted for enrollment in a follow-up study? In parallel with work being done to address issues of ethics and governance for this type of data capture and management, researchers are working to develop tools and terminologies to facilitate research permissions management (Obeid et al. 2010; Grando and Schwab 2013). Researchers at the University of California San Diego created iCONCUR, a web-based informed consent tool to enable tiered preferences for use of de-identified data (Kim et al. 2017).

At the bedside end of the translational spectrum, clinicians do not have the time, nor often the training, to analyze the underlying data. They need easy access to what a patient's genotype, protein biomarker pattern, or metabolite profile means, without having to wade through volumes of sequence and biomarker data. Even summary information about test results is not likely to be sufficient;

rather, the clinician needs to be provided with *knowledge* of what the test results mean for subsequent treatment decisions. They may also want to know some type of confidence or quality score for the data provided. HL7's Clinical Genomics Workgroup is working to develop an HL7 standard in this area based on HL7's FHIR API (Alterovitz et al. 2015). Incorporating omic data into the EHR (► Chap. 14) will not improve clinical care without the incorporation of these data types into clinical guidelines and tools for clinical decision support as discussed in ► Chap. 24 (Hoffman 2007).

### 26.3.2 Biomarkers

---

Fundamentally, advancements in the ability to analyze and interpret high-throughput molecular datasets advances the discovery of **biomarkers**. The term biomarker has been used for decades, referring to any observation that could be used as an indication of an underlying physiological state. One commonly accepted definition is "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention" (Atkinson et al. 2001). Exactly what constitutes a biomarker has historically depended in part on what types of observations could be made. Early biomarkers would have included fever, increased respiratory rate, or a rash. As our ability to probe living organisms increased, the domain of biomarkers expanded to the presence or concentration of specific molecules in the blood. For example, increased levels of glucose are indicative of diabetes. Omics-era methodologies give us new types of markers to which we can apply novel analytic methods to anticipate disease and monitor progression. In the genomic era, biomarkers may consist of not just one but many different characteristics, which together give insight into underlying states or processes. Gene expression signatures are a common example of this type of multi-dimensional biomarker.

One important distinction to be made is that of predictive versus mechanistic

biomarkers. Predictive biomarkers are essentially correlative markers of a given observation or outcome. They may or may not be causal for that outcome, but they can assist both clinicians and researchers by anticipating outcomes or suggesting new focus areas for research. Mechanistic biomarkers, on the other hand, can help shed light on what is happening at the molecular level that causes, for example, pathology, disease progression, or sensitivity to a given drug. Understanding a mechanism allows researchers to try to modify it through the activation or inhibition of specific molecules or pathways.

#### ■ Predictive Biomarkers for Clinical Use

Predictive biomarkers can facilitate decision making in a number of ways. A biomarker indicating poor prognosis might suggest a more aggressive course of therapy than if that biomarker were not present. A signature indicating that lifestyle changes are likely to offer significant benefit to a patient could provide the motivation needed to follow through. For example, a signature indicating that weight loss is likely to improve insulin resistance could identify individuals for whom an intensive lifestyle changes is likely to have the most impact. Shah et al. were able to identify a **metabolomic** profile in subjects who had lost weight that, while independent of the amount of weight lost, was correlated with changes in insulin resistance (Shah et al. 2009b). On the flip side, a signature indicating that lifestyle changes alone are unlikely to confer the desired benefits may suggest that pharmaceutical intervention should be considered as well. Even if a biomarker is in no way actionable *yet*, it can be useful for biomedical research. As an example, osteoarthritis is a debilitating disease that is treated primarily through palliative measures to alleviate symptoms, but for which no disease-modifying therapeutic agents exist. One reason for this is the time and cost required to carry out a clinical trial. Without knowledge of which subjects are likely to progress, studies must enroll large numbers of participants in order to be significantly powered. Identifying biomarkers to predict progression would enable cohort enrichment for individuals in whom disease

progression is more likely, thus cutting the total number of subjects required and hence the cost of the trial (Kraus et al. 2011).

Biomarkers that are not clinically actionable may be personally actionable. For example, relapsing-remitting multiple sclerosis (RRMS) is a form of multiple sclerosis in which the patient experiences exacerbations or relapses of neurologic symptoms, followed by periods of partial or complete recovery. If a test could be developed to enable RRMS patients to know in advance if relapses were likely to occur within an upcoming span of weeks or months, it could enable them to make more informed personal or professional decisions, such as when to plan a vacation, or whether to take a new job (Gregory 2011).

One major area for biomarker use is that of pharmacogenomics, described in Sect. 26.5 below. In many cases, a therapeutic gold standard exists, but only a fraction of patients respond to the given therapy. Knowing in advance who is likely not to respond to therapy, or who needs a higher or lower dose than the standard guidelines suggest, can be useful for tailoring therapeutic interventions. Interestingly, while the success of genetic biomarker discovery for common disease has been limited, genotypic biomarkers for response to drugs may be more promising because these variations would not have been selected against through evolution (Cirulli and Goldstein 2010). This may explain why, among published GWAS finding to date, the pharmacogenetic associations tend to have much higher odds ratios than those of genes associated with common diseases.

#### ■ Molecular Mechanism for Therapeutic Targeting

Biomarkers may also be used for elucidation of disease mechanism which can then enable therapeutic targeting toward a specific molecule or pathway. Comparative analysis of high dimensional molecular signatures in patients versus healthy volunteers, tumors versus normal tissue, responders versus non-responders, etc., can reveal a set of molecules that are differentially expressed among these groups. One can then study those specific molecules

more closely, or the pathways in which those molecules are involved, for example through gene ontology (GO) enrichment (see Sect. 26.6.2) or analysis using a curated pathway database such as Reactome (Fabregat et al. 2018), Ingenuity's IPA, or Thomson Reuter's MetaCore (Nikolsky et al. 2005). These types of tools also help to address a major challenge with pattern detection in high throughput data. Particularly in human data sets where differences are observational and not perturbation-based, it can be difficult, if not impossible, to know what is causal and what is simply correlated. Systems biology, described in ► Chap. 9, attempts to address this.

## 26.4 Biomarker Discovery

One of the most common uses of biomarkers is to categorize samples or patients: cancerous samples versus normal tissues, good versus poor prognosis, bacterial versus viral infection. There are a number of ways to approach this problem, all of which fall under the heading of **supervised learning**. Fundamentally, supervised learning entails taking a set of inputs and corresponding outputs to try to learn a model that will enable one to predict output when faced with a previously unseen input. One is trying to predict one value, the *dependent variable*, based on some number of other values, also called *features* (in computer science), *independent variables* (in statistics), or *risk factors* (in clinical practice). If the dependent variable is categorical, typically one is actually predicting the probability of belonging to one class or the other. For example, one might want to predict whether a person will have a heart attack based on age, race, gender, weight, and cholesterol level. Or, in the context of TBI, one might want to predict the likelihood of a heart attack based on gene expression. Note that this latter approach is useful only if the gene expression signature increases the predictive capabilities beyond that offered by the clinical variables, which are typically easier to collect. Algorithmic approaches to classification and prediction are described in ► Chap. 9.

### 26.4.1 Clinical Relevance Versus Statistical Significance

Statistical significance (typically conveyed via p-values) quantifies whether a difference is reliably *measurable* via a test. With large datasets, most differences detected are statistically significant in the sense that such a difference would not be due to just sampling variation. However, the presence of statistical significance does not guarantee clinical relevance. Clinical relevance is a measure of how valuable information provided by the test is in guiding clinical care. It incorporates not only statistics, but also efficacy, safety, and cost.

A test may be able to predict with 90% precision whether, for example, a patient is likely to respond better to a treatment with unpleasant side effects over another, more innocuous therapy. However, if those side effects would significantly lower the patient's quality of life, then the test, while statistically significant, may not be clinically relevant. Similarly, if the cost of a false negative is very high, for example if a test predicts with 90% precision that a patient will survive without a given intervention, that intervention will likely still be administered. On the other hand, if a test predicts with 90%, or even 100%, precision that a patient is likely to live 1 month longer with a given intervention but the intervention costs \$1 million, this highly statistically significant test is still not likely to affect clinical care. Thus, incorporation of molecular data or improvement in an analytic method may make a test's result *statistically* significant while still not affecting clinical practice.

There are various ways to convey a test's "accuracy". The most common metric, which conveys the ability of a test to discriminate two classes, is measured by the Area Under the **receiver operating characteristic (AUROC)** curve (see ► Chap. 3), or the **C statistic**. The ideal ROC curve goes straight up the y-axis at  $x = 0$ , and then straight across the x-axis at  $y = 1$ , giving an AUC of 1. The more reliable a test, the closer it comes to that perfect path. ■ Figure 26.3 shows hypothetical ROC curves for two tests. Test 2 is a more reliable

**Fig. 26.3** A comparison between two Receiver Operator Characteristic (ROC) curves. The area under the curve (AUC) or C statistic is higher for Test 2 (gray) than for Test 1 (diagonal lines) to a statistically significant degree, but this increased accuracy does not necessarily imply clinical relevance

test in that it has a statistically significant higher C statistic, but as with the examples above, that may not change any clinical decisions. Much has been written about the limitations of the AUROC, which is not a good measure when the test needs to discriminate between two outcomes where one is very rare (Cook 2007). In such situations, the Area Under Precision Recall Curve (AUPRC) may be more meaningful. Instead of 1-specificity on the x-axis and sensitivity on the y-axis, AUPRC plots recall (which is the same as sensitivity) on the x-axis and precision (positive predictive value) on the y-axis. This means it is not skewed by the low absolute number of true positives.

It has been proposed that a better measure than area under a curve is needed for judging the incremental value of novel biomarkers and analytical approaches (Pencina et al. 2008). Alternative methods include **net reclassification improvement (NRI)**, a measure of the net fraction of reclassifications made in the correct direction using the given biomarker or method over a method without the designated improvement (Steyerberg et al. 2011). This concept is illustrated in Table 26.1. Rows

**Table 26.1** Hypothetical reclassification of disease risk between two prognostic tests

	Number of individuals (actual rate)			
	Predicted 5-year risk for test 2			
Predicted 5-year risk for Test 1	0–5%	300 (3%)	20 (2%)	0
	5–20%	30 (3%)	300 (11%)	40 (37%)
	>20%	0	10 (35%)	300 (42%)

represent the risk level predicted by the hypothetical Test 1 for 1000 subjects, columns represent the risk level predicted by Test 2. Values along the diagonal were predicted to have the same risk by both tests. **Subjects in the black cells (30 + 40 = 70) were correctly reclassified by Test 2 (i.e., the actual rate in parentheses matches the appropriate risk category).** **Subjects in the light gray cells (10 + 20 = 30) were reclassified incorrectly.** The resulting net

reclassification improvement is  $(70-30)/1000$ , or 4%.

One final characteristic of a good test is its calibration, the extent to which a test correctly measures absolute risk. That is, do the risk values predicted by the test reflect the actual risk observed in the population. Calibration may differ across the population at different levels of predicted risk, which may in turn affect the test's utility.

### 26.4.2 Biomarkers for Drug Repurposing

One very promising area for use of biomarkers is in **drug repurposing**, or drug repositioning. That is, identifying existing drugs that may be useful for indications other than those for which they were initially approved. Doing so avoids early clinical trials for toxicity as those have already been performed. A number of different approaches have been used to identify candidates for repositioning. In some cases, overlapping symptoms may suggest a potential match between one disease area and another. In other cases, empirical observation of unexpected positive effects may suggest alternative uses for a given drug. With omic-scale biomarker discovery, it is possible to use underlying molecular pathway signatures to suggest new uses for existing drugs.

One of the prominent early examples of this approach came from the Broad Institute in the form of the “Connectivity Map,” a resource intended to enable researchers to identify functional connections between drugs, genes, and diseases (Lamb 2007). The general idea was to identify a gene expression signature in a state of interest, e.g. a disease, and then compare that signature to the gene expression patterns observed upon exposure to a number of different compounds. Correlated signatures suggested pathways that were similarly perturbed between a disease state and an intervention. More importantly, anti-correlated signatures suggested potential utility for a given compound in trying to reverse the underlying molecular mechanisms of a given disease. A similar approach was

**Fig. 26.4** A computational approach to candidate selection for drug repurposing. Sirota et al. first generated genomic signatures representing both diseases and drug exposure. For each disease signature, they compared it to the panel of drug signatures and assigned a drug-disease score based on profile similarity. Drugs whose pattern were most significantly *dissimilar* to the disease state were ranked as lead candidates to treat the disease of interest

used by Sirota et al. to identify the anti-ulcer drug cimetidine as a candidate agent to treat lung adenocarcinoma. They were then able to validate this alternate use *in vivo* using an animal model of the disease (Sirota et al. 2011). Their approach is illustrated in **Fig. 26.4**.

### 26.4.3 Genomic Data Resources

Fundamental to advancement in biomarker discovery are high-throughput genomic measurements that have been enabled since the human genome draft was published. Fortunately, the genomic community has been moving toward a culture of data sharing, NIH broadens genomic data-sharing policy (2014) making experimental data via publicly available data repositories (Kaye

et al. 2009, 2014). Resources for genomic data include:

#### ■ Genetic variation

According to the *Policy for Sharing of Data Obtained in NIH Supported or Conducted Genome-Wide Association Studies (GWAS)*,<sup>5</sup> genotypic data must be deposited to the NIH database of Genotypes and Phenotypes (dbGaP). Genomic variation data is also available through a number of other online resources—see ► Sect. 9.3 and (Sherry et al. 2001; WTCCC 2007; Altshuler, et al. 2010). The HapMap projects catalog variation over a wide variety of ethnic populations, in order to define the occurrence and frequency of common genetic variations (Rusk 2010). The 1000 Genomes project is taking HapMap further to categorize the occurrence of more rare variations (changes in single DNA bases, as well as insertions/deletions, segmental duplications, and larger scale inversions and translocations) (Via et al. 2010). There are also resources about copy number variations.<sup>6</sup>

dbSNP—database of Single Nucleotide Polymorphisms is a publicly available catalog of genome variation (Sherry et al. 2001). Contents primarily represent single nucleotide substitutions, but also include a small number of other types of variation, for example microsatellite repeats and small insertions and deletions (Homerova et al. 2002). The PharmGKB resource specifically annotates genetic variations relevant to drug response (Altman 2007). The increase in exome and genome sequencing has led to powerful resources for assessing human genome variation across diverse populations. Key resources include the Exome Aggregation Consortium (Lek et al. 2016), the Exome Sequencing Project (ESP) (Auer, et al. 2016) and others. There are also pharmacogenomics-specific studies of key pharmacogenes, such as the Pharmacogenetic Research Network

Sequence Project (PGRNSeq) (Bush et al. 2016).

#### ■ Gene expression information

The Gene Expression Omnibus (GEO) (Barrett et al. 2013) contains an extremely large and diverse collection of high throughput gene expression experiments which allow one to evaluate whether a disease (or drug exposure) leads to up- or down-regulation of gene expression (Edgar et al. 2002). Particularly useful examples of gene expression for drug response are the Connectivity Map data set in which gene expression in response to 164 drugs was measured (Lamb et al. 2006). Similarly, the NCI 60 is a set of 60 cancer cell lines that have been exposed to hundreds of drugs in order to determine their sensitivity (Ross et al. 2000). Other efforts have looked at genetic variations that correlate with gene expression in order to associate these genomic regions with the function of the correlated genes (Gamazon et al. 2010; Nicolae et al. 2010). ArrayExpress, developed by EMBL-EBI (European Molecular Biology Laboratory- European Bioinformatics Institute), is a European analog of GEO, containing microarray and sequencing data for functional genomics (Kolesnikov et al. 2015).

#### ■ Gene associations

The Genetic Association Database (Becker et al. 2004) provides curated information about the results of genetic association studies, including those studies that relate genetic variation to variation in drug response. The Human Genome Mutation Database (HGMD) also provides this information in a highly curated form (Stenson et al. 2009, 2017). dbGaP— database of Genotypes and Phenotypes is a resource to archive and distribute information about the interaction between genotype and phenotype (Mailman et al. 2007). The PharmGKB resource is devoted entirely to providing information about associations between human genetic variation and drug response phenotypes (Altman 2007). The GWAS Catalog (MacArthur et al. 2017) is a very useful database of genome wide association study (GWAS) hits. ClinVar aggregates genomic variation and their relationship

5 ► <http://grants.nih.gov/grants/guide/notice-files/NOT-OD-07-088.html> (Accessed 12/6/2012).

6 ► <http://humanparalogy.gs.washington.edu/structuralvariation/general/intro.html> (Accessed 12/3/2012).

to human phenotypes (Landrum et al. 2016). Finally, ClinGen (Clinical Genome Resource) represents a manually curated collection of genetic variants and their clinical relevance (Rehm, et al. 2015).

#### ■ Genetic pathways

Understanding drug action requires understanding the pathways and networks of drug action and drug metabolism. The PharmGKB provides curated drug pathways for both drug action and drug metabolism, and has links to relevant external pathways created by the National Cancer Institute Pathway Interaction Database (Schaefer et al. 2009), Reactome (Joshi-Tope et al. 2005), and others.

## 26.5 Pharmacogenomics

---

**Pharmacogenomics**, a prominent subtype of biomarker discovery, is the study of how genes and genetic variation influence drug response. The primary challenges for pharmacogenomics are to (1) identify the key genes that influence drug response, and (2) understand how specific variations in these genes modulate drug response. The term **pharmacogenetics** generally refers to drug-gene relationships that are dominated by a single gene, whereas the more general term refers to drug responses that result from a combination of interacting gene products. In this section, we use the word “gene” loosely to refer not only to the DNA coding regions for proteins and RNAs but also the protein and RNA products themselves. In many cases, the gene-drug relationship is really a relationship between the drug and the gene’s protein product (or even its non-coding RNA product).

Pharmacogenomics is a prototypical TBI activity because it involves clinical entities such as drugs, diseases, and symptoms as well as molecular entities such as genes, proteins, DNA, RNA, and small molecules. Because drug response is the key phenotype of interest, it is useful to review the basis for drug response. When a drug is administered, there are two distinct genetic “programs” that are relevant. The first is the **pharmacokinetic**

**program** or PK, which describes the absorption, distribution, metabolism and excretion of the drug in the body. Genes implement this program (they encode transporter molecules that move the drug across membranes and the liver enzymes that transform the drug and prepare it for elimination via the kidney or liver) and variation in these genes can lead to a different blood level of drugs or a different timing of these levels. The second is the **pharmacodynamics program** or PD, which describes how the drug works, its protein target, and the mechanism by which it impacts cellular physiology in order to alleviate or cure disease. Genes are clearly also involved in this program (they encode the drug’s primary targets, and the other proteins that interact with these targets to create the cellular response to the drug), and variation in these genes can lead to a different response to the drug. In short, PK is “what the body does to the drug”, and PD is “what the drug does to the body.” The goal of pharmacogenomics is to understand, for every drug, the key PK and PD genes, and which variation impacts their response. This will allow us to realize the vision of using the genome to choose drugs based on maximizing their likely efficacy and minimizing their likely toxicity.

### 26.5.1 Key Entities and Associated Data Resources

---

The key computational entities in pharmacogenomics are genes, drugs, and drug-related phenotypes (indications and effects, including side effects). There exist good informatics resources for all of these:

#### ■ Genes

These are typically specified using the Human Genome Nomenclature Committee (HGNC) standard (Seal et al. 2011). They are typically situated within the genome as a series of exons that are spliced together to create a mature mRNA transcript that is then translated into a protein. This basic concept is made more complex because the strategy for splicing the exons may be variable (alternative splicing)

thereby leading to several proteins, the RNA transcript may be degraded before it is translated, and the proteins may be modified after they are created. There are many resources on the web for gene information, and many

aggregators of this information. These create a remarkably powerful network of associations that can be used creatively to make new associations. For example, Fig. 26.5 shows the links on PharmGKB (Pharmacogenomics

The screenshot shows the PharmGKB website interface for the VKORC1 gene. At the top, there is a search bar with 'VKORC1' entered and a 'Menu' button. Below the search bar is a navigation menu with tabs: Overview, PGx Prescribing Info, Drug Labels, Clinical Annotations, Variant Annotations, Haplotypes, Literature, Pathways, Related To, and Links & Downloads. The 'Links & Downloads' tab is selected, displaying a grid of links to various databases. The databases listed are: Comparative Toxicogenomics Database (79001), Ensembl (ENSG00000167397), GO (GO:0005783, GO:0016020, GO:0016021, GO:0016491, GO:0047057), Gene Ontology (endoplasmic reticulum, endoplasmic reticulum membrane, integral to membrane, membrane, microsome, oxidation reduction, oxidoreductase activity, positive regulation of coagulation, regulation of blood coagulation, response to antibiotic, response to organic cyclic substance, response to organic nitrogen, vitamin K metabolic process, vitamin-K-epoxide reductase (warfarin-insensitive) activity, vitamin-K-epoxide reductase (warfarin-sensitive) activity), Genetic Testing Registry (VKORC1[sym]), HGNC (23663), HumanCyc Gene (HS15548), ModBase (O9B0B6), NCBI Gene (79001), OMIM (122700, 607473, 608547), RefSeq DNA (NG\_011564, NT\_010393), RefSeq Protein (NP\_076869, NP\_996560), RefSeq RNA (NM\_024006, NM\_206824), and UniProtKB (A6NIQ6\_HUMAN (A6NIQ6), VKOR1\_HUMAN (O9B0B6)).

■ Fig. 26.5 PharmGKB gene pages are organized by tabs and the “Downloads/LinkOuts” tab shown here has links to many other sites with valuable information

about human genes. (Copyright PharmGKB, used with permission from PharmGKB and Stanford University)

Knowledge Base) for the drug VKORC1 and includes links to:

- Entrez Gene: summarizes the sequence, variations, homologs across species
- OMIM: provides information about rare genetic diseases involving this gene
- UniProt: provides mapping information to relate this gene to its protein products
- GeneCards: provides aggregated information about function, tissue localization, expression levels, literature references, and more

#### ■ Drugs and small molecules

RxNorm is a terminology standard for specifying drugs (Parrish et al. 2006). DrugBank provides information about drugs, their targets, pharmacology, uses, and many other characteristics (Knox et al. 2011). There are only around 2000 approved drugs in the United States, and so this list is relatively short. The list of small molecules that are not drugs is much larger and includes the contents of PubChem (Wang et al. 2009, 2010), an NIH-built resource with basic information about the structure, function and literature on small molecules. The Zinc Database (Irwin and Shoichet 2005) lists 13 million commercially available compounds that can be purchased for use in research. Much drug information is contained within the “package insert” that is included in most drug packaging. This is information created by the drug company, but approved by the FDA. The FDA makes these available on a drug information site called DailyMed. For patients, the National Library of Medicine’s MedlinePlus resource provides basic drug information as well.

#### ■ Drug indications and drug effects

Drugs are used to treat particular diseases, and so controlled terminologies of drug indications and drug effects are useful for computational efforts. At the organism level, indications and effects are often diseases (diabetes is an indication) or side effects (hyperglycemia is a side effect). The UMLS and MeSH terminologies are often used to characterize such disease phenotypes (Bodenreider

2004). Of course, other disease terminologies such as SNOMED are also useful (Spackman et al. 1997). For side effects, there are specialized terminologies, including the MedDRA terminology used by the FDA in adverse event reporting (MedDRA replaced a previous terminology called COSTART), and the WHOART (World Health Organization Adverse Reactions Terminology) dictionary for adverse reactions (Brown et al. 1999; Alecu et al. 2006). The SIDER database (Kuhn et al. 2010) provides information mined from drug package inserts about drug indications and side effects. The Anatomic Therapeutic Chemical classification (ATC) from the World Health Organization provides a high level classification of drugs organized hierarchically by the anatomical location of target, the therapeutic category, the pharmacological subgroup, chemical subgroup and precise chemical substance (Miller and Britt 1995).

#### ■ Pharmacological properties of drugs

There are resources on the web that provide molecular level assay data related to small molecules, including many drugs. The ChEMBLdb resource provides the ability to find targets, binding affinities, inhibition concentrations and information about other drug-oriented assays (Overington 2009). BindingDB also provides binding affinities for small molecules and proteins (Liu et al. 2007). In addition, RxNorm includes an RxClass API for accessing drug classes and members of a given class (Bahr et al. 2017).

#### ■ Population-based data on drug effects

The FDA maintains information about all reports of adverse events in the FDA Adverse Event Reporting System (FDA AERS). These reports include demographic information, indications for treatment, drugs administered, side effects experienced and a summary of clinical outcomes. They are freely available at the FDA website. The Canadian equivalent system, also making data freely available, is available through the Health Canada website. These data are very noisy and have many confounding variables, but nonetheless can

be useful for discovering “signals” suggesting dangerous side effects or drug-drug interactions (Tatonetti et al. 2011b).

## 26.5.2 TBI Applications in Pharmacogenomics

26

The network of data described above is a rich potential source of hypotheses about how genes combine to create drug response, as well as for predicting the particular consequences of genetic variation. This is still a new field, and there remain many opportunities for innovative use of these data. We highlight a few here to illustrate how integration of data can lead to novel discoveries.

### ■ GWAS to Discover Drug Response Genes

The most straightforward way to associate genes with drug response is to perform a genome-wide association study (GWAS) in which two groups are compared. (See ► Chap. 28 for more on GWAS.) One group (cases) has a drug response of interest (e.g., an adverse event in response to the drug or a particularly good response to it) and the other group (controls) does not have the drug response of interest. It is critical to ensure that the phenotype or response is carefully defined and measured. With each group, DNA is collected and typically 500,000 or 1,000,000 SNPs (single nucleotide polymorphisms) are measured using microarray technology. Then, for each SNP, an association is measured between the genotypes in cases and controls and the response of interest using a simple statistical test such as the chi-squared test. The SNPs that are most highly associated may represent regions of the genome that are involved in the response. These must be carefully vetted statistically, as there are many potential confounding variables. For example, it is important that the cases and controls are drawn from populations with similar ethnic origin, and that the significance remains after correcting for multiple testing. When one tests 500,000 or 1,000,000 hypotheses, adjustments such as Bonferroni correction (see ► Chap. 24) must be made in order to take into account

the chance that an association is spurious. If the result is real, then the SNP may be used to identify nearby genes in the region that may be important for the drug response. For example, Shuldiner and colleagues were interested in the ability of the drug clopidogrel to protect patients from cardiovascular events. They found that a polymorphism RS12777823 was associated with a high likelihood of having a cardiovascular event. They noted that this SNP was very close to the metabolizing enzyme CYP2C19, and in particular the “risk” allele for this SNP co-occurred with the CYP2C19\*2 variant. Thus, they showed that CYP2C19 is important for the desired effect of clopidogrel, and found a variation of this gene that predicted poor response to the drug in affected patients (Shuldiner et al. 2009).

### ■ Mining the FDA AERS to Find Drug-Drug Interactions

The FDA Adverse Events database associates multiple drugs with multiple diseases as indications as well as side effects. This database shows promise as a way to find new associations between single drugs and their side effects, as well as multiple drugs and their side effects. As mentioned above, the SIDER database is a “top down” database of side effects derived from the package label of drugs. Another approach to getting good lists of side effects is a more data-driven approach. One way to do this is to look for patterns of side effects associated with certain types of drugs using machine learning. For example, one may analyze the side effects of drugs that alter glucose in order to create a signature of the “typical” profile of side effects associated with a glucose-altering drug. Then, one can search a database of side effects (such as FDA AERS) for other drugs that match this profile. This was done by Tatonetti et al., who created a profile for glucose-altering drugs and found a set of 10 side effects either enriched or deficient (compared to background) in these drugs: hyperglycemia, diarrhea, hypoglycemia, and pain were higher than others, and paresthesia, nausea, pyrexia, abdominal pain, and anorexia were less likely than others (Tatonetti et al. 2011a). Using this pattern,

more than 93% of drugs that are known to alter glucose could be recovered. More interestingly, however, this pattern could be applied to patients on pairs of drugs to search for pairs that altered glucose. A highly correlated combination was the antidepressant paroxetine and the cholesterol medication pravastatin (Tatonetti et al. 2011a). In subsequent validation in three independent EHR systems, large increases in glucose were observed in patients on these two drugs, and in mouse studies of these two drugs, glucose was substantially increased. Thus, the adverse event patterns could be used to create patterns and detect new signals, not specifically reported in the database, but implied by the pattern of other side effects observed.

#### ■ Mining the Literature to Build a Database of Gene-Drug Associations

Biomedical text can also be an important source of high quality information about the relationships among genes, drugs, and diseases (Garten et al. 2010). High fidelity natural language processing techniques (► Chap. 7) can be used to extract information about gene-drug interactions. In some cases, the association between genes and drugs can be inferred simply by their co-occurrence in sentences (Garten and Altman 2009). In these cases, however, there can be many false positives due to sentences in which genes and drugs are mentioned, but are not actually interacting. A more precise method is based on careful parsing of sentences to find subjects and objects that are genes and drugs, and which are related by verbs that connect them (e.g. “CYP2D metabolizes codeine” has CYP2D as the subject, codeine as the object, and the verb “metabolizes” establishes their relationship) (Coulet et al. 2010). The rate of false positives is reduced in this case because more strict criteria are applied before claiming a relationship. These high quality interactions can be chained together to infer new knowledge. For example, drug-drug interactions often occur because two drugs share a common metabolizing gene and that gene becomes saturated in the presence of both drugs, and cannot adequately metabolize both of them. Thus, the observations that “CYP2D metab-

olizes codeine” and “CYP2D metabolizes metoprolol” might be combined to infer that codeine and metoprolol have a potential drug-drug interaction. There are a large number of similar inferences that could be drawn about the relationships between genes, drugs and diseases given a high quality database of pairwise interactions drawn from the published literature. Of course, some pairwise interactions may be incorrect, and so evidence for interactions should be combined from several sources (including EMR validation, for example) and once predictions are made, they should be embraced only with skepticism. A comprehensive text-based search for relationships between genes, drugs and diseases over all PubMed abstracts yielded a publicly available database of more than 2 million high quality associations (Percha and Altman 2015, 2018).

#### ■ Using Drug-Target Interactions to Predict New Ones

Another way to find new uses for old drugs is to predict interactions between drugs and new potential targets. Many drugs are designed to interact with a single target based on a detailed understanding of disease pathology. Once the drugs are administered, however, they may not bind only the original target, but they may unexpectedly have effects based on their binding to other targets. Most commonly, these “off target” effects are considered side effects and are avoided. In some cases, however, the “off target” effect may be beneficial in the setting of some other disease. Thus, both for explaining the molecular basis of side effects and for finding new molecular evidence for beneficial novel effects, it is useful to connect drugs to proteins. One way to do this is to build computational and visualization methods for docking a 3D representation of a small molecule into the 3D structure of a target protein. This can be very successful, and has led to the hypothesis that a Parkinson’s disease drug may treat tuberculosis (Kinnings et al. 2009)! In that case, the 3D structure of a tuberculosis protein had a pocket that appeared to have high binding potential to a known Parkinson’s disease drug, and thus the hypothesis arose that the

Parkinson's drug might inhibit TB growth. These structure-based methods are powerful but limited because we have the 3D structure of only a subset of human proteins. Another approach, therefore, is based on looking for similarities in the list of drugs that have been shown experimentally to bind a protein. In this case, all that is needed are data from chemical assays showing which drugs bind which proteins. These are routinely collected in large screening experiments, and are available at the ChEMBL resource (Heikamp and Bajorath 2011), for example. Given two proteins with two lists of interacting drugs, we can compare the list of drugs to look for commonalities. If there are many commonalities between protein A and protein B, then one might conclude that the drugs that bind protein A may also bind protein B. This was the approach taken in the Similarity Ensemble Approach (SEA) where the list of drugs binding two proteins are compared using a measure of chemical similarity (Keiser et al. 2009). When the chemicals on the two lists are statistically similar (more than would be expected by chance), then the SEA method predicts cross-binding of ligands for the two structures. When this was applied to a large set of proteins, the authors found that the antidepressant fluoxetine (Prozac) had high potential binding to the beta-adrenergic receptor, and this was found experimentally to block the beta-1 receptor—demonstrating that Prozac is a type of beta-blocker!

#### ■ Identifying Drug Targets Using Side-Effect Similarity

A critical goal in pharmacogenomics is to associate drugs with their target proteins (and thus their coding genes) in order to know where to look for variation that may affect drug response. Determining drug targets can involve a difficult and lengthy experimental program. Thus, it would be very useful to have computational methods for determining targets. One way to do this is to associate drugs to their side effects, and to look for side effect profiles that are similar across drugs. If one drug has a known target, and if another drug has a similar pattern of side effects, then the two drugs may share that target. This is

based on the assumption that side effects arise from a few common mechanisms, and so genes involved in this mechanism may be targeted by multiple drugs or drug classes. In one study, Campillos et al. showed that they could create 1018 drug-drug relationships based on shared side effects (Campillos et al. 2008). The side effects were taken from the SIDER database, and the drugs came from a list of 746 marketed drugs. Twenty of these drug-drug relationships were tested experimentally, and 13 of them were shown to bind common targets. Thus, a relatively straightforward association of drugs based on side effects allowed the definition of molecular targets. In related work, Hansen et al. showed that genes could be ranked by their likelihood of interacting with a drug based on looking at the degree of similarity between chemical structure and indications-of-use between the query drugs, and small molecules known to interact with the gene products and their close protein interaction neighbors (Hansen et al. 2009). The pattern of predicted binding of a small molecule to protein off-targets can also yield information about the likely side effect profile for that molecule (Liu and Altman 2015).

The examples we have discussed have several common features: they deal with the basic objects of diseases, drugs, and disease or adverse-event phenotypes; they integrate at least two sources of data to establish new relationships between these basic objects; and they connect clinical entities (drugs and diseases or adverse events) to molecular entities. Such examples represent only a small subset of the types of questions that can be asked with these valuable datasets. The key technical challenges are typically (1) finding adequate gold standards (► Chap. 2) to evaluate the success of methods before applying them for novel discoveries; (2) understanding the sources of error and bias so that predictions are as reliable as possible; (3) designing careful statistical tests to ensure that the scoring and estimates of significance are accurate and useful (minimizing false positives, in particular); and (4) identifying and engaging experimental collaborators who can, when appropriate, test the predictions that are made in human or model systems. Recently, it has become clear

that despite their shortcomings, EHRs can be extremely useful for initial validation of hypotheses about connections between drugs and adverse events (Tatonetti et al. 2011a). Gene-drug associations are typically tested in model systems with genes altered in order to reduce or eliminate their normal function, or by looking for covariation in human subjects.

### 26.5.3 Challenges for Pharmacogenomics

---

#### ■ Target Expansion: Molecules to Networks

The emerging field of systems pharmacology is abandoning the view of “one drug, one target” and moving instead toward a view that “the network is the target.” That is, the larger network of interacting genes is targeted by a drug at several points, and thus the systemic effects of drugs need to be evaluated in order to understand better the molecular underpinnings of drug response. The challenges to systems pharmacology are similar to the challenges to the more general systems biology: defining the network topology and key players, creating ways to measure parameters, modeling nonlinear responses, and understanding how variation in the basic molecular players impacts the resulting phenotype—in this case drug response phenotypes.

#### ■ Rare Variants

As whole genome sequencing increasingly provides data about rare variants, the paradigm of looking for common genetic variation that explains variation in drug response will need to be modified. There may be cases when variation in drug response is explained by multiple rare variants rather than one or a few common variants. This is particularly challenging because there will often be insufficient statistics to evaluate rare variants. In some cases, huge population-based studies may provide enough samples, but in other cases even these large cohorts will not have sufficient examples of any rare variant to allow statistical validation. In those cases, we will have to rely on computational techniques to assess the significance of very rare variations.

#### ■ Computational Methods to Leverage Stem Cell-Based Model Systems and CRISPR Assays

The rise in the use of stem cells will create opportunities for combining direct measurements of cellular response to drugs with systems models of response, whole genome variation, and epigenetic information. As we perfect methods for creating induced pluripotent stem cells and differentiating them into the target tissues, we will be in a position to measure the response to drugs directly on these cells, with identical genetic and perhaps epigenetic backgrounds. Computational methods for analyzing these responses and relating them to the expected response in the patients from whom these cells are derived will be a major challenge in the years ahead. Similarly, the increased availability and ease of generating genome wide CRISPR libraries that allow genes to be knocked out alone and in combination promises to usher in an era of unprecedented data about the effects of genes on drug response (Kweon and Kim 2018).

### 26.6 Ontologies for Translational Research

---

In order to apply computational methods for biomarker discovery, one needs a consistent way to refer to genes, diseases, drugs, devices, etc. Several ontologies exist in the biomedical domain, many under active development, that provide the necessary terms for creating consistent annotations—preferably in an automated manner—for the various datasets that are at the core of conducting research in TBI. One primary need in TBI is to identify and refer unambiguously to diseases using one or more disease ontologies. We use the term **disease ontology** to refer to artifacts—terminologies and vocabularies as well as true ontologies—that can provide a hierarchy of parent-child terms for disease conditions. Disease-specific and other clinically-oriented ontologies are discussed in detail in ► Chap. 7.

The Ontology for Biomedical Investigations (OBI) was developed as a collaboration among a number of experimental communities around the world in order to represent com-

mon aspects of biological and clinical investigations. It includes broadly applicable terms such as *assay*, as well as more specific terms, such as *transcription profiling by array assay*. It is particularly useful for annotation of experimental metadata, for example to record that a *protein expression profiling assay* was performed on a *blood specimen* (Brinkman et al. 2010).

### 26.6.1 Ontology-Related Resources for Translational Scientists

The use of ontology-based analyses for TBI, especially disease and drug ontologies as well as analyses using multiple ontologies, is a recent development and the adoption and use of ontologies is likely to accelerate. Several resources are available for researchers who wish to use ontologies in making sense of large-scale datasets. The UMLS, or Unified Medical Language System (see ► Chaps. 2 and 7), is a set of files and software that brings together many health and biomedical vocabularies and standards to enable interoperability among computer systems. The UMLS has many uses, including search engine retrieval, data mining, public health statistics reporting, and terminology research. In the field of TBI, the UMLS is a relatively underutilized resource, but that is changing with the increase in the variety of access options (Aronson 2001; Bodenreider 2004; Aronson et al. 2008; Shah and Musen 2008; Aronson and Lang 2010; Mork et al. 2010) and heightened dissemination efforts by the National Library of Medicine.

The National Center for Biomedical Ontology maintains a repository of biomedical ontologies called BioPortal (Musen, et al. 2011) which provides access through both Web pages and Web Services to more than 600 biomedical ontologies and controlled terminologies. Users go to the BioPortal Web site to browse biomedical ontologies and to search for specific ontologies relevant to their work. BioPortal also provides tools such as the Ontology Recommender (Jonquet et al. 2010), which takes as input representative tex-

tual data relevant to a domain of interest and returns as output an ordered list of ontologies that would be most appropriate for annotating the corresponding text. By browsing ontologies on BioPortal and using tools such as the ontology recommender, a cancer biologist may find, for example, that although the Gene Ontology offers some terms for annotating her experimental data related to cell division, there are more precise terms in the NCIt. She may discover that the Foundational Model of Anatomy ontology provides terms for consistently naming body parts from which the experimental specimens were obtained, or that the National Drug File – Reference Terminology (NDF-RT) provides the properties of the drugs used in generating the experimental data. BioPortal allows users to navigate ontologies using a tree browser or visualize ontologies as a graph that offer cognitive support for understanding the complexities of large ontologies (■ Fig. 26.6).

To provide the relationships between terms in two *different* ontologies, BioPortal provides mappings between the terms (Ghazvinian et al. 2009). The mappings can inform the user that the term *Melanoma* in the NCI Thesaurus is related to the term *Malignant, Melanoma* in SNOMED-CT and to *Melanoma* in the Human Disease Ontology. These mappings allow users to compare the use of related terms in different ontologies and to analyze how whole ontologies compare with one another (Ghazvinian et al. 2011). In addition to curated mappings from the UMLS metathesaurus, BioPortal enables algorithmic and user-generated mappings as well.

### 26.6.2 Enrichment Analysis

**Enrichment analysis** is a statistical method to determine whether, for a set of items, a given concept or value is statistically over-represented compared to what one would expect by chance. For example, informatics-related terms are over-represented in this book compared to what one would expect to find in a random sampling of words from all textbooks. The canonical example of enrich-

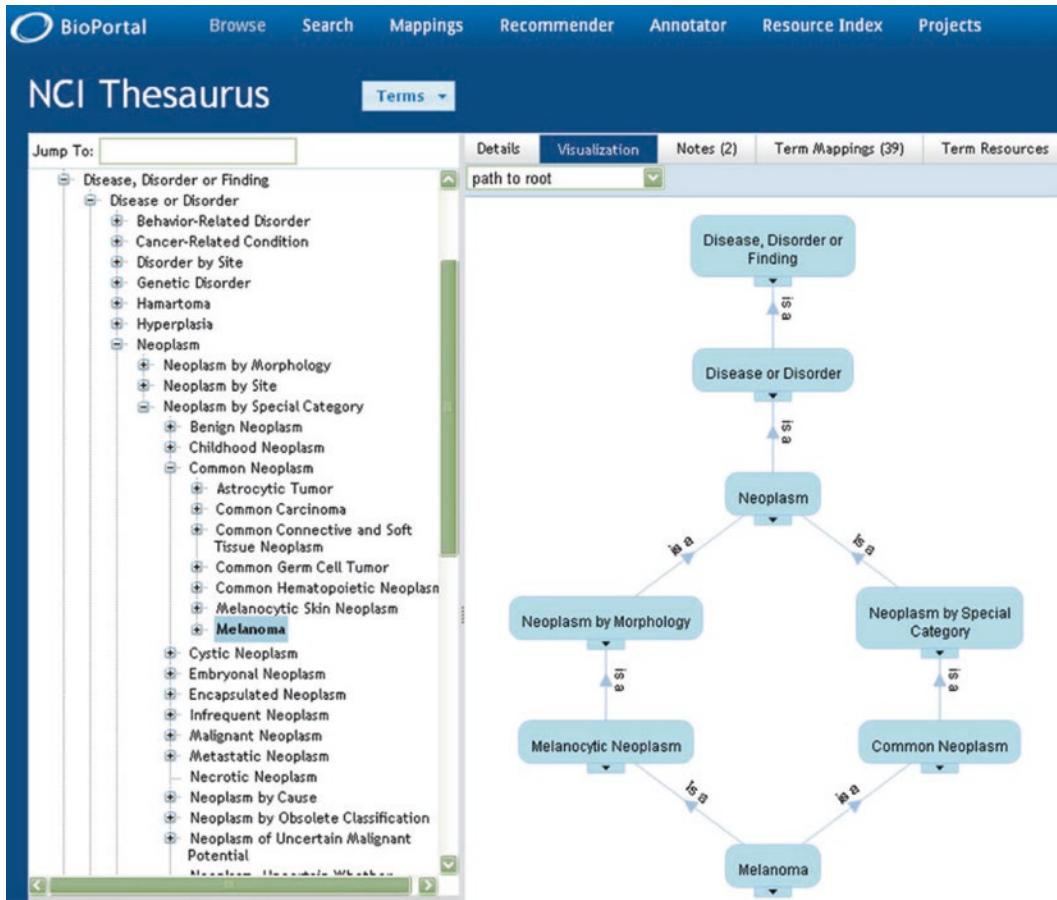

Fig. 26.6 A portion of the National Cancer Institute’s thesaurus. The left pane shows a standard tree view for the term ‘Melanoma’. The right pane shows a visualization that provides additional context by showing the parent classes of melanoma, all the way to the

root node of ‘Disease, Disorder or Finding’. The navigation bar just above the graphical visualization provides access to additional information, such as mappings which provide hooks into other disease ontologies that contain the concept Melanoma

ment analysis involves a list of genes differentially expressed in some condition. To determine the biological meaning of such a list, the usual solution is to perform enrichment analysis with the GO (Gene Ontology), which provides terms for consistent naming of the cellular component (CC) of gene products, the molecular functions (MF) they carry out, and the biological processes (BP) in which they participate. Several curation projects use GO terms to annotate gene products from multiple organisms with terms from the three branches (CC, MF, BP) (Camon et al. 2003). These annotations form the basis for enrichment analysis in which we can aggregate

the annotating GO concepts for each gene in this list, and arrive at a profile of the biological processes or mechanisms affected by the condition under study. This approach does have certain limitations, for example incomplete annotations for a number of genes, lack of conditional independence between annotations, sensitivity to GO version, and lack of a systematic mechanism to compensate for differing levels of depths in different branches of the ontology hierarchy (Khatri and Draghici 2005; Rhee et al. 2008; Tomczak et al. 2018). Despite this, such analysis is widely popular in the bioinformatics community and has resulted in over 100 tools listed

on the GO website<sup>7</sup> and over 7000 citations to the landmark paper on the Gene Ontology (Ashburner et al. 2000).

Disease and drug ontologies can be used to perform enrichment analysis in a manner similar to GO-based analyses for gene expression data (Subramanian et al. 2005; LePendou et al. 2011a). Just as scientists can ask *Which biological process is over-represented in my set of interesting genes or proteins*, we can also ask *Which disease (or class of diseases) is over-represented in my set of interesting genes or proteins?* For example, by annotating known protein mutations with disease terms, Mort et al. were able to identify a class of diseases—blood coagulation disorders—that were associated with a lower than expected rate of amino acid substitutions at O-linked glycosylation sites (Mort et al. 2010).

## 26.7 Natural Language Processing for Information Extraction

Ontologies are also useful in the context of extracting information from a body of text. In-depth methods for natural language processing are discussed in ► Chap. 7. Here we describe some applications in the context of translational research.

### 26.7.1 Mining Electronic Health Records

Researchers have shown that it is possible to profile patient cohorts from EHRs using a variety of ontologies including SNOMED CT, MedDRA, and RxNorm (LePendou et al. 2011b). For example, LePendou et al. developed methods to annotate clinical text and methods for the mining of the resulting annotations to compute the risk of having a myocardial infarction on taking Vioxx (rofecoxib) for Rheumatoid arthritis. Subsequently they demonstrated that it is possible to apply anno-

tation analysis methods for detecting drug safety signals using electronic medical records up to 2 years before a drug's recall (LePendou et al. 2013).

Mining EHR data has also been proposed as a solution to the challenge of the large number of subjects that are needed for genome wide association studies (GWAS). Patients are increasingly able to consent to, or in some cases to opt out of, allowing excess biospecimens taken in the course of clinical care to be used in a de-identified fashion for genomic testing. Even for relatively strong genetic effects, GWAS requires thousands of individuals for sufficient statistical power (► Chap. 11). For weaker effects, tens of thousands of subjects are likely to be needed. Although the cost of genotyping continues to decrease, recruitment and sample collection for these large numbers is both costly and labor-intensive. Leveraging the health care system and EHRs for research recruitment offers a potential approach to circumvent this problem. Ritchie et al. demonstrated the feasibility of this approach by using EHR data and an associated biobank to replicate a number of previously discovered genotype-phenotype associations (Ritchie et al. 2010).

One major initiative in this area is the eMERGE (Electronic Medical Records and Genomics) Network, whose initial aim was to demonstrate that data captured through routine clinical care are sufficient to identify cases and controls accurately for GWAS (Thorisson et al. 2005). As of 2018, the eMERGE consortium includes eleven institutions with DNA repositories and associated electronic medical record systems. For each site, ontology-based data extraction and natural language processing algorithms are applied to the EHR in order to determine phenotypes such as dementia, cataracts, peripheral artery disease, type 2 diabetes, and cardiac conduction defects. This analysis is performed in a high-throughput, scalable fashion with results compared to a manually curated gold standard in order to determine positive and negative predictive values for cases and controls for the phenotypes in question (Kho et al. 2011). The consortium also looks at cross-institutional algorithm application, ethical, legal, and social issues

7 ► <http://www.geneontology.org/GO.tools.shtml#alphabet> (Accessed 12/3/2012).

around DNA biobanks, and the potential for future incorporation of GWAS findings into clinical care (Liu et al. 2012; Rohrer Vitek et al. 2017; Wan et al. 2017).

These types of EMR-associated biobank resources enable a number of other approaches to data mining. For example, Denny et al. used BioVU at Vanderbilt University to perform what they called a “PheWAS,” or a systematic, high-throughput **phenome-wide association scan** (Denny et al. 2010). Instead of measuring whole genomes across thousands of patients in order to find a gene associated with a phenotype in question, they measured only five alleles across thousands of patients and performed enrichment analysis for various diseases based on ICD9 codes. They then were able to reproduce known associations between those genes and certain diagnoses, *and* to generate new hypotheses for associations between these genes and other diagnoses that were statistically enriched for a given genotype. The ability to connect, at a molecular level, diseases that were not previously associated can have implications for therapeutic intervention (Denny et al. 2016).

### 26.7.2 Dataset Annotations

---

In addition to EHRs, public repositories for omics-scale datasets remain a valuable but underutilized resource for data mining. Upon submission, these datasets typically contain only free-text descriptions. Addressing the lack of annotations, researchers demonstrated that translational analyses are enabled by automatically annotating tissue and gene microarray datasets with ontology terms (Shah et al. 2009a; Doan et al. 2014). Butte et al. employed a crowd-sourcing approach to annotate samples from the Gene Expression Omnibus (Hadley et al. 2017). Such automated annotation approaches have been generalized to create systems that process the free text metadata of diverse database elements such as gene expression data sets, descriptions of radiology images, clinical-trial reports, and PubMed article abstracts to annotate and index them with concepts from appropriate ontologies (Jonquet et al. 2011). Doing so

has enabled novel analyses from already collected molecular and clinical data (Garber et al. 2017; Sweeney et al. 2018a, b). Such annotation represents a large part of the work required to address the ‘F’ in FAIR data, making data ‘findable.’

The utility of consistent annotation of research datasets is now widely accepted. As a result, there are several initiatives to build tools for consistent meta-data assignment, as well as indices of available datasets corresponding to specific terms of interest. CeDAR, the Center for Expanded Data Annotation and Retrieval, was formed with a goal of developing information technology to facilitate authoring and adoption of metadata (Musen, et al. 2015). BioCADDIE (Biomedical and healthCare Data Discovery Index Ecosystem) is an international effort to promote biomedical data discovery through the creation of a data discovery index called DataMed (Chen et al. 2018).

## 26.8 Network Analysis

---

Biology lends itself in various ways to modeling through networks or **graphs**. The term “graph” simply refers to a set of *nodes* or circles connected by a set of *edges* or lines. In a molecular context, a node represents a molecular entity, and an edge represents some form of relationship between those molecular entities. This relationship may be a physical interaction (e.g., binds to), an influence (e.g., activates), or a similarity (e.g., is co-expressed with), among other possibilities. One frequently sees graphical models of gene regulatory networks, protein-protein interactions, and signaling cascades. The set of all of these sorts of physical interactions has been referred to as the **interactome** (Barabasi et al. 2011). Studying this interactome and its properties from a graph theory perspective enables useful insights regarding gene modules and pathways, and how these are disrupted in disease.

A number of researchers have attempted to develop gene association networks using gene expression data either alone or together with other sources of network data such as protein-protein interactions. The general idea is that

**Fig. 26.7** Three possible causal relationships between two co-expressed genes. **a** Gene X affects Y. **b** Gene Y affects X. **c** Both X and Y are affected by a third causal gene Z

co-expressed genes are likely to interact with each other or participate in the same pathway. But of course, correlation does not equal causality, and to be useful from a translational perspective, it is important to know the directionality of the influence between two molecules. Consider two genes, X and Y, whose expression is correlated (see **Fig. 26.7**). One can conclude that the genes interact in some way, whether directly or indirectly (i.e., through another molecule). However, without additional knowledge of any sort, we cannot know whether X influences Y (**Fig. 26.7a**), or Y influences X (**Fig. 26.7b**) or they share a third causal gene, Z (**Fig. 26.7c**). Which model represents the true underlying relationship is important to know because if Y is involved in poor outcome, then targeting X will help to alleviate this condition in the first model, but not in the second or third.

One way to determine the actual underlying relationship, used frequently in model systems, is to actively perturb a specific variable in the system. If the other molecule changes accordingly, then we know that the perturbed variable was causal. This is the approach frequently used in a **systems biology** approach (see **Chap. 9**). Unfortunately, this is much harder to do in human beings than in *E. coli* or yeast. One clever approach to determination of causality in human biological networks is to integrate gene expression with genotypic information, in which case DNA sequence can be assumed to be the independent variable. If differential gene expression is correlated with differential genotype, one can conclude that the genotype caused the gene expression pattern and not the other way around. This is the

basis for the approach taken by Eric Schadt et al. to develop **probabilistic causal networks** which can then be used to identify key drivers of disease (Zhu et al. 2008).

Network analysis in translational research need not be confined to concrete objects such as molecules. The Human Disease Network is a graphical model where nodes represent both known disease genes and disorders, linked by known associations between a given gene and disease (Goh et al. 2007). **Figure 26.8** shows the “diseaseome” bipartite network, as well as the Human Disease Network, which connects diseases based on common genes, and the Disease Gene Network, connecting genes based on diseases in common. Combining these disparate data types enables a graph theoretic approach to study the genetic basis for disease. Using this framework, one can analyze similarity between genes based not on co-expression or GO term annotation but based on the pathologies in which a gene is known to be involved. Such similarities could easily go undetected through gene expression analysis if, for example, the different diseases are caused by over-activation or inhibition of the gene respectively. A disease-gene network also enables the comparison of diseases not traditionally studied together, based on common underlying molecular mechanisms. Identifying disease similarities based on gene expression requires that one analyze expression data from those two diseases together in the first place, making it more difficult to discover novel, previously unsuspected relationships.

Building upon the Human Disease Network, Yildirim et al. created a network of drug-gene target interactions, thus enabling an additional layer of analysis regarding similarity between different drugs based on targeted genes, and between target molecules based on the drugs that target them (Yildirim et al. 2007). This type of network can be used as the basis for a number of different observations, including trends in drug development over time. For example, analysis of the structure of the graph revealed significant clustering of drug-gene interactions, suggesting a significant “me too” pattern to drug

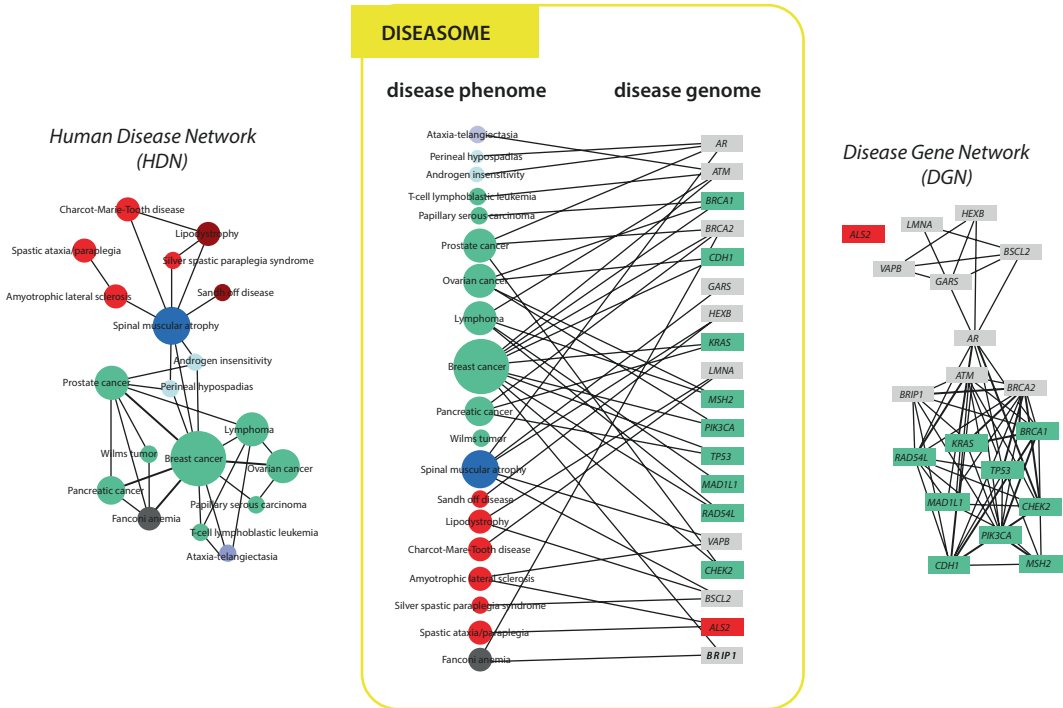

Fig. 26.8 The Human Disease Network. The middle panel shows a small subset of the bi-partite gene-disease network based on OMIM (Online Mendelian Inheritance in Man) gene-disease relationships. The Human Disease Network on the left shows diseases as nodes, with connections representing common related genes.

The Disease Gene Network on the right depicts genes as node, with connections indicating that they have been implicated in one or more of the same disorders. (From Goh et al. (2007), ©2007 National Academy of Sciences, U.S.A. with permission)

development (see Fig. 26.9). Inclusion of drugs still under investigation, i.e., not yet FDA approved at the time of analysis, demonstrated that the breadth of drug targets is expanding, suggesting a trend toward target diversity. Incorporating the cellular component of target proteins showed that the distribution of cellular location for target proteins, previously nearly two-thirds membrane-associated, is becoming more diverse, better matching the known distribution for disease proteins. Finally, this group incorporated protein-protein interaction data to facilitate the study of network properties of drug target gene products. They looked for the shortest path between drug target genes and known disease genes for the disorder that drug was intended to treat and found that this number appears to be decreasing over time, suggesting that drugs are moving from a palliative approach (i.e. treating the symptoms and not

the cause) to rational drug design (Yildirim et al. 2007). More recently, Hu et al. used a network-based approach to look at comorbidities and the effects of environmental perturbations (Hu et al. 2016). Using this approach they were able to generate hypotheses for molecular mechanisms of comorbidity which in turn can facilitate drug repurposing and the development of targeted therapeutics.

### 26.9 Basepairs to Bedside

Although the sequenced human genome has not been a panacea for human disease, it has enabled the beginnings of a new approach to human health and to the practice of precision medicine (Collins and Varmus 2015). As the price of genomic sequencing falls and as our knowledge regarding the meaning of genomic variation increases, genotypic data

**Fig. 26.9** Yildirim et al.'s Drug-Target network. Circles represent FDA-approved drugs and rectangles represent target proteins. Diseases are color-coded by anatomical system and protein targets according to

their cellular location. Clusters of drugs associated with one target reflect the pharmaceutical industry's tendency to develop 'follow-on' drugs. (Courtesy of Albert-Laszlo Barabasi, MD, with permission)

is poised to become a standard component of a person's medical record. In this section we describe the translational path of genomics, from sequencing in the lab to clinical relevance for individuals.

### 26.9.1 Whole Genome Sequencing

#### ■ Technologic Advances

The DNA-probe approach to genotyping, described in ► Chap. 9, may be compared to looking for one's car keys under the proverbial street lamp. That is, the technology shines the light on a certain portion of the genetic landscape, and that is where we look. Which SNPs are included on a chip is determined in large part by which SNPs have been detected in the past, for example through the HapMap project (Kang et al. 2006). A number of new associations have been found in

this way, whether because the SNPs themselves were of interest, or due to genetic linkage—the tendency for alleles located close to one another on a chromosome to be inherited together. However, more recent findings have demonstrated that the concept of “common disease-common variant” is flawed (Zhu et al. 2011). Indeed, there has been some disappointment in the extent to which GWAS has been able to explain common diseases with known genetic components (Manolio et al. 2009). Whole genome or, in some cases, whole exome sequencing allows researchers to identify rare variants (i.e., those with a minor allele frequency of <1%) that account for genetic disease. Advances in sequencing technologies (e.g., “**nextgen**” sequencing, and **third-generation sequencing**, see ► Chap. 9) and the corresponding decrease in cost, make genome-scale sequencing increasingly feasible in translational research and even in clinical care.

### ■ Whole Genome Versus Exome

Even with recent advances in genome sequencing technology, the cost to sequence a full genome at a rate of coverage that enables the identification of novel SNPs is still significant, on the order of one thousand dollars. However, recall that only about 1% of the genome actually codes for proteins and 85% of known disease-causing mutations with large effects occur in proteins (Choi et al. 2009). One way to further decrease the time and cost of sequencing is to look at only those stretches that code for actual proteins. This can be justified because most variants known to underlie Mendelian disorders disrupt protein-coding sequences. Of course, this approach will miss causal variations if they exist in the other 99% of the genome. Moreover, a recent cluster of publications from the ENCODE (**E**ncyclopedia of **D**N **E**lements) Consortium asserts assignment of biochemical function for 80% of the genome (Dunham et al. 2012). Some additional components, such as regulatory regions or splice acceptor and donor sites may be included as well to increase sensitivity without incurring significant additional cost. Exome sequencing in a small number of individuals has been used to identify the causal variant for rare diseases such as Miller's syndrome, a multiple malformation disorder (Ng et al. 2010), and Proteus syndrome, a disorder causing the overgrowth of tissues and organs, thought to have afflicted the nineteenth century Englishman known as *The Elephant Man* (Lindhurst et al. 2011).

### ■ Genomic Data Sharing

In 2008, researchers demonstrated that the presence of a single genome within a complex mixture of DNA samples could be ascertained (Homer et al. 2008). This caused both NIH and the Wellcome Trust<sup>8</sup> to limit access not only to individual genomes, but to aggregate genomic information as well. (Note that the ability to determine the presence or absence of an individual's DNA in a heterogeneous sample presupposes the availability of detailed

genomic information about the individual in question.) These actions prompted responses that ranged from “too little, too late” to “a heavy-handed bureaucratic response to a practically minimal risk that will unnecessarily inhibit scientific research” (Church et al. 2009). Current NIH policy allows investigators to submit a data access request to be reviewed by an NIH Data Access Committee. Access to data is granted once a Data Use Certification is co-signed both by the investigator and the appropriate official[s] at the investigator's affiliated institution.<sup>9</sup>

The Global Alliance for Genomics & Health is a policy and standards oriented organization aimed at enabling responsible data sharing (Terry 2014). It was founded in 2013 when 50 colleagues from 8 countries met to discuss challenges and opportunities in genomic research and medicine, and now comprises more than 500 organizational members from 71 different countries. A number of Work Streams and Driver Projects guide development efforts and serve to pilot the organization's tools. In a similar vein, the RDA (Research Data Alliance) is an international organization meant to promote data sharing and data driven research, and to develop and promote the technical infrastructure to that end. The RDA's scope goes beyond genomic and biomedical data, but the mission is highly aligned with GA4GH. One of the RDA's many Working Groups is called “FAIRSharing Registry WG: connecting (meta) data standards, repositories, and policies.”<sup>10</sup>

Additional online genomic resources include TCGA (The Cancer Genome Atlas) and WTCCC (Wellcome Trust Case Control Consortium). TCGA is a joint effort of the National Cancer Institute (NCI) and the National Human Genome Research Institute (NHGRI) to accelerate understanding of the molecular basis for cancer through appli-

cation of genomic technologies, including genome sequencing.<sup>11</sup> The WTCCC, established in 2005, comprises 50 research groups across the UK who have performed a series of genome-wide association studies and made the data available through application to a Consortium Data Access Committee.<sup>12</sup>

## 26.9.2 Here Are Some Human Beings

### ■ The Personal Genome Project (PGP)

Promising though genomic medicine may be, much remains to be worked out technically, scientifically, and from the ELSI (ethical, legal, and social implications) perspective (see ► Chap. 12). Some notable pilot projects have been embarked upon in order to catalyze progress in all of these areas. Craig Venter was the first person to have his complete genome published in 2007. Since then, a number of human genomes have been sequenced, and some of those have been made available in the public domain. The question becomes: now what? What can any given individual learn from his or her complete genomic sequence? What does an individual *want* to learn, or not want to learn, as the case may be? The only reliable way to answer these questions is with empirical input.

George Church is a pioneer in genomic sequencing, inventor of the Polonator sequencer, and founder of personal genome sequencing company Knome. In 2005, Church started the Personal Genome Project (PGP), ultimately aiming to sequence 100,000 individuals in order to advance understanding of how genes contribute, along with environment, to human traits. The project “hopes to make personal genome sequencing more affordable, accessible, and useful for humankind.”<sup>13</sup> A vanguard of ten vol-

unteers—the PGP-10—were selected to have their genomes sequenced. This endeavor differs from other projects in one crucial way: in addition to making the sequence data publicly available, complete phenotypic data, including personal and health information, family history, and even name and photographs would be shared as well. This was a departure for the type of projects the NIH typically funds and supports. Generally, informed consent includes information on how the research team plans to secure privacy and confidentiality for the subject. In this case, sharing of personal data was part of the protocol itself. The first set of integrated data from this group was made available in October 2008.

Making this type of data both publicly available and personally identifiable was stepping out into socio-scientific *terra incognita*, generating some worry that it could affect health care, employment, insurance, and more. In 2008, the Genetic Information Nondiscrimination Act (GINA) was signed into law, but its scope is limited to employment and health care insurance. It does not address life, disability, or long term care insurance (Hudson et al. 2008; Tenenbaum and Goodman 2017). Though rare, there are a few notorious examples of lawsuits where employers performed genetic and health-related testing on employees without their consent (Angrist 2010), and though unlikely, the PGP warns prospective participants that their DNA could be artificially synthesized and planted at a crime scene (Lunshof et al. 2010).

As much as the PGP has pushed the boundaries and helped to advance the technology, data management, and clinical issues involved with personal genomes, and will continue to do so, it also serves as a weather balloon from the ELSI perspective, generating empirical data on sociological atmosphere, ethical pressures, and legal winds of change (see ► Chap. 12 for additional discussion on these points). Misha Angrist, a bioethicist at Duke University, is PGP Participant #4. As documented in his book *Here Is a Human Being: At the Dawn of Personal Genomics*, the early sequencing was slow going, the technology took time to work out the kinks, and the preliminary results were underwhelming even

11 ► <http://cancergenome.nih.gov/> (Accessed 10/29/2018).

12 ► <https://www.wtccc.org.uk/index.shtml> (Accessed 10/29/2018).

13 ► <http://www.personalgenomes.org/> (Accessed 10/29/2018).

to the individuals who had been sequenced (Angrist 2010). The infrastructure is not yet in place to empower someone with his complete genomic profile to do much with that information. Angrist describes his own attempts to make use of tools for genomic interpretation—SNPedia,<sup>14</sup> Sequence Variant Analyzer (Ge et al. 2011), and the Church lab's open source Trait-o-Matic<sup>15</sup>—which he compared to the dial-up days of the internet. Out of all of the variants carried by the PGP10, only one was deemed serious. Steven Pinker carried a mutation for MYL2, which had been shown in some cases to cause hypertrophic cardiomyopathy (Angrist 2010).

The resource created by the PGP enabled the Critical Assessment of Genome Interpretation (CAGI) to create a community challenge to assess the ability to predict traits from whole genomes in which researchers were asked to predict whether an individual had a particular trait or profile based on their whole genome. Overall, findings showed that predicting individual traits is difficult and that matching genomes to trait profiles depends strongly on a small number of common traits like ancestry, blood type, and eye color (Cai et al. 2017). Equally important, however, the project has created a publicly available, integrated resource for genomic, environmental, and trait (GET) data (Lunshof et al. 2010) and an empirical test bed for tackling the ELSI issues brought to bear by such a resource.

#### ■ A personal genome for clinical assessment

As another proof of concept, collaborators at Stanford and Harvard did a complete sequencing, analysis, and genetic counseling for a 40-year-old male with family history of sudden death from cardiac arrest (Ashley et al. 2010). The goal was to determine how whole genome sequencing would translate to clinical application. The patient was found to have increased risk for myocardial infarction, type 2 diabetes, and some cancers. While most of the

findings were not actionable, the patient had both increased risk for cardiovascular disease and genetic disposition to benefit from the use of statins and aspirin. Despite this, just over a year after publication, the patient maintained that he had “not been convinced that statins or aspirin would have enough beneficial effect relative to their risks,” and had not therefore changed his pharmaceutical behavior (Quake, S, 2011, personal communication).

Just over a year after the Quake profile, the same group published their findings from performing whole exome sequencing on the first healthy nuclear family (Dewey et al. 2011). They generated an ethnically concordant reference sequence (i.e. a reference sequence based on a European population, reflecting the European background of the family in question), which enabled increased accuracy for rare mutations. Findings included high resolution inference of sites of recombination (i.e., where the parents' chromosomes “cross over” during meiosis), and a novel approach to HLA (Human Leukocyte Antigen) typing—important for risk in a number of diseases, particularly autoimmune disorders. For the family in question, they were able to determine that the father had passed down to his daughter a mutation for Factor V Leiden that poses increased risk for blood clotting. This is actionable information for women as the Factor V mutation is a contraindication for estrogen-based birth control pills (Singer 2011), and inherited thrombophilia is a known risk factor for pregnancy outcomes (Tenenbaum et al. 2012). Note that Factor V mutations are also included in chip-based genotyping services, so whole genome sequencing was not the key enabling technology in this case.

One key item reported in the paper by Ashley et al. was the fact that, in the absence of a centrally curated resource of all rare and disease-associated variants, the authors spent *hundreds of hours* reviewing databases. Moreover, the work was a collaborative effort among a number of highly trained experts in clinical genetics, genetic counseling, bioinformatics, internal medicine, pharmacogenomics, etc. (Ormond et al. 2010). Clearly new

14 ► <http://www.snpedia.com/index.php/SNPedia> (Accessed 12/6/2012).

15 ► <https://github.com/xwu/trait-o-matic/wiki> (Accessed 12/19/2012).

tools, automation, and infrastructure, as well as a whole new paradigm in genetic counseling, are required to make incorporation of genomic data into health care feasible for the population at large.

#### ■ Ethical, Legal, and Social Issues (ELSI)

Pursuit of genomic medicine raises a number of ethical, legal, and social issues (see also ► Chap. 12). Some worry that people are ill-equipped to process the results of these tests. But it is not clear that a paternalistic approach is a better alternative; there was a time when it was considered acceptable for a doctor not to disclose a cancer diagnosis to the patient himself (Novack et al. 1979). In addition, new discoveries are being made all the time—what are the obligations to follow up if something new (and dire? and actionable?) is discovered about a given subject? Other questions include whether enough is known for the results to be of any practical use, whether the service should be provided outside of the context of a relationship with a clinical caregiver, and whether results could have detrimental effects on a person's ability to secure health insurance. Some states have banned the services, others have made stipulations requiring clinician involvement and **CLIA certification** for the labs that handle the samples and process the results.<sup>16</sup>

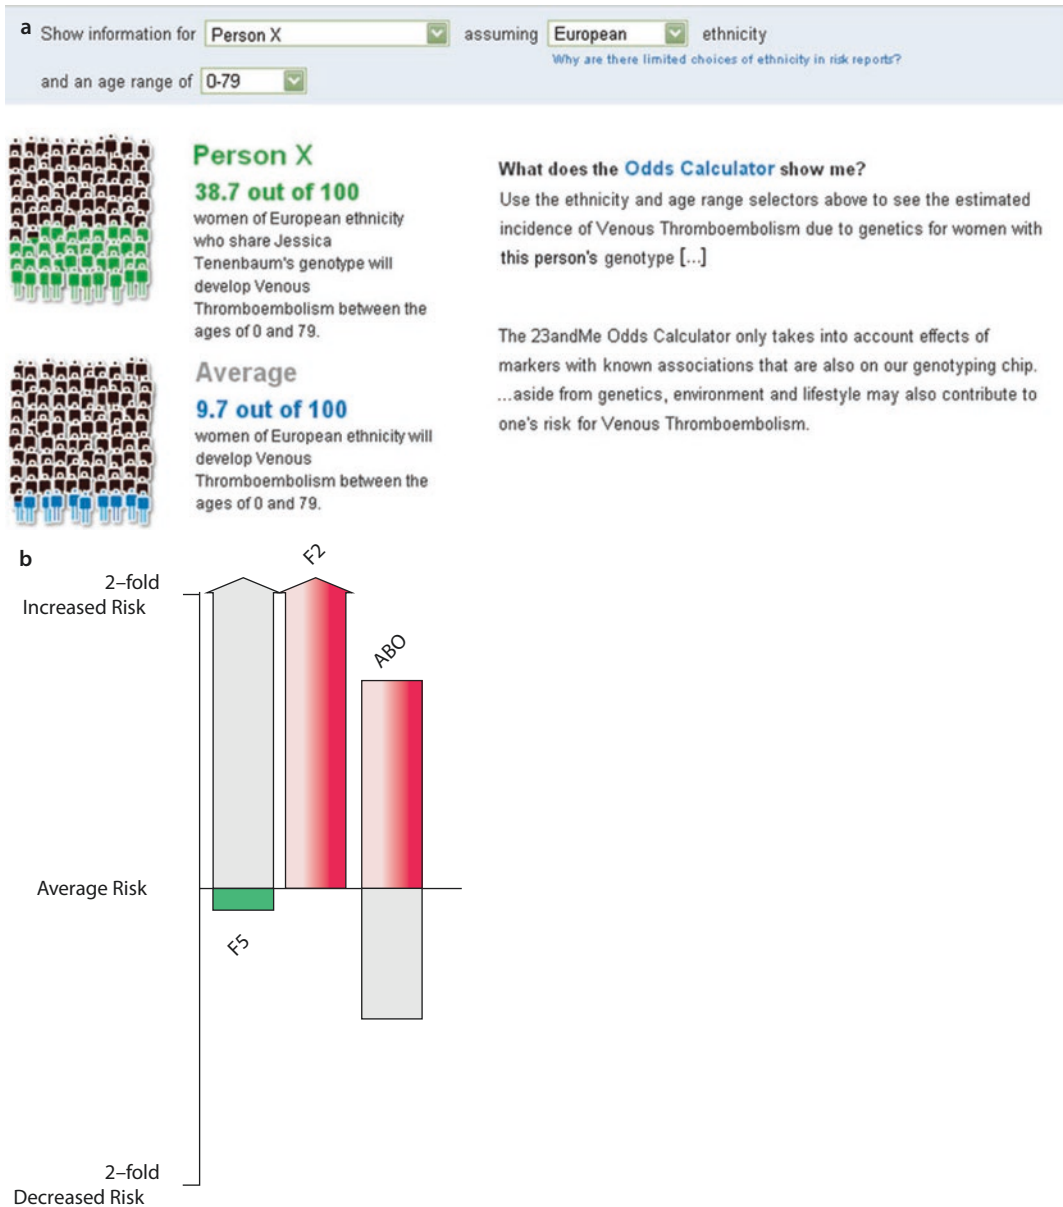

In a companion article to the Quake profile, it was asserted that consent for a process in which the risks of knowledge gained are not wholly understood is more complex than for simple genetic testing. People have trouble interpreting probabilities. Patients must be advised that they may find out things they did not want to know about. The eminent scientist James Watson made a point of requesting that his ApoE status be redacted from the release of his full genome because he did not want to know if he was at risk. His grandmother had died of Alzheimer's at 83, and he did not want to worry that every subsequent memory lapse marked the onset of dementia (Angrist 2010).

Statistics predict that any given patient will find out he is a carrier for *some* lethal autosomal recessive disease. Illness aside, the average global non-paternity rate has been estimated to be as high as 10% (Olson 2007), though it is likely closer to 1% (Larmuseau et al. 2016). Genetic information could also have implications for the patient's children, present or future, and for other family members. Patients, this group concluded, must have access to trained professionals to provide answers to their questions, where answers exist. This will be difficult, lengthy, and expensive, but not to do it would undermine the consent process (Ormond et al. 2010).

Although knowing the “parts list” for the human genome is an important step, much remains to be understood about how genes factor into human health and disease. For most diseases, the environment plays as much, if not more, of a role as a person's DNA. Aside from some notable, deterministic exceptions such as Huntington's disease, most known risk alleles confer fairly low odds ratios unto themselves (see ► Chap. 3), making an individual, for example, approximately 1.1 times as likely as the average individual to develop a given condition. Even when ratios are as high as, say, twofold, it is of dubious actual utility to know that based on one's genotype, the odds of being diagnosed with Crohn's disease went from 0.5 in 100 to 1 in 100.

For certain disease markers, such as Alzheimer's or BRCA1 and BRCA2, it was, and largely still is, unknown what impact negative results might have on a customer's mental and emotion well-being. Some studies have shown that while a person experiences negative emotions immediately in the wake of learning the bad news, over a time period of months there is no significant difference in anxiety, depression, or test-related distress (Green et al. 2009). In any case, DTC genetics companies' websites must provide the ability to view sensitive results while protecting the customer from stumbling on these findings unintentionally. 23andMe, as an example, has spent considerable resources on the design of a user-friendly interface through which to present an individual's “health reports,” or their individual genotype for markers that

16 ► <http://www.genomeweb.com/dxpgx/will-other-states-follow-ny-calif-taking-dtc-genetic-testing-firms> (Accessed 12/6/2012).

**Fig. 26.10** 23andMe's graphical representation of relative risk from their website before the FDA stepped in to regulate DTC genetic testing. **a** Colored figures represent the number of people on average out of 100 who are likely to develop venous thromboembolism over the course of a lifetime. Green figures represent the individual's personal reported risk; blue figures represent the average risk for females of European descent. (Accompanying text has been shortened for clarity.) **b**

The individual's relative risk for each of three reported markers: factor 5, factor 2, and ABO. (Specific values were displayed on the website when the user hovered the mouse over the colored bars.) In a later version of the website, risk for hereditary thrombophilia was based only on factor 2 and factor 5; ABO was no longer included. (© 23andMe, Inc. 2007–2012. All rights reserved; distributed pursuant to a Limited License from 23andMe)

have been characterized through reliable, established research methods. Along with a text explanation, these health reports give a graphical depiction of a person's relative risk.

**Figure 26.10** shows such a graphic for an individual's risk of venous thromboembolism from a circa 2012 version of the website, before the FDA began to regulate DTC genetic test-

ing. The graphical representation has been modified in more recent versions of the site to be less specific, more accurately reflecting the underlying uncertainty. For sensitive results such as BRCA1 and 2, and markers for Alzheimer's and Parkinson's disease, the information is initially "locked." Users must explicitly click through an additional screen to confirm that they truly want to know genotype and relative risk for that trait.

### ■ Rulings and Regulations

From a regulatory perspective, it was not initially clear whether these services qualify as medical devices as defined by the FDA, and are therefore subject to regulation by the Agency. In fall of 2013, the FDA sent a letter to 23andMe ordering it to "immediately discontinue marketing the PGS [Saliva Collection Kit and Personal Genome Service] until such time as it receives FDA marketing authorization for the device." (Annas and Elias 2014) A few weeks later, 23andMe announced that it was complying with the FDA's demands and suspending their health-related genetic tests. 23andMe continued to offer (and market) their ancestry-related testing, and less than 2 years later announced FDA approval for a carrier screening test for Bloom syndrome, with wording that left the option open for additional carrier screening tests without premarket review (Annas and Elias 2014, 2015). In October, 2017, the company announced that it would offer genetic risk for ten medical conditions including Parkinson's disease and late-onset Alzheimer's (Check Hayden 2017). The DTC testing landscape is still rapidly evolving, and will continue to do so for the foreseeable future.

Logistically, a prospective customer typically registers on the DTC company's website and a sample collection kit is sent in the mail, though 23andMe's kit is also available for purchase through ► [Amazon.com](https://www.amazon.com) and even on the shelves of local brick-and-mortar pharmacies. In May 2010, Pathway Genomics and Walgreens announced a plan to sell these kits in Walgreens drugstores, but the FDA sent a letter to Pathway Genomics indicating their belief that the company's genomic report qualified as medical device (Bradley et al. 2011) and as such required FDA approval.

Plans to sell the saliva collection container in brick-and-mortar stores were put on hold until the regulatory issues could be resolved, or at least addressed.

Another high profile legal issue is the case of *Assoc. for Molecular Pathology v. Myriad Genetics, Inc., et al.*, regarding Myriad's patent on the BRCA1 and BRCA2 genes, which were included in 23andMe's offerings,<sup>17</sup> and more generally whether genes should be patentable at all. In 2011, a federal appeals court overturned a lower court in the case of and found that genes can, in fact, be patented (Pollack 2011). This ruling was upheld in a court of appeals in 2012, however, in 2013, the Supreme Court partially overturned that ruling and found that isolated genomic DNA (gDNA) is not patent-eligible, but cDNA is. Disappointingly, this ruling did not do much to reduce ambiguity around these issues.

## 26.10 Challenges and Future Directions

TBI as a discipline continues to evolve in an exciting and dynamic phase. Though challenges remain, the field is poised to become an increasingly crucial element of biomedical research and clinical practice in the era of precision medicine (Tenenbaum et al. 2016). We conclude this chapter with a discussion of future directions and key challenges for this burgeoning discipline.

### 26.10.1 Expansion of Data Types

Genomic data are already being used to guide clinical care. Genomic data themselves are relatively straightforward in that an individual's genome is relatively static, and through the intrinsic physical properties of ribonucleic acids and the transcriptional process, DNA and RNA are relatively easy to capture, observe, and quantify. Proteins and metabolites are more challenging in this regard. Proteomic

17 ► <https://www.23andme.com/health/BRCA-Cancer/> (Accessed 12/19/12).

and metabolomic methodologies have primarily centered around isotopic labeling, but more recent approaches enable unbiased label-free identification and even quantification (Du et al. 2008; Wishart 2011). Identification of metabolites associated with disease has already enabled enzymatic drug targeting in diabetes, obesity, cardiovascular disease, and cancer, among other conditions (Chan and Ginsburg 2011). We expect that as proteomics and metabolomics standards and technologies continue to mature, they will play an increasingly significant role in translational research and practice.

The role of epigenetics needs to be understood more fully. It is clear that the environment can induce changes in the packaging and labeling of DNA. These environmental cues can include lifetime exposures to toxins, viruses, bacteria and nutritional compounds as well as drug exposures. Understanding the ways in which these epigenetic modifications affect phenotype is in its infancy, and so we must understand how to measure these effects, and then compute with them. The human microbiome is also an active area for translational research. Though one might expect associations between the gut microbiome and various gastro-intestinal conditions, surprising correlations and even causal relationships have been discovered with cancer, neurological, and even psychiatric disorders (Mayer et al. 2014; Zitvogel et al. 2015; Zheng et al. 2016; Clapp et al. 2017).

Finally, as standards are developed and clinicians and researchers see the value to be gained from structured data collection through studies such as The National Children's Study (Landrigan et al. 2006), structured environmental data is likely to be increasingly available to complete the picture for gene-environment interactions (Schwartz and Collins 2007).

### 26.10.2 Changes for Medical Training, Practice, and Support

---

Clinicians will need enhanced training in genetics and other areas described above. Curricular components relating to genet-

ics, pharmacogenomics, statistics, and data standards will be increasingly important. Expertise in these fields will also need to be supplemented by an expanded workforce of genetic counselors. Increasingly, therapies will require accompanying diagnostic tests. As the opportunities for use of genomic data in clinical care continue to advance, it will become increasingly important to incorporate this information into both the electronic health record and into machine readable clinical care guidelines for clinical decision support. This in turn will require new standards to capture genomic findings, and new decision support tools to enable clinicians to incorporate this ever-increasing amount of information into their therapeutic decision making processes (Hoffman 2007). A number of standards exist in this space; the key will be in educating prospective users and enforcing adoption. This applies to the full translational spectrum, from annotation of experimentally generated datasets to a common format for the exchange of clinically relevant omic information between EHR systems. Most doctors have only a basic level of training in genetics, and are ill-equipped to answer in-depth questions from patients who bring to an appointment printouts of their results from these services (Frueh and Gurwitz 2004). More knowledge is required, in addition to training and tools, before family care providers, internists, and even specialists, are prepared to incorporate genomic information into their clinical practice (Ormond et al. 2010; Chan and Ginsburg 2011).

## 26.11 Conclusions

---

As the cost of data generation and storage continues to decrease, and the methods for data analysis and interpretation continue to advance, TBI is poised to be a key enabler of precision medicine (Tenenbaum et al. 2016). One can imagine a day when every newborn has his or her genome sequenced and this information becomes a part of the medical record, much as blood type is recorded today. The biggest challenges to achieving this vision are likely not to be technical ones, but rather

ethical, legal, and economic in nature (Schadt 2012). Society must strike a balance between privacy protection and facilitating progress in biomedical research. Legal issues will need to be worked out around direct-to-consumer genetic testing, gene patenting, preventing genetic discrimination, and many other such issues. Return on investment will need to be established through economic analysis combined with comparative effectiveness research (see ► Chaps. 11 and 26). Ultimately, someone will have to pay for these accompanying diagnostic tests. Major change is unlikely until an organization like the Center for Medicare and Medicaid Services (CMS) changes its policies. For example, CMS coverage for the genetic test to guide warfarin dosing is currently conditional upon it being ordered as part of a research protocol (Meckley and Neumann 2010). TBI will continue to play a key role in transforming these types of scientific discoveries into improvements in human health.

### Suggested Readings

- Altman, R. B., & Miller, K. S. (2011). 2010 translational bioinformatics year in review. *Journal of the American Medical Informatics Association*, 18, 358–366. This article summarizes Dr. Altman's third annual "year in review" presentation delivered at the 2010 AMIA Joint Summits on Translational Science in San Francisco.
- Angrist, M. (2010). *Here is a human being: At the dawn of personal genomics*. New York: Harper. This text is written by one of the Personal Genome Project's first subjects, describing the project, the cohort, and the experience. It also gives a good overview of the background of the project and a number of ethical, legal, and social issues that it raises.
- Capriotti, E., Nehrt, N. L., Kann, M. G., & Bromberg, Y. (2012, July). Bioinformatics for personal genome interpretation. *Briefings in Bioinformatics*, 13(4), 495–512. The authors of this review summarize key databases and bioinformatics tools that have been developed in recent years to aid in the interpretation of genomic variance. Resources covered include databases of variants, genotype/phenotype annotation databases, tools for gene prioritization and tools for interpretation of single nucleotide variants.
- Davies, K. (2010). This text, written by the editor of *BioIT World* magazine, documents the characters, events, and issues in the race to achieve the \$1000 Genome. In *The \$1000 genome: The revolution in DNA sequencing and the new era of personalized medicine*. New York: Free Press.
- Hastie, T., Tibshirani, R., & Friedman, J. H. (2009). *The elements of statistical learning: Data mining, inference, and prediction*. New York: Springer. A useful primer on the statistical concepts underlying machine learning approaches to biomarker discovery.
- Kann, M. G., & Lewitter, F. (Eds.). (2012). *Translational bioinformatics*. PLOS Computational Biology Collections eBook. This eBook represents both the first "textbook" devoted entirely to TBI, and the first online, open access textbook from PLOS. In addition to many of the topics covered in this chapter, the collection includes chapters on related topics such as cancer genome analysis, microbiome analysis, structural variation, and protein interactions in disease.
- Masys, D. R., Jarvik, G. P., Abernethy, N. F., Anderson, N. R., Papanicolaou, G. J., Paltoo, D. N., Hoffman, M. A., Kohane, I. S., & Levy, H. P. (2012). Technical desiderata for the integration of genomic data into electronic health records. *Journal of Biomedical Informatics*, 45(3), 419–422. The authors describe the characteristics of biomolecular data that differentiate it from other EHR data, enumerate a set of technical desiderata for management of biomolecular data in clinical settings (e.g., separation of molecular data observations from clinical interpretation, lossless data compression, support for readability by both humans and machines), and propose a technical approach to its representation.
- Sarkar, I. N., & Payne, P. R. O. (2011, December). The joint summits on translational science: crossing the translational chasm. *Journal of Biomedical Informatics*, 44(Suppl 1), S1–S2. This editorial discusses the spectrum of biomedical informatics, from biology to medicine, in the context of the NIH Roadmap and the Clinical and Translational Science Award program. It gives the history of the AMIA Joint

Summits on Translational Science, and explains the emergence of TBI and CRI as disciplines unto themselves, intended to address the same issues that motivated those initiatives- namely translating scientific discoveries into meaningful changes in health care delivery.

Sarkar, I. N., Butte, A. J., Lussier, Y. A., Tarczy-Hornoch, P., & Ohno-Machado, L. (2011). Translational bioinformatics: Linking knowledge across biological and clinical realms. *Journal of the American Medical Informatics Association*, 18, 354–357. The authors present the field of TBI in the context of successes from bioinformatics and health informatics.

### Questions for Discussion

1. Should DTC genetic testing for health-related traits be regulated by the FDA?
2. Should genes be patentable?
3. Are there sufficient legal protections in place to prevent discrimination based on genomic information? If not, what regulations are needed?
4. Are we headed toward full disclosure of genomic information?
5. What are some reasons a researcher might not want to share research data? Should they be required to share? If so, under what circumstances (e.g., 6 months after first publication)?
6. For novel analyses applied to complex, high-dimensional datasets, should there be new guidelines in place to prevent reporting erroneous results through user error or data fraud? Why or why not?
7. What are the major barriers to incorporating the benefits of personalized medicine fully into standard practice?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- What is clinical research and what factors influence the design of clinical studies?
- What are the types of information needs inherent to clinical research and how can those information needs be stratified by research project phase or activity?
- What types of information systems can be used to address or satisfy the information needs of clinical research teams?
- How can multi-purpose platforms, such as electronic health record (EHR) systems (see ► Chap. 14), be leveraged to enable clinical research?
- What is the role of a clinical trial or research management system (CTMS/CRMS) for supporting and enabling clinical research, and what types of functionality are common to such systems?
- What is the role of standards in supporting interoperability across and between actors and entities involved in clinical research?
- What are current and future clinical research informatics (CRI) research and development questions and how will they optimize or otherwise alter the conduct of clinical research?

## 27.1 Introduction

The conduct of clinical research is fundamental to the generation of evidence that can in turn facilitate improvements in human health. However, the design, execution, and analysis of clinical research is an inherently complex information- and resource-intensive endeavor, involving a broad variety of stakeholders, workflows, processes, data types, and computational resources. At the intersection point between biomedical informatics and clinical research, a robust and growing sub-discipline of informatics has emerged, which for the remainder of this chapter we will refer to as

**Clinical Research Informatics (CRI)** (P. J. Embi and Payne 2009). Numerous reports have shown that innovations and best practices generated by the CRI community have contributed to improvements in the quality, efficiency, and expediency of clinical research (P. Embi 2013; P. J. Embi and Payne 2009, 2013; Johnson et al. 2016; Payne et al. 2005; Weng and Kahn 2016). Such benefits can be situated in a full spectrum of contexts that extends from the activities of individual clinical investigators to the operations of multi-center research consortia that involve geographically and temporally distributed participants.

Given the recognition of CRI as a distinct and increasingly important sub-discipline of biomedical informatics, it is imperative that a common basis for defining and understanding CRI science and practice be established. Such a foundation must, by necessity, include explicit linkages to the major challenges and opportunities associated with the planning, conduct, and evaluation of clinical research programs. To provide a common frame of reference for the remainder of this chapter, we will use the National Cancer Institute's (NCI) definition of clinical research, as follows:

- » *Research in which people, or data or samples of tissue from people, are studied to understand health and disease. Clinical research helps find new and better ways to detect, diagnose, treat, and prevent disease. Types of clinical research include clinical trials, which test new treatments for a disease, and natural history studies, which collect health information to understand how a disease develops and progresses over time.*<sup>1</sup>

A lack of sufficient information technology (IT) and biomedical informatics tools and platforms, as well as relevant expertise and methodological frameworks, account for significant impediments to the rapid, effective, and resource-efficient conduct of clinical research projects (Payne et al. 2010; Payne

1 ► <https://www.cancer.gov/publications/dictionaries/cancer-terms/def/clinical-research> (Accessed January 1, 2019).

et al. 2005; Payne et al. 2013). Compounding these challenges is the rapid pace of advancement in biomedical research and the resulting need for advances in diagnostics and therapeutics that can be validated and disseminated quickly and cost effectively (Brightling 2017; Saad et al. 2017; Tenenbaum et al. 2016; Weng and Kahn 2016). The confluence of these factors has led to a number of major challenges and opportunities related to current and future CRI research and practice. For example, the importance of making clinical phenotype data available for the secondary use in support of clinical research has become a competitive requirement for research enterprises of all sizes. Similarly, the increasing complexity of clinical research programs and the difficulty of recruiting sufficiently large patient cohorts, when combined with the regulatory overhead of conducting studies in large academic institutions, has led to an increase in the conduct of clinical studies in community practice settings. Such community-based research paradigms introduce new levels of complexity to the technical and policy aspects of data capture, management, and sharing plans. This rapid evolution and the realities of an increasingly expansive clinical research landscape have led investigators and other decision makers in the health care and life sciences communities to call for increased investments in and delivery of innovative solutions to such information needs (P. J. Embi and Payne 2014; Pencina and Peterson 2016; R. Richesson et al. 2014; Saad et al. 2017; Tenenbaum et al. 2016). At the highest level, clinical research is a domain that has substantial information management needs, representing both a challenge and opportunity for biomedical informatics researchers and practitioners. Simultaneously, clinical research is an area of scientific endeavor that is at the forefront of attention for the governmental, academic, and private sectors, all of which have significant scientific and financial interests in the conduct and outcomes of such efforts. When viewed collectively, many have called, and continue to call, for the development and validation of innovative biomedical informatics methods and tools specifically designed to address clinical research informa-

tion needs (P. J. Embi and Payne 2014; Pencina and Peterson 2016; R. Richesson et al. 2014; Saad et al. 2017; Tenenbaum et al. 2016). It is this overall context that has motivated an increasing focus on both basic and applied Clinical Research Informatics (CRI), which can be defined broadly as follows (P. J. Embi and Payne 2009):

***Clinical Research Informatics (CRI) is the sub-domain of biomedical informatics concerned with the development, evaluation and application of informatics theory, methods and systems to improve the design and conduct of clinical research and to disseminate the knowledge gained.***

Examples of focus areas in which CRI researchers and practitioners apply biomedical informatics theories and methods can include the following:

- Evaluating and modeling of clinical research workflow
- Social and behavioral studies involving clinical research professionals and participants
- Designing optimal human-computer interaction models for clinical research applications
- Improving information capture and data flow in clinical research
- Leveraging data collected in EHRs
- Optimizing site selection, investigator and patient recruitment
- Improving reporting to regulatory agencies
- Enhancing clinical and research data mining, integration, and analysis
- Phenomic characterization of patients for cohort discovery and analytical purposes
- Integrating research findings into individual and population level health care
- Defining and promoting ethical standards in CRI practice
- Educating researchers, informaticians, and organizational leaders about CRI
- Driving public policy around clinical and translational research informatics

Building upon the preceding definitions and state of knowledge and practice relevant to CRI, in the remainder of this chapter we will provide an overview of the types of activities commonly undertaken as part of a variety

of representative clinical research use cases, introduce the role of major classes and types of information system that enable or facilitate such activities, and conclude with a set analyses regarding the future directions of the field. The overall objective of this chapter is to provide the reader with the ability to evaluate critically the current and anticipated roles of biomedical informatics knowledge and practice as applied to clinical research.

## 27.2 A Primer on Clinical Research

In the following section, we will briefly introduce the characteristics of the modern clinical research environment, including the design and execution of an exemplary class of clinical studies that are known as randomized controlled trials (RCTs). This primer on clinical research will serve as the context for the remainder of the chapter, in which we will introduce major information needs and their relationships to a variety of basic and applied biomedical informatics practice areas and IT tools/platforms.

### 27.2.1 The Modern Clinical Research Environment

Clinical research comes in many forms and may include a variety of specific activities. All forms, however, share a common set of requirements related to the comprehensive management of study data – specifically, the collection of data on human research subjects – and analysis of those data. As clinical research designs span the spectrum from passive or observational studies to interventional trials, the acuity of activities and associated data-management needs increase commensurately. For example, in a retrospective study subjects are selected based on the presence or absence of a particular condition and retrospective or pre-existing data are obtained from historical records (such as EHRs, disease registries, and research-specific databases), whereas in natural history studies, subjects are recruited and followed in prospective manner,

with additional collection of data performed solely for the purposes of research, rather than the normal process of patient care.

Further along the spectrum are clinical trials, in which research subjects participate in some additional activity, or *intervention*, that is intended either to induce a change in the subject or to prevent the occurrence of some change that would otherwise be expected. The intervention might be as simple as administering a substance already found in the human body (such as a vitamin) to measuring a change in that substance (such as the amount of the vitamin found in the blood or urine). More complex studies involve interventions that have an impact on human disease, such as the administration of a preventive vaccine, the administration of a curative drug, or a surgical procedure to remove, insert, repair or replace a structure or device in the subject's body. As with passive studies, data collection is critical to the proper performance of research and may become intense, with the collection of clinical information occurring more frequently and involving data describing the intervention materials (such as the purity of a drug or the performance of a device) in addition to data related to the human subject and their response to the intervention under study.

Although not an intrinsic requirement of clinical research, the inclusion of comparison groups is usually considered an important part of rigorous and reproducible clinical research method. In some cases, **historical controls** can be used for comparison with a group of subjects under study. For example, if a disease is known to have a particular fatality rate, subjects could be given a potentially life-saving treatment, and their fatality rate can be measured and compared to past experience. In **quasi-experiments**, comparison subject groups can also be selected based on some known characteristic that distinguishes the two groups, such as gender or race, or their willingness to undergo a particular intervention.

A more rigorous method of establishing comparison groups is through randomization, in which prospective subjects are assigned to

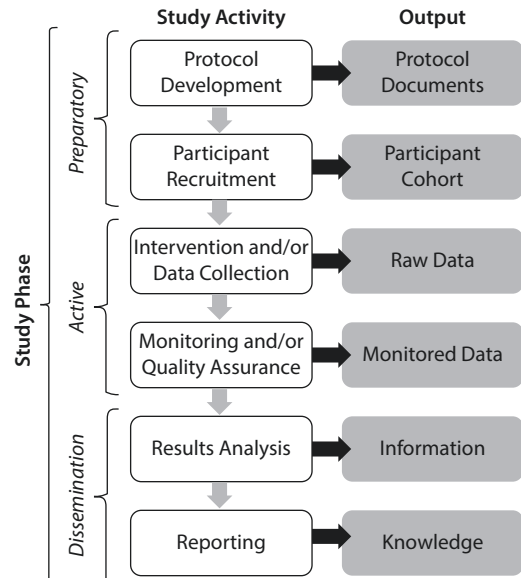

different groups (often referred to as **study arms**) and undergo different interventions as a result of the arm to which they are assigned. Typically, randomization might account for observable characteristics (such as gender, ethnicity, and race) to create balanced groups, especially where the characteristics are known to have some influence on the effect of the intended intervention. Randomization also serves to distribute subjects based on unobserved characteristics, for example, unknown genetic traits, in order to reduce differences in the groups that might bias the results of the study. In a randomized controlled trial (RCT), one subject group will often receive a **control intervention** (for example, the usual treatment or treatments for a condition, or even no treatment) while one or more other groups receive an **experimental intervention**.

Although intended to reduce bias, the randomization process itself must be carefully executed such that it does not introduce new sources of bias. For example, randomization can include **blinding**, in which the subject, the investigator, or both (as in **double-blinded studies**), are kept unaware of group assignment until after all assessments have been made. This might include the use of a **placebo** for a group receiving no treatment, in order to avoid the possibility that subjective improvement in a prior condition or the occurrence of random events (such as normally occurring illnesses), or are not ascribed to the intervention. This also may prevent subjects from deciding not to participate after randomization in a way that might unbalance the study groups (for example, if subjects prefer not to participate if they know they are not getting the experimental intervention) or even bias the assignments (for example, people less prone to take care of themselves might drop out if they find they are assigned to an intervention that requires a great deal of effort on their part).

The gold standard of clinical studies is the double-blinded, randomized, placebo-controlled trial (Hulley et al. 2013). However, such studies may not always be practical. For example, the use of a placebo when an effective therapy is known may be unethical, the blinding of a surgical repair may not be

practical, or the condition under study may be so rare that only historical controls are available.

While different study designs have unique and differentiated data, information, and knowledge management needs, they usually involve some form of systematic data management, as noted previously. Such data management activities usually include initial data collection, aggregation, analysis, and results dissemination, to name a few of many such tasks. As shown in Fig. 27.1, different study methods introduce new issues as successively more complex interventions and study design patterns are employed. For the remainder of this chapter, we will focus our discussion on RCTs as our prototypical study design, as they tend to involve most if not all of the informatics issues and information needs encountered in other study designs. Further information on the design characteristics, data management needs, and associated best practices related to various types of clinical trials can be found in

**Fig. 27.1** Overview of clinical study phases and associated information and data management needs. Underlying such design patterns are a common thread of systematic data management, leveraging resources such as health records, research-specific laboratory data, as well as broader knowledge collections such as the published biomedical literature

a number of excellent works concerning this subject (Bhatt and Mehta 2016; Hulley et al. 2013; Prokscha 2011), and further discussion is beyond the scope of this chapter.

### 27.2.1.1 Phased Randomized Controlled Trials

Most clinical studies begin with the identification of a set of driving or motivating hypotheses. The research questions that serve to define such hypotheses might be raised through an analysis of gaps in knowledge as found in the published biomedical literature or be informed by the results of a previous study. It is important to note that clinical research endeavors exist on a spectrum of scientific activity that is often referred to as **clinical and translational research**. A particular type of translational research, often referred to as T1-type translation, is a process by which basic science discoveries are used to design novel therapies (Sung et al. 2003). Such discoveries are then evaluated during clinical research studies, first pre-clinical and subsequent clinical trial phases (Payne et al. 2005). A second type of translational research, often referred to as T2 translation, involves methods such as those borrowed from **implementation science** and clinical informatics, and focus on translating the findings of such clinical research studies into common practice (Sung et al. 2003). A common colloquialism for this process of translating a novel basic science discovery through clinical research and into clinical practice is “bench to bedside” science.

Individual and distinct RCTs are often conducted for different purposes, most often motivated by the need to fill fundamental knowledge gaps about a particular intervention under study. By combining such knowledge gaps with the underlying biomedical mechanisms of physiology and disease, a motivating hypothesis or collections of hypotheses are established as to why a given intervention might lead to a given result or finding. Such hypotheses result in a natural sequence of research questions that can be asked relative to a novel intervention. Usually, an individual research study is designed to address one specific research question and hypothesis. In the case of the development and evaluation

of a new therapeutic intervention, like a new drug, an individual research study is designed to address each **phase** in a line of research inquiry that will determine the efficacy and effectiveness of such a therapy (Spilker 1984). In most cases, this adheres to the following model:

- **Phase I:** Investigators evaluate the novel therapy in a small group of participants in order to assess overall safety. This safety assessment includes dosing levels in the case of non-interventional therapeutic trials, and potential side effects or adverse effects of the therapy. Often, Phase I trials of non-interventional therapies involve the use of normal volunteers who do not have the disease state targeted by the novel therapy.
- **Phase II:** Investigators evaluate the novel therapy in a larger group of participants in order to assess the efficacy of the treatment in the targeted disease state. During this phase, assessment of overall safety is continued.
- **Phase III:** Investigators evaluate the novel therapy in an even larger group of participants and compare its performance to a reference standard which is usually the current standard of care for the targeted disease state. This phase typically employs an RCT design, and often a multi-center RCT given the numbers of variation of subjects that must be recruited to test the hypothesis. In general, this is the final study phase to be performed before seeking regulatory approval for the novel therapy and broader use in standard-of-care environments.
- **Phase IV:** Investigators study the performance and safety of the novel therapy after it has been approved and marketed. This type of study is performed in order to detect long-term outcomes and effects of the therapy. It is often called “post-market surveillance” and is, in fact, not an RCT at all, but a less formal, observational study.

The phase of an RCT has implications for the kinds of questions being asked and the kinds of processes carried out to answer them. From an informatics perspective, however, the

tasks are usually very similar. At a high level, the conduct of a Phase I, II or III clinical trial can be thought of in an operational sense as consisting of three major stages: preparatory, active, and dissemination. During these three stages, a specific temporal series of processes is executed. First, during the **preparatory phase**, a protocol document is generated as part of the project development process. The protocol document usually contains background information, scientific goals, aims, hypotheses and research questions to be addressed by the trial. In addition, the protocol describes policies, procedures, and data collection or analysis requirements. A critical aspect of the protocol document is the definition of a protocol schema, which defines at a highly granular level the temporal sequence of tasks and events required to both deliver the intervention under study and to ensure that data are collected and managed in a systematic manner commensurate with the study hypotheses and aims.

Once a protocol is deemed ready for execution, the feasibility of the study design (e.g., addressing questions such as “are there enough participants available in the targeted population to satisfy the study design defined in the protocol document?” is assessed either quantitatively (e.g., using historical data) and/or heuristically). Throughout the preparatory phase, a concurrent process of seeking regulatory approval from local and national bodies (e.g., local Institutional Review Boards, the Food and Drug Administration) occurs. Once a protocol plan is complete, deemed feasible, and regulatory approval has been received, potential participants are recruited and screened to determine if they meet the inclusion and exclusion criteria for the study (e.g., specific demographic and/or clinical parameters required for subjects to be eligible for the study). Once a potential participant has been deemed eligible for the study, they are provided with an informed consent document, which must be signed prior to proceeding with the enrollment process. **Enrollment** in the context of clinical trials means officially registering as a study subject, and the subsequent assignment of a study-specific identifier. Once a person agrees to become a participant, they

are enrolled, and in the case of studies with multiple study groups or arms, randomized into one of those arms.

The preceding activities lead to the initiation of the next step in the research process, which we refer to as the **active phase**. During the active phase, the participant receives the therapeutic intervention indicated by their study arm and is actively monitored to enable the collection of study-specific data. This therapeutic intervention and active monitoring process is often iterative, involving multiple cycles of interventions and active monitoring. Follow-up activities begin once a participant has completed the interventional stage of a study. During this stage, subjects are contacted on a specified temporal basis in order to collect additional data of interest, such as long-term treatment effects, disease status or survival status.

Finally, during the **dissemination phase**, the results of the study are evaluated and formalized in publications or other knowledge dissemination media, for translation into the next phase of an RCT or into clinical practice. In some cases, such as is adaptive study designs (Bhatt and Mehta 2016), this dissemination phase feeds back into the planning and active phases. Such feedback cycles enable rapid revision of a study design, iterative participant enrollment, and dynamic data collection in support of such revised hypotheses and designs. Of note, these types of adaptive trial designs are particularly helpful when conducting studies of conditions where large numbers of patients may not be present for recruitment purposes, so that patients are assigned to an intervention and/or monitored in a manner that maximizes data collection that is most likely to demonstrate the safety, efficacy, and comparative effectiveness of the diagnostic or therapeutic approach being evaluated (Bhatt and Mehta 2016).

The quality of data produced by a clinical trial is assessed using multi-dimensional metrics that account for the design, execution, analysis and dissemination of the study results. The quality of a clinical trial is also judged with respect to the significance or relevance of the reported study results within a clinical context (Hulley et al. 2013; Prokscha

2011; Spilker 1984). One key metric used to assess clinical trial quality is validity, which can be defined both internally and externally.

**Internal validity** is defined as the minimization of potential biases during the design and execution of the trial, while **external validity** is the ability to generalize study results into clinical care. It is important to note in a discussion of the role of biomedical informatics relative to clinical research that such platforms, interventions, and methods can play a major role in reducing or mitigating such sources of bias, thus enhancing the validity and generalizability of study results.

## 27.2.2 Information Needs and Systems in the Clinical Research Environment

As can be inferred by the preceding introduction to the definitional aspects of clinical research, such activities regularly involve a variety of data, information, and knowledge sources, as well a complicated set of complementary and overlapping workflows. At the highest level, these characteristics of the clinical research environment can be related to a number of critical information needs, as summarized in [Table 27.1](#). This representation of the information needs inherent to clinical research is presented using the specific context of a prototypical RCT, but the basic types of needs and example solutions provided can be extended to apply to the broader spectrum of research designs and patterns introduced earlier.

Building upon this broad definition of the information needs inherent to clinical research, in the following sub-sections we: (1) review the types of information systems that can support the phases that comprise a clinical study, (2) explore the functional components that make up a clinical trials management system, (3) identify current consortia that share clinical and research data, and (4) discuss the role of standards in enabling interoperability between such information systems.

### 27.2.2.1 Information Systems Supporting Clinical Research Programs

It is helpful to conceptualize the conduct of clinical research studies as a multiple-stage sequential model, as was introduced previously and is expanded upon in this section (Payne et al. 2005). At each stage in such a model, a combination of research-specific and general technologies can be employed to support or address related information needs ([Fig. 27.2](#)).

There are numerous examples of general-purpose and clinical systems that are able to support the conduct of clinical research:

- **Publication (or bibliographic) databases and information retrieval (IR) tools** such as PubMed, Google Scholar, and OVID can be used to assist in conducting the background research necessary for the preparation of protocol documents.
- **Electronic health records (EHRs)** can be used to collect clinical data on research participants in a structured form that can reduce redundant data entry.
- **Data warehouses and associated data or text mining tools** can be used in multiple capacities, including: (1) determining if participant cohorts who meet the study inclusion or exclusion criteria can be practically recruited given historical trends, and (2) identifying specific participants and related data within existing databases.
- **Clinical decision-support systems (CDSS)** can be used to alert providers at the point-of-care that an individual may be eligible for a clinical trial

In addition to the preceding general technologies, a number of research-specific technologies have been developed:

- **Feasibility analysis applications and data simulation and visualization tools** can streamline the pre-clinical research process (e.g., disease models) and assist in the analysis of complex data sets in order to assess the feasibility of a given study design.

**Table 27.1** Overview of definitional information needs in the clinical research environment, contextualized using the design of RCTs

Information needs	Major sub-components	Description
Support for research planning and conduct	Collaborative document and knowledge management	<p><i>Study teams often involve geographically and temporally distributed participants, who need to engage in iterative protocol development and approval processes. Such activities by necessity incorporate document versioning, annotation, and associated metadata management tasks. Once a protocol has been developed, access to data sets for the purposes of assessing the feasibility of a given study design is critical, and often involves the use of de-identified data sets drawn from a data warehouse or research registry. Finally, the submission, tracking, and documentation of regulatory approvals often necessitate the coordination and management of complex, document-oriented workflows and record keeping tasks.</i></p>
	Data sources and tools for feasibility analyses	
	Regulatory approval workflows	
Facilitation of data management, access, and integration	Secondary-use of EHR-derived data for research purposes	<p><i>The ability to use primary clinical data from EHR or equivalent platforms to support secondary use in a research program has the potential to reduce redundancy and potential errors while increasing data quality. However, using such data in a secondary capacity also requires that appropriately structured data be captured and codified in clinical systems, and then be made available to research teams and research data management systems in a timely and resource efficient manner. In addition to such secondary use of clinical data, most clinical studies require the regular capture and management of study-specific data elements, a task that is usually accomplished via the use of Electronic Data Capture (EDC) or Clinical Trial Management Systems (CTMS). Finally, given the propensity to conduct studies that span traditional organizational boundaries in order to realize economies of scale and/or access sufficiently large patient populations, it is often necessary to query, integrate, and manage distributed data sets, and ensure their syntactic and semantic interoperability. Such a need is usually addressed through the use of Service Oriented Architectures, Cloud Computing, Data Warehousing, and Metadata Management technologies.</i></p>
	Research project specific data capture, management, and reporting	
	Distributed data management (spanning traditional organizational boundaries)	
	Syntactic and semantic interoperability	
Workforce training and support	Dissemination of study, methodological, and technical training materials	<p><i>A central need when conducting clinical studies is the ability to ensure that individuals involved in the execution of a protocol share common methods, data management practices, and workflows (thus reducing potential sources of study bias). Ensuring such shared knowledge and practices, particularly in distributed or multi-site settings, requires the use of distance education and team-science tools and platforms to enable knowledge sharing and distance learning paradigms.</i></p>
	Support for team collaboration and knowledge sharing	

(continued)

Table 27.1 (continued)

Information needs	Major sub-components	Description
Management information capture and reporting	Support for research billing	<p><i>The business and management aspects of the conduct of clinical studies is complex, often requiring the disambiguation of standard-of-care and research specific charges as part of billing operations, as well as the tracking of key performance and data quality metrics that may be required to satisfy contractual commitments to the entities funding such studies. Furthermore, the monitoring of study data for critical or sentinel events that should or must be reported for regulatory purposes is both necessary and of extreme importance. All of the aforementioned activities require the application of a variety of management information system, business intelligence, and reporting tools, leveraging a broad variety of enterprise, administrative, and study-specific data sources.</i></p>
	Operational instrumentation and reporting	
	Regulatory monitoring	
	Data quality assurance	
Participant recruitment tools and methods	Cohort discovery	<p><i>The identification of participant cohorts that satisfy key study design criteria, such as inclusion and exclusion criteria, is frequently a major barrier to the timely and efficient execution of clinical studies. A variety of information needs, related to the identification and engagement of such cohorts, to point-of-care alerting regarding potential study eligibility, to the management of registration, consent, and enrollment records is inherent to this information need. Such requirements are usually satisfied through a multi-modal approach, leveraging both clinical and research-specific information systems.</i></p>
	Eligibility determination and alerting	
	Participant registration, consent, and enrollment execution and tracking	
Data standards	Standards for interoperability between research systems	<p><i>As has been noted relative to several of the preceding information needs, there is a frequent and reoccurring requirement for both syntactic and semantic interoperability between research-specific information systems, as well as between research-specific and clinical or administrative systems. Such a need necessitates the design, selection, and application of a variety of data standards, as well as the ability to map and harmonize between shared information models to support interactions between systems using a variety of standards.</i></p>
	Standards for interoperability between research, enterprise (e.g. EHR), and administrative systems	
Workflow support	Integration of tools for combined standard-of-care and research visits	<p><i>Much as was the case related to data standards, a closely aligned information need exists relative to the ability to support complex workflows between information systems and actors involved in the conduct of clinical research. Such workflow support requires both computational and application-level workflow orchestration, as well as the ability to define and apply reusable data analytic “pipelines.”</i></p>
	Data, information, and knowledge transfer between stakeholders, project phases, activities, and associated information systems or tools.	

Table 27.1 (continued)

Information needs	Major sub-components	Description
Data, information and knowledge dissemination	Knowledge management for clinical evidence generated during trials	<i>The ultimate objective of clinical research is to generate and apply new evidence in support of improvements in clinical care and human health. In order to do so, it is necessary to disseminate the findings generated during such studies in a variety of formats, including reusable/actionable knowledge resources, clinical guidelines, decision support rules, and/or publications and reports. In addition, increasing emphasis is being placed on the transparency and reproducibility of study designs, which is often accomplished through the creation of public registries via which study data sets can be shared and made available to the broader biomedical community.</i>
	Guidelines and CDSS delivery mechanisms	
	Publication mechanisms	
	Data registries	

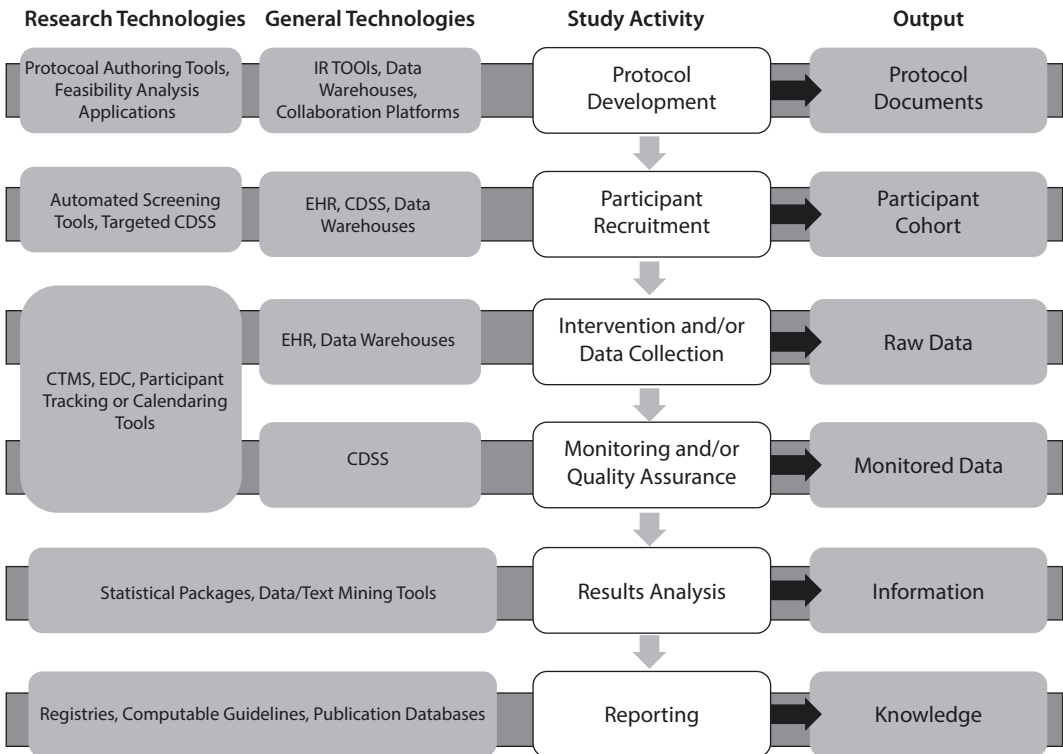

Fig. 27.2 Overview of study activities, and related research-specific and general information technologies, as well as targeted products or outputs associated with the sequential clinical research workflow paradigm

- **Protocol authoring tools** can allow geographically distributed authors to collaborate on complex protocol documents.
- **Automated screening tools and targeted alerts** can assist in the identification and registration of research participants.
- **Electronic data capture (EDC) and Clinical Trial and/or Research Management Systems (CTMS/CRMS)** can be used to collect research-specific data in a structured form and reduce the need for redundant and potentially error-prone paper-based

data collection techniques. More detail on these types of systems is provided in the following section of this chapter.

- **Research-specific decision support systems such as participant tracking or calendaring tools** provide protocol-specific guidelines and alerts to researchers, for example tracking the status of participants to ensure protocol compliance.

### 27.2.2.2 Clinical Research Management Systems

One of the most widely used technology platforms in the clinical research domain is the **clinical trial or research management system (CTMS/CRMS)**. Such platforms were historically referred to as clinical *trials* management systems (CTMS), but the term CRMS is gaining popularity as such systems are increasingly used to manage the conduct of studies including but not limited to trials. CRMS platforms are usually architected as composite systems that incorporate a number of task and role-specific modules intended to address core research-related information needs (P. J. Embi and Payne 2009; Johnson et al. 2016; Payne et al. 2005). Exemplary instances of such modules include the following:

- **Protocol Management** components that support document management functionality to enable the submission, version control, and dissemination of protocol related artifacts and associated metadata annotations.
- **Participant Screening and Registration** tools that allow for the application of electronic eligibility “check lists” to individual patients or cohorts in order to assess study eligibility, and when appropriate, record the registration and associated “baseline” data that are required per the study protocol.
- **Participant Calendaring** functionality allows for the instantiation of general protocol schemas (e.g., a definition of a protocol’s temporal series of tasks, events, and associated data collection tasks) in a participant specific manner, accounting for complex reasoning tasks including the dynamic recalculation of temporal intervals between events based on actual completion dates/times, as well as the

“windowing” of events in which a given task or event is allowed to fall within a range of dates rather a specific, atomic temporal specification.

- **Electronic Data Capture (EDC)** components allow for the definition, instantiation, and use of electronic case report forms (e.g., forms that define study and task/event specific data elements to be collected in support of a given trial or research program). Such **electronic case report forms (eCRFs)** are the basic instrument by which the majority of study-specific data are collected and are usually populated via a combination of: (1) manual data entry (including abstraction from source documentation such as medical records); (2) the importation of secondary use data from clinical systems; or (3) a hybrid of the two preceding approaches.
- **Monitoring tools** enable the application of logical rules and conditions (e.g., range-checking, enforcement of data completion, etc.) using a rules engine or equivalent technology, in order to ensure the completeness and quality of research related data. Such tools may also be used to monitor patient compliance with study schemas, as reflected in the previously described patient calendar functionality.
- **Query and Reporting Tools** support the planned and ad-hoc extraction and aggregation of data sets from multiple eCRFs or equivalent data capture instruments as used with the CTMS. These types of tools are often used by biostatisticians and other quantitative scientists to perform interim and final analyses of study results, outcomes, and to enable higher-order safety analyses. In addition, such tools may be employed to comply with a broad variety of data submission and reporting standard set by both public- and private-sector entities.
- **Security and Auditing** functionality enables site, role, and study-specific access controls and end-user authentication/authorization relative to all of the preceding functionality, as well as the ability to track and report upon end-user interaction with and modifications to data con-

tained in the CRMS. Such functionality is critical to enabling compliance with a broad variety of regulatory and privacy/confidentiality frameworks that apply to the use of protected health information (PHI) for research purposes.

In most CRMS platforms, the aforementioned functional modules share one or more common research databases or in the case of service-oriented architectures (SOA), common data services. In more advanced platforms, these common data structures are populated with research-specific and/or clinical data from enterprise systems and sources (such as EHRs, personal health records, and data warehousing platforms) via either **API-level integration** (e.g., data service publication and consumption) or an **extract, transform, and load (ETL) based approach** (Raths 2013).

### 27.3 Data Sharing Resources and Networks for Clinical Research

---

In the following section, we provide an overview of the various data sharing resources and networks that are commonly encountered in the clinical research domain. These environments are used both for the design and execution of observational or pragmatic studies, as well as the conduct of retrospective analyses or de-novo re-analysis of data collected via clinical trials. Further, they also serve as a basis for disseminating the results and ensuring the reproducibility and rigor of a broad spectrum of clinical studies.

#### 27.3.1 Publicly Deposited Clinical Research Metadata and Data Resources

---

For those seeking to share data, and to avail themselves of data shared by others, the National Center for Biotechnology Information (NCBI) at the NIH's National Library of Medicine has created a public repository of individual-level data, including

exposure history, signs, symptoms, diagnostic test results, and genetic data. Called the **Database of Genome and Phenome (dbGAP)**, this project provides stable data sets that allow multiple researchers to reference the same samples in their publications of secondary analyses of the data (Mailman et al. 2007). Additional data from clinical trials, currently limited to summary results, are also being made available by the NLM through the ► [ClinicalTrials.gov](http://ClinicalTrials.gov) resource, which is a repository of descriptive metadata related to historical and actively recruiting clinical trials (Tse et al. 2009).

#### 27.3.2 Clinical and Translational Science Award (CTSA) Network

---

The National Center for Advancing Clinical and Translational Science (NCATS) has – and continues to – fund a national-consortium of academic health centers (AHC) that are engaged in clinical and translational research under the auspices of the Clinical and Translational Science Award (CTSA) program (Zhang and Patel 2006). Each member of this network, known as a “hub”, is responsible for creating a professional home that supports and enables the conduct of clinical and translational research. Such support includes the provision of Biomedical Informatics infrastructure and expertise is needed to facilitate the capture, storage, management, and analysis of data resulting from such research efforts. As such, the CTSA Network provides an important basis for the conduct of large-scale programs that involve the sharing of such data across and between “hubs.” To coordinate and harmonize data sharing across this CTSA Network, NCATS has created a number of centers and sub-networks, including the Accrual to Clinical Trials Network (ACT, described in more detail below),<sup>2</sup> the Trial

---

2 ► <http://www.actnetwork.us> (Accessed January 27, 2019).

Innovation Network (TIN),<sup>3</sup> the Recruitment Innovation Center (RIC),<sup>4</sup> and the Center for Data 2 Health (CD2H)<sup>5</sup> which is charged with the coordination of network-wide informatics activities. These centers and sub-networks within the broader CTSA network engage in a range of activities, such as: (1) leveraging local data repositories and federated data query tools to enable the rapid assessment of feasibility when designing multi-site clinical trials (ACT); (2) providing expertise and shared best practices as they relate to study designs and regulatory frameworks for such multi-site clinical trials (TIN); (3) delivering novel tools and methods to accelerate the recruitment of participants into those trials (RIC); and (4) helping the Biomedical Informatics components at CTSA hubs to collaborate, share knowledge and tools, and harmonize data assets (CD2H).

### 27.3.3 i2b2 and SHRINE

One popular warehouse software platform that is frequently used in the context of clinical research activities is **Informatics for Integrating Biology and the Bedside (i2b2)**, developed under a National Center for Biomedical Computing grant from NIH to Partners HealthCare System and Harvard University. i2b2 provides an information system framework to allow clinical researchers to use existing clinical data for discovery research (Murphy et al. 2010). Many of the over 60 institutions receiving CTSA grants have adopted i2b2 technologies to support research and collaboration.

A companion to i2b2 is the **Shared Health Research Information Network (SHRINE)**, which is a version of i2b2 that can pass data queries entered by a local user off to other i2b2 instances to provide patient counts and demographic information that is summa-

rized for all remote sites (Weber et al. 2009). SHRINE networks have been established by many research institutions to support, among other functions, the estimation of available cohort sizes for multi-institutional clinical trials.

### 27.3.4 Accrual to Clinical Trials (ACT) Network

Recently, NCATS has funded the **Accrual to Clinical Trials (ACT)** network to bring together CTSA sites into a single SHINE network. Its intent is to allow clinical researchers to query the network in real time and to obtain aggregate counts of patients who meet clinical trial inclusion and exclusion criteria from sites across the United States (Visweswaran et al. 2018). Currently, 31 CTSA sites are fully operational in the ACT network, with an additional 15 being “staged” for integration.<sup>6</sup> Although the ACT SHRINE network currently returns only summary statistics for each site, future plans include the ability to obtain detailed patient data sets and, working with researchers are member sites, being able to contact individual patients for potential recruitment into clinical studies.

### 27.3.5 PCORNet

Another clinical research data sharing consortium is **PCORNet**, which is funded by the **Patient-Centered Outcomes Research Institute (PCORI)**, a non-profit corporation established by the **Patient Protection and Affordable Care Act** (see ► Chap. 12) to support a national clinical research agenda (Fleurence et al. 2014). PCORNet is made of clinical data research networks (CDRNs) that each have access to EHR data on a million or more patients, patient-powered research networks (PPRNs) that are led by patients and patient advocates with an interest in a particular disease (common or rare), and Health Plan

6 ► <http://www.actnetwork.us/national/get-to-know-46EU-1128WI.html> (Accessed January 1, 2019).

Research Networks (HPRNs) that link EHR data with insurance claims data (Fleurence et al. 2014). There are currently 13 CDRNs, 20 PPRNs, and 2 HPRNs nation-wide.<sup>7</sup> The intent of these networks is to provide data that can be used directly to answer clinical research questions based on the health data of large patient cohorts. Clinical researchers can also use the networks to help identify and contact patients who might be suitable for clinical studies.

### 27.3.6 Observational Health Data Sciences and Informatics (OHDSI)

The Observational Health Data Sciences and Informatics (or OHDSI, pronounced “Odyssey”) program is an international network of researchers and health databases (primarily EHRs) that work together to develop and share data query and analytic tools that can operate on members’ databases. OHDSI grew out of the Observational Medical Outcomes Partnership (OMOP), which was a public-private partnership established in the US study how patient care databases could be used to study the effects (both beneficial and adverse) of medical products (Hripcsak et al. 2015). OHDSI currently involves 106 collaborators from 23 countries on six continents.<sup>8</sup>

Current tools include a browser-based data visualization tool called ACHILLES (Automated Characterization of Health Information at Large-scale Longitudinal Exploration System), a vocabulary browsing tool called HERMES (Health Entity Relationship and Metadata Exploration System), a predictive analytics tool called PLATO (Patient-Level Assessment of Treatment Outcomes), a cohort development tool called HERACLES (Health Enterprise Resource and Care Learning Exploration System) that includes analytic tools perform-

ing clinical quality metrics, and HOMER (Health Outcomes and Medical Effectiveness Research), a tool for risk identification and comparative effectiveness studies.

The OHDSI Research Network allows researchers at member sites to query data repositories to obtain high-quality observational data that can be used for study design, execution, and data analysis. An OHDSI research defines a “project” which is actualized as a query for specific patient data. Data owners are invited to participate in projects by querying their own databases and conducting data analysis locally, with results sent back to the initial research team for compilation and analysis.

### 27.3.7 Commercial and Health Care Information Technology Vendor Networks

In addition to the public and non-profit networks, commercial entities have begun to appear that bring private investment resources to bear on some of the challenges of access and integration of data. For example, the TriNetX network (Topaloglu and Palchuk 2018) includes over 20 academic and private health systems that agree to share data over the network in order to enable data queries that can be used to identify cohorts for studies, either led by institutional investigators or biopharmaceutical companies.

Another entity is Flatiron Health, a company recently acquired by Roche (Petrone 2018), which focuses on data from cancer patients. Rather than creating distributed queries against disparate data sets, Flatiron obtains data from major academic medical centers (currently 7<sup>9</sup>), and processes the data centrally, enhancing its utility through natural language processing machine learning to obtain a better understanding of the course of patients’ conditions and their response to therapy.

7 ► <https://pcornet.org/participating-networks> (Accessed January 1, 2019).

8 ► <https://www.ohdsi.org/who-we-are/collaborators> (Accessed January 1, 2019).

9 ► <https://flatiron.com/about-us> (Accessed January 1, 2019).

Electronic Health Record (EHR) vendors are also creating networks to support or enable research data sharing among their clients. For example, Epic Corporation began working with a group of academic health center customers in 2013 on such a data sharing network and created an advisory group of CRI experts from such sites to inform governance, infrastructure, and research data sharing processes. Similarly, Cerner corporation has created a centralized data sharing platform that enables their clients to combine and access large volumes of de-identified patient-level data for trial design and population health management purposes.

Further, major computing and cloud computing vendors, such as Amazon, Apple, Facebook, Google, and Microsoft, have launched initiatives to provide patient-centered data sharing capabilities, which empower individuals to aggregate and share their own health care data from a variety of sources (“Large technology companies continue to ramp up healthcare forays,” 2018). These capabilities introduce new data sharing scenarios in which individual patients will have the ability to “donate their data” to research projects without engaging their health care providers as intermediaries in such transactions. The impact of all of these activities remains to be understood, given their relative immaturity at the time this chapter is being written.

### 27.3.8 All of Us

The All of Us Research Program is the principle component of the US government’s Precision Medicine Initiative (PMI), established in 2016 to establish a cohort of one million Americans who provide health status data, blood, and urine specimens for clinical and genetic analysis, and access to their complete EHR data (Collins and Varmus 2015). Recruitment is currently being carried out

primarily by 11 consortia across the country, involving 51 health care organizations.<sup>10</sup>

Unlike other consortia described above, data and specimens are being consolidated centrally at a Data and Research Center (DRC) and a biobank, respectively. Plans include the collection of data from all of the participants’ EHRs, not just those at recruitment centers, and the sequencing of participants full genomes.

The All of Us Research Program also differs from other consortia in its patient-centered focus. All of Us asks participants for full access to their fully identified data for use by researchers without prior approval of specific studies. In return, patients are repaid through full transparency and partnership. Participants have access to their information and play a role in helping to identify important research priorities for the program.

## 27.4 Data Standards in Clinical Research

The use of standards to represent clinical research information provides the same challenges and benefits found in other informatics application areas. Data may be captured with standard terminologies or translated into standards to support data reporting and sharing which, in turn, require agreed-upon standard frameworks to support such exchanges. Standards are even being developed for the representation of clinical trial protocols themselves. ■ Figure 27.3 depicts how the various kinds of standards fit into the overall schema of clinical research, ranging from data models that define how data are to be represented, through standards for terminologies to actu-

<sup>10</sup> ► <https://allofus.nih.gov/about/program-partners/health-care-provider-organizations> (Accessed January 1, 2019).

■ **Fig. 27.3** Relationships among various general purpose and CRI-specific standards that are relevant to the design, conduct, and dissemination of clinical research studies. Data modeling determines how terms from terminologies and ontologies will be recorded in clinical research databases. Exchange standards determine how

data will map from the model to the messages used for interchanging the data. The use of messages is determined by the requirements of regulatory agencies and collaborating research groups. See text for an explanation of acronyms used in this figure

ally represent the data and structures for exchanging them, out to standards for reporting and sharing. The standards described here are some of the current and most prevalent ones, but they continue to evolve and new standards relevant to the CRI domain are constantly emerging.

### 27.4.1 Data Modeling Standards to Support Clinical Research

Formats for data sharing typically include a data model for the information to be shared, leaving to individual contributors the later task of mapping local data into the exchange model. For example, i2b2 uses a standard data model internally that is based on a generic **entity-attribute-value model (EAV)** that essentially allows any data to be stored using any desired controlled terminology (Klann et al. 2016). This allows queries to be conducted across multiple i2b2 databases,

as with SHRINE, but consolidation of the data may still require mapping of data to a common terminology (although the ACT network requires using a shared ontology for representing data). Note that the data model used for storing the data in a database (i2b2, for example) may not be acceptable for data exchange.

An alternative approach is the model-driven architecture, in which an underlying data model is created for the express purpose of representing all aspects of an information design, including data representation. Previously, the models used for clinical research management systems have been those required to support system functionality. New efforts are underway to create standards for modeling the actual research protocols, to enable a logical representation that includes the semantic aspects of the protocol (for example, the relationships between specific interventions and observations intended to measure their effects). While use of such mod-

els may make the research process somewhat more complicated, the mapping to standards used for exchanging data becomes greatly simplified.

For example, Health-Level 7 (HL7; see ► Chap. 7) is an open standards development organization that develops consensus standards for all manner of clinical and administrative data, and is also working on clinical research-specific standards, such as the **Regulated Clinical Research Information Management (RCRIM)** model in order to define messages, document structures, terminology, and semantics related to the collection, storage, distribution, integration and analysis of research information (R. L. Richesson and Krischer 2007). The main focus of the work is on data related to studies involving US Food and Drug Administration (FDA) regulated products (drugs and devices).

The **Biomedical Research Integrated Domain Group (BRIDG) Model**<sup>11</sup> is designed to harmonize models from the HL7 RCRIM, the **Clinical Data Interchange Standards Consortium (CDISC)** a standards group motivated by the needs of the pharmaceutical and bio-technology industry entities that sponsor or otherwise support many clinical studies. CDISC provides a standard for submitting regulatory information to the FDA (Fridsma et al. 2008).

In a similar manner, HL7 has created a standard **Clinical Document Architecture (CDA)**; see ► Chap. 7) that specifies the structure and semantics of “clinical documents” for the purpose of data exchange. A CDA can contain any type of clinical content, including clinical notes typically found in EHRs but may also include case report forms from research studies. **HL7 Fast Healthcare Interoperability Resources (FHIR)**; see ► Chap. 8) supports the exchange of CDA documents (Bender and Sartipi 2013).

The consortia that share clinical data various consortia have each developed their own data models to cover the common elements found in EHRs: patient demograph-

ics, encounters, diagnoses, laboratory results, procedures, and medications. PCORI uses the **PCORNet Common Data Model** (Belenkaya et al. 2015) based on the data model used in the FDA’s Sentinel Initiative,<sup>12</sup> while OHDSI uses the **OMOP Common Data Model** (Ryan et al. 2009). The All of Us program has adopted the OMOP model as well.

## 27.4.2 Terminology Standards to Support Clinical Research

As described previously, the design of clinical protocols includes rigorous attention to the types of data to be collected and the format of those data. This often involves the use of controlled terminologies to capture categorical data. The terminology may be as small as “yes/no” or a ten-point pain scale for capturing subjects’ symptoms, or it may be as vast as a list of all possible drugs or diseases in a subject’s medical history. In many cases, researchers will simply compose sets of terms that meet their immediate needs and then require all investigators participating in the study to apply them consistently.

Because the terms used in clinical research are often identical to those used in clinical care, standard multi-use terminologies (such as those described in ► Chap. 7) are often appropriate for use in capturing clinical research data. However, there are some aspects of clinical research that are not well represented in mainstream terminologies; and in these cases, terminologies and their richer forms, ontologies, that are more focused on clinical research, are required. In particular, clinical research data and workflow models require controlled terminologies and ontologies that define domain-specific concepts and standard **common data elements (CDEs)**. Collections of standard terms for CDEs can be found in the NIH’s Common Data Element server (Rubinstein and McInnes 2015).<sup>13</sup> In a

11 ► <https://www.cdisc.org/standards/domain-information-module/bridg> (Accessed January 1, 2019).

12 ► <https://www.sentinelinitiative.org> (Accessed January 1, 2019).

13 ► <https://www.nlm.nih.gov/cde> (Accessed January 1, 2019).

similar manner, the Ontology for Biomedical Investigations (OBI) (Bandrowski et al. 2016) has been developed by a consortium of representatives from across the spectrum of biomedical research, and includes terms to represent the design of protocols and data collection methods, as well as the types of data obtained and the analyses performed on them.

There are several reasons for considering the use of *standard* controlled terminologies in the capture of clinical research data. One reason is to take advantage of clinical data that are already being collected on research subjects for other purposes. A common example is the use of data on morbidity and mortality that are collected using one of the various versions and derivatives of the **International Classification of Diseases** (ICD; see ► Chap. 7). In the US, for example, patient diagnoses are reported for billing purposes using the *Clinical Modifications* of the tenth edition of ICD (ICD-10-CM). While such coded information is readily available, researchers repeatedly find that ICD-10-CM codes assigned to patient records have an undesired level of reliability or granularity, especially when compared to with the actual content of the records (Topaz et al. 2013). Thus, the convenience of using such standard codes may be outweighed by the imprecision, which can adversely affect study design and analytical results.

A second reason for adopting a standard controlled terminology is simply to avoid “reinventing the wheel.” As is described in ► Chap. 7, a great deal of effort has been expended in the creation of domain-specific terminologies that are comprehensive, unambiguous, and maintained over time. Designating such terminologies for use in a protocol design can relieve researchers of having to worry about the quality of the terminology. For example, a researcher is unlikely to encounter novel concepts when recording subjects’ demographic data, such as gender, marital status, religion, and race. Specifying, for example, that ISO standards should be used for these data elements greatly simplifies the protocol-design process.

A third reason for choosing standard terminologies relates to the ability to compare data collected in one study with those collected

in others. For example, the use of a standard scale for recording a subject’s pain will allow comparison of results from a study of one treatment with those from a second study of another treatment. The selection of an appropriate standard for a particular purpose is not straightforward (for example, the NIH Pain Consortium lists six different scales<sup>14</sup>). The choice may be determined simply based on the emerging popularity of one terminology over another in a wide community of those investigating similar problems. PCORNet, OHDSI, and All of Us each specify the use of terminologies such as ICD, SNOMED, CPT, and LOINC (See ► Chap. 7).

A fourth use of standard terminologies relates to reporting requirements. Government agencies sometimes require the reporting of clinical research data and, when they do, often require certain data to be reported using a particular standard. For example, the FDA requires the use of the **Medical Dictionary for Regulatory Activities (MedDRA)** for reporting all adverse events occurring in drug trials (Brown et al. 1999), while the **Cancer Therapy Evaluation Program (CTEP)** at the National Cancer Institute (NCI) requires the use of **Common Terminology Criteria for Adverse Events (CTCAE)** (Colevas and Setser 2004). In an analogous manner, at the international level, the World Health Organization requires the use of the Adverse Reactions Terminology (WHO-ART).<sup>15</sup> Faced with such reporting requirements, researchers sometimes choose to record data in these terminologies as they are being captured. In those cases where the clinical questions being answered require more detailed data, however, researchers must resort to recording data with some other standard (such as SNOMED; see ► Chap. 7), or a controlled terminology of their own creation, and then translating them to the terminology or terminologies required for reporting purposes.

### 27.4.3 Clinical Research Reporting Requirements

Requirements for reporting research data, particularly those related to outcomes and adverse events, are generally accompanied by specifications for the format of the data being reported. For example, the FDA's Center for Drug Evaluation and Research (CDER) accepts reports using the HL7 Individual Case Safety Report, while the NCI's CTEP allows submission of adverse event information to its Cancer Therapy Evaluation Program Adverse Event Reporting System (CTEP-AERS<sup>16</sup>) either manually, using a Web-based application, or electronically via a web-services API. As mentioned earlier in this section, these agencies require that data be coded with standard terminologies, such as MedDRA and CTCAE, respectively.

Several reporting requirements have emerged for the purpose of making clinical trial results publicly available, both to support reuse of the data by researchers and as information sources for patients and their families. In 2000, the US National Library of Medicine launched [▶ ClinicalTrials.gov](https://clinicaltrials.gov) to provide a mechanism for researchers to voluntarily register their trials so that those interested in participating as research subjects can identify, via the World Wide Web, studies relevant to their condition. [▶ ClinicalTrials.gov](https://clinicaltrials.gov) currently includes information from over 300,000 trials from over 207 countries. In 2004, the European Union initiated a similar effort, called the European Union Drug Regulating Authorities Clinical Trials (EudraCT). [▶ ClinicalTrials.gov](https://clinicaltrials.gov) and EudraCT also support the reporting of the clinical trials results. While the submissions are nominally voluntary, federal agencies often mandate the reporting as a requirement for obtaining research funds or to obtain approval for regulated drugs and devices. In the US, for example, the Food and Drug Administration Amendments Act of 2007 (FDAAA) strongly reinforced these

requirements. In addition, the over 4829 peer-reviewed biomedical journals that participate in the International Consortium of Medical Journal Editors (ICJME) now require public, prospective registration in [▶ ClinicalTrials.gov](https://clinicaltrials.gov) or similar databases of clinical trials of all interventions (including devices) in order for resultant manuscripts to be considered for publication.<sup>17</sup>

Each repository has defined its own mechanisms for transmitting protocol data. [▶ ClinicalTrials.gov](https://clinicaltrials.gov), for example, allows investigators to enter their data through an interactive Web site or to upload data in a defined XML (**eXtensible Markup Language**) format (see [▶ Chap. 7](#)). Clinical research data management systems that can export their study in this format can save the researcher much manual effort and assure accurate data entry (Zarin et al. 2011).

### 27.5 CRI and the COVID-19 Pandemic

The emergence in 2020 of the COVID-19 pandemic has raised many biomedical and health issues on which informatics can have a major impact. Novel challenges include alteration of data collection functions of EHRs ([▶ Chap. 14](#)) and telemedicine ([▶ Chap. 20](#)) to support the needs of patient care and research functions. New data to be captured with these technologies will need to be met with advancements in data sharing and research analytics.

EHRs will need to be easily modifiable to capture new kinds of data when needed for patient care and for research. COVID-19 and other recent epidemics have demonstrated that patient travel and contact information need to be incorporated into the record for risk assessment (e.g., intensity of social contact; Meinert et al. 2020). Such data, in turn, can be used to study epidemiologic patterns across patient populations (e.g., developing predictive risk scores for disease exposure; Liu et al. 2020).

16 [▶ https://ctep.cancer.gov/protocolDevelopment/electronic\\_applications/adverse\\_events.htm](https://ctep.cancer.gov/protocolDevelopment/electronic_applications/adverse_events.htm) (Accessed January 1, 2019).

17 [▶ http://www.icjme.org/journals-following-the-icjme-recommendations](http://www.icjme.org/journals-following-the-icjme-recommendations) (Accessed January 1, 2019).

The value of telemedicine for bringing medical expertise to patients located in an area where expertise is lacking is well demonstrated. In a pandemic, such as the COVID-19 outbreak, the patients are by definition located almost everywhere, while expertise in this new condition is limited to a relatively small number of academic and government institutions. Perhaps as never before, telemedicine is also needed to protect the clinicians and other caregivers who must minimize contact with contagious patients. The technologies of telemedicine are also being exploited for “tele-research” where, again, potential research subjects are widely dispersed and hard to reach and at the same time pose a potential danger to the researchers. COVID-19 researchers are drawing lessons on research at a distance, including effective recruitment and consent, from previous work in HIV (Mgbako et al. 2020) and geriatric research (Nicol et al. 2020).

The rapid expansion of data collection in response to new domains and data types often outstrips the ability of standards organizations to keep up. This poses challenges for the sharing, aggregation, and analysis of data for surveillance, understanding natural history of the disease, and patient recruitment. In COVID-19, new data types and domains have outstripped the standards development organization’s ability to keep up. As a result, consortia such as the the ACT network (see Sect. 29.3.4) and CD2H consortium in the CTSA network (see Sect. 29.3.2), both sponsored by NCATS, as well as the NIH-sponsored All of Us network (see Sect. 29.3.8) have had to develop their own criteria for inferring which patients in EHR databases have COVID-19.<sup>18</sup> For ACT, the criteria support cross-institutional queries to obtain summary results that can be used for patient enrollment.<sup>19</sup> All of Us is ramping up data submissions from healthcare organizations to obtain more timely data on their par-

ticipants who are afflicted with COVID-19. CD2H has established the National Clinical COVID Collaboratory (N3C) to create a centrally sponsored “data enclave”, composed of de-identified COVID-19 patient records from CTSA-sponsored institutions that can be used directly for data analysis (see ■ Fig. 27.4).<sup>20</sup>

COVID-19 research has placed new demands for analytic support. In part, this is due to the perceived urgency to find answers to epidemiologic, preventive, diagnostic, prognostic and therapeutic questions. Another issue is diversity of data sharing and harmonization efforts that exist at the regional and national levels (described above). Researchers are overwhelmed with trying to understand how to navigate various resources, their contents, and associated regulatory constraints, to find the best “fit” given a driving problem or hypothesis (see ■ Fig. 27.5).

## 27.6 Future Directions for CRI

As the preceding sections illustrate, significant progress has been made to advance the state of the CRI domain, and such advances have already begun to enable significant improvements in the quality and efficiency of clinical research. These advances can be viewed as having been achieved at the individual investigator level (e.g., improvements in protocol development, study design, participant recruitment, etc.), through approaches and resources developed and implemented at the institutional level (e.g., development of methods and resources in data warehousing that enable storage and retrieval of clinical data for research, development of novel clinical trials management systems, etc.), and through mechanisms that have enabled and facilitated the endeavors multi-center research consortia to drive team science (e.g., innovations that enable data management and interchange for multi-center studies) (Bourne et al. 2015; P. J. Embi et al. 2019; Payne et al. 2018; Sanchez-Pinto et al. 2017; Smoyer et al. 2016).

# NATIONAL COVID COHORT COLLABORATIVE (N3C)

National Center for Advancing Translational Sciences

## WHY JOIN N3C

There is no shortage of clinical data within institutions; however, in the United States these data are not structured the same way nor are they accessible for shared analytics by our nation's scientists. It is imperative that we overcome these technical and regulatory barriers to address the COVID-19 pandemic. The N3C aims to unite COVID-19 data, enabling innovative machine learning and statistical analyses that require a large amount of data—more than is available in any given institution. The goal is to enable rapid collaboration among clinicians, researchers, and data scientists to identify treatments, specialize care, and to reduce the overall severity of COVID-19. Visit [covid.cd2h.org/join](https://covid.cd2h.org/join) to learn more.

**PARTNERS:** NATIONAL CENTER FOR DATA TO HEALTH | ACT The ACT Network | pcornet | OHDSI | TriNetX

**JOIN US:** [covid.cd2h.org/join](https://covid.cd2h.org/join) | [data2health@gmail.com](mailto:data2health@gmail.com) | [@data2health](https://twitter.com/data2health) #N3C

Fig. 27.4 The National COVID Cohort Collaboratory is a project at the National Institute for the Advancement of Translational Science (NCATS) which is pooling electronic data on COVID-19 patients in order to provide researchers with access to data on patient sets that are larger than those available in a single institution. Efforts include data acquisition and har-

monization, creation of a centralized data enclave to support collaborative analytics, and development of a synthetic data set based on actual patient data, that can be downloaded for analysis but poses no risk of reidentification. (See <https://covid.cd2h.org>. Courtesy of the U.S. National Library of Medicine)

**Fig. 27.5** The emergence of the COVID-19 pandemic has engendered many efforts to share clinical and epidemiologic data in order to rapidly learn patterns of natural history, predictions of risk for exposure and

severe disease, and therapeutic outcomes. Efforts include local sharing in patient care networks as well as national coalitions established to support both patient care and research

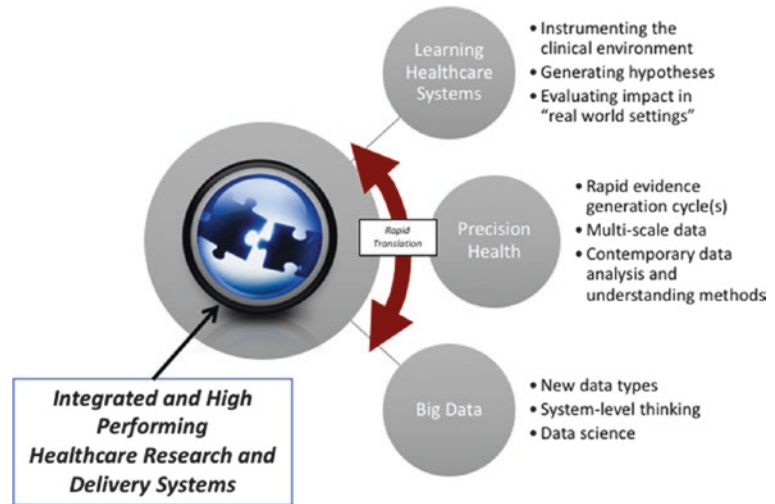

Looking towards the future of the field of CRI, a number of national- and international-level trends are introducing new or evolved challenges and opportunities, including:

- Nearly ubiquitous adoption of EHRs at the national level, as well as the availability of lightweight and scalable data-level and platform-independent interoperability standards are making it possible to **build and leverage learning health care systems at-scale**, in which every patient encounter is an opportunity to learn and improve that patients care as well as the care delivered to broader populations (Friedman et al. 2010). However, while such systems do enable the pragmatic collection and integration of increasingly large volumes of clinical phenotype data, these “real world” data also exhibit new types of challenges in terms of scope, completeness, quality, and domain coverage. As such, new methods are needed to enable the characterization and analysis of such data in a rigorous and reproducible manner.
- Mobile, wearable, and other sensor technologies, in conjunction with new mechanisms for collecting patient reported outcome (PRO) data, are allowing for the conduct of **clinical research studies that**

**incorporate data from beyond the clinic and hospital settings.** However, the temporality, granularity, and reliability of such data is vastly different from that collected via more “traditional” mechanisms as have been introduced in this chapter. As a result, important questions are now being raised concerning how such emergent data sources can/should be integrated with those “traditional” data types, and further, the methods that are appropriate when seeking to identify meaningful “signals” within ensuing multi-scale and complex data sets.

- The ready availability of **artificial intelligence (AI)** platforms and methods (e.g., knowledge-based systems, cognitive computing, high-throughput machine learning, deep learning, etc.) are making it possible to perform **analyses across and between data scales**, for example, identifying meaningful patterns that incorporate genomic, clinical, demographic, social, and environmental measures. Such multi-scale reasoning is essential to the generation of evidence in support of precision medicine and/or health paradigms, but also introduce critical questions concerning how to design and execute such

■ **Fig. 27.6** Aspirational integrated and high performing healthcare research and delivery system model, enabled via emergent CRI frameworks, methods, and technologies

data-intensive studies, again emphasizing reproducibility and rigor as was the case in the two preceding trends.

As CRI capabilities and systems continue to evolve, an ability to assess the maturity of such systems and environments will become increasingly important. As with maturity assessments of EHR deployments and their use across health systems, so too will maturity and deployment models emerge for measuring the deployment and use of CRI systems to enable robust research enterprises (Knosp et al. 2017; Pettit 2013).

One key aspect of system maturity will be a mature workforce of CRI professionals and leaders. Such a workforce will become increasingly important to the successful deployment, management, and optimal use of CRI systems. Examples of such leaders, like the Chief Research Information Officer (CRIO) role first established in 2010, will continue to become common and as essential to the functioning of mature clinical and translational research enterprises as are their health IT (e.g., CIO) and clinical informatics (e.g., CMIO) leader counterparts (Sanchez-Pinto et al. 2017).

When viewed collectively, these emergent challenges and opportunities help to define a rapidly evolving CRI environment, in which we have the ability to create integrated and high performing health care research and

delivery systems (■ Fig. 27.6), driven by rapid translation between and across:

- Functional **learning health care systems** in which we instrument the clinical environment to generate large-scale and pragmatic data, generate hypothesis to be testing in view of such data, and then evaluate the impact of ensuing data-driven intervention in such "real word settings."
- **Precision health** frameworks wherein the translation between research-generated evidence and practice is both rapid and cyclical, acting upon multi-scale data, and using contemporary analysis and understanding methods, such as those being made available through advances in artificial intelligence (AI).
- **Big data** resources, generated via the preceding areas and incorporating new or emergent data types, leveraging systems-level thinking (e.g., across scales) and employing data science methodologies to identify important signals or motifs in such high volume, velocity, and variability data.

## 27.7 Conclusion

This chapter has sought to introduce the following major themes: (1) design characteristics that serve to define contemporary clinical studies; (2) foundational information

needs inherent to clinical research programs and the types of information systems can be used to address or satisfy such requirements; (3) the role of multi-purpose platforms, such as Electronic Health Record (EHR) systems, that can be leveraged to enable clinical research programs; (4) the role of standards in supporting interoperability across and between actors and entities involved in clinical research activities; and (5) future directions for the CRI domain and how such endeavors may alter or optimize the conduct of clinical research. As we have explained, the clinical research environment is data, information, and knowledge intensive, thus calling for the application of biomedical informatics theories and methods. This set of features explains and justifies CRI's emergence as a distinct and highly valued sub-discipline of the broader field of biomedical informatics. Part of the evolution of CRI can be attributed to the extraordinary increase in the scope and pace of clinical and translational science research and development that has been catalyzed by a variety of funding and policy initiatives that seek to re-engineer the way in which governmental, public, and private entities advance basic science discoveries into practical therapies. Such evolution is further bolstered by technical and environmental changes, such as the advent of learning health care systems, the availability of new and novel data capture/generation mechanisms, and advances in our ability to analyze and understand "big data." As such, CRI has accordingly become a dynamic and relevant sub-domain of biomedical informatics knowledge and practice, providing a broad spectrum of research and development opportunities in context of both basic and applied informatics science.

Facilitating phenotype transfer using a common data model. *Journal of Biomedical Informatics*, 96, 103253. This report outlines the role of common data models in facilitating the systematic and reproducible phenotyping of individual patients as well as populations. In addition, the report provides a comparative assessment of existing data models and their utility for computational phenotyping and resultant data analyses.

Payne, P. R., Johnson, S. B., Starren, J. B., Tilson, H. H., & Dowdy, D. (2005). Breaking the translational barriers: The value of integrating biomedical informatics and translational research. *Journal of Investigative Medicine*, 53(4), 192–201. This report describes the critical role of biomedical informatics theories and methods in overcoming the T1 and T2 clinical and translational barriers. It also provides a conceptual model for the alignment of such capabilities with the spectrum of activi-

ties that make up the clinical and translational research “lifecycle.”

Tenenbaum, J. D., Avillach, P., Benham-Hutchins, M., Breitenstein, M. K., Crowgey, E. L., Hoffman, M. A., et al. (2016). An informatics research agenda to support precision medicine: Seven key areas. *Journal of the American Medical Informatics Association*, 23(4), 791–795. This perspective introduces an agenda for informatics research and practice in the context of precision medicine. The authors describe multiple axes of how supporting theoretical frameworks and applied methods can generate and deliver evidence in support of precision risk management, diagnosis, and treatment planning.

Weng, C., Shah, N., & Hripcsak, G. (2020). Deep phenotyping: Embracing complexity and temporality—Towards scalability, portability, and interoperability. *Journal of Biomedical Informatics*. As clinical and translational research becomes increasingly multi-institutional and involves the sharing of deep phenotypes across and between traditional organizational boundaries, there is a need for common tools and methods to derive and represent such constructs. This report outlines the current state-of-the-art in terms of computational phenotyping methods and interchange standards.

## ? Questions for Discussion

1. How do the foundational information needs of clinical research differ depending on the type and phase of study being undertaken? Do study phases have an impact on the primacy of such information needs?
2. What is the role of biomedical informatics with regard to decreasing bias in RCTs and thus enhancing the internal validity, external validity, and generalizability of study results?
3. How can clinical or general-purpose information systems and research-specific tools be employed synergistically to address clinical research-specific information needs, such as participant recruitment or the population of study-specific data capture instruments?

4. How do the core functional components of common clinical trial management systems (CTMS) overlap with or otherwise replicate the functionality of electronic health record (EHR) systems? To what extent does this similarity or difference inform the need for syntactic and/or semantic interoperability among such systems?
5. In what situations is the use of clinical research-specific terminologies or ontologies appropriate? In such situations, what challenges exist relative to the selection, use, and maintenance of appropriate standards?
6. What is the role of data standards in enabling the dissemination and reuse of study-generated data sets? How can the use of such standards enable the cross-linkage or integrative analysis of data sets derived from multiple but independent studies?
7. Compare and contrast the future directions of CRI with those of other BMI sub-disciplines and focus areas described in this book. To what extent are they similar and different, and what are the implications of such findings relative to the role of common informatics theories and methods and their applicability to the clinical research domain?

**Learning Objectives**

After reading this chapter, you should know the answers to these questions:

- What is precision medicine, and how does it differ from traditional medical practice?
- How can Electronic Health Records (EHRs) be used to advance precision medicine discovery?
- How to identify and evaluate phenotypes algorithms from EHRs?
- How are EHRs aiding in implementation of precision medicine?
- How are genomic data being used today in research, clinical care, and consumer health?
- What is Mendelian randomization?
- What are some of the large cohorts being used to advance precision medicine, and what is the importance of diversity in these cohorts to accelerate discovery?

**28.1 What Is Precision Medicine?**

**Precision medicine** is a field focused on understanding the role molecular, environmental, and phenomic variation play in healthcare with the goals of more rational therapeutics, improved understandings of prognos-

is, and more optimal healthcare delivery. Fundamentally, precision medicine focuses on data-driven optimization of health care. This includes more precise understanding of disease through the amassing of both large research studies and amalgamations of truly massive amounts of routinely collected healthcare information from electronic health records. In addition, precision medicine is leveraging new technologies such as sensor-based measurements and omic technologies. The most commonly used technology is genomic assays, such as genotyping (which uses probes to assay large numbers of specific variants) or genomic sequencing (which assess each base pair present within a region or across the genome). However, epigenomics, transcriptomics, proteomics, microbiomes, and metabolomics are also being used and hold promise for further research and clinical care in precision medicine. The rapid growth and availability of other technologies such as sensors and imaging data will also contribute. The ultimate goals are to use all of these data to better guide diagnosis, improve understandings of prognosis, optimize existing treatments, develop new therapies, and design novel prevention schemes (■ Fig. 28.1).

Precision medicine as a field is closely related to personalized medicine, P4 medicine, individualized medicine, genomic medicine,

■ Fig. 28.1 Overview of the goals of Precision Medicine

and other similar recent fields to all share as a goal improvement of health for both individual patients and populations through use of data. Indeed, in practice, most of these terms are used fairly interchangeably amongst most institutions focusing on discovery and implementation of precision medicine approaches. A key differentiator is that precision medicine focuses primarily on its goals through enhanced understandings and new taxonomies that lead to redefinition of the diseases themselves. Precision medicine shares with these other terms the centuries-old goal of individualizing care for individual patients, following Sir William Osler's maxim: "The good physician treats the disease; the great physician treats the patient who has the disease." The primary difference between now and then is the deluge of new modalities and quantities of information truly allowing us to leverage big data to solve problems of individual health in new ways. Such scale of huge data sets is needed, for instance, to untangle the contribution of rare genomic variation to the clinical impact on individual patients. For example, out of 6.4 billion base pairs in the (diploid) human genome, an average patient genome may have 4.1 million to 5 million genetic variants (1000 Genomes Project Consortium et al., 2015). Distilling the impact of these variants in such a way that clinicians can make use of this information is a substantial challenge for both rare and common disorders.

In this chapter, we will focus on the informatics resources for and implications of precision medicine. We will also provide a basic overview of precision medicine. Informatics is needed for the capture of data, transformation of data into information and knowledge, and – perhaps most importantly – implementation of precision medicine – acting on that new knowledge to improve the health of real people. Electronic health record (EHRs) are an important part of precision medicine both by providing a real world data source as well as a key modality for its implementation. Relevant other chapters to this chapter include ► Chaps. 9 and 26.

## 28.2 Using EHRs for Genomic Discovery

Electronic health records (EHRs) have been an important part of clinical care for decades, but over the last decade have become an increasing part of discovery to advance precision medicine. While retrospective epidemiological research has been performed using claims data for decades, the more recent use of electronic health records for molecular research, especially genomics, over the last decade has become transformational. EHRs contain a wealth of dense patient data that are valuable for discovery, and that would cost significant sums to reproduce in a research cohort (► Fig. 28.2). As such, they have become a valuable source of information for retrospective research (Robinson, Wei, Roden, & Denny, 2018).

The first successful use of electronic health records for genetic discovery was in 2010. Four papers published that year used EHR data as the sole phenotypic information to replicate known genetic effects (Denny, Ritchie, Basford, et al., 2010; Denny, Ritchie, Crawford, et al., 2010; Kullo, Ding, Jouni, Smith, & Chute, 2010; Ritchie et al., 2010). Ritchie et al. tested for the associations between 5 diseases and 21 SNPs that were known to be associated from prior literature and replicated all associations for which the study was adequately powered (Ritchie et al., 2010). The other studies added replications with endophenotypes of cardiac conduction and red blood cell traits. These studies included the first EHR-based **genome-wide association studies (GWAS; ► Fig. 28.3a)** – studies which test for association between a phenotype and hundreds of thousands to millions of single nucleotide polymorphisms (SNPs). GWAS is discussed more in ► Sect. 28.4.1. Importantly, these studies suggested a process for developing phenotype algorithms that identified both cases and controls as two separate groups. Each algorithm used a variety of types of EHR data to identify their populations with high positive predictive values (analytics for phenotype algorithms are

Robinson JR, et al. 2018.  
*Annu. Rev. Biomed. Data Sci.* 1:69–92

**Fig. 28.2** Density of phenotypic data in an EHR linked biobank. All rows represent data from patients that enrolled in BioVU, the Vanderbilt DNA biobank. The first patient enrolled in 2007. This figure demonstrates that individuals can have decades of extant EHR

data prior to their enrollment, allowing both cross-sectional and *in silico* longitudinal studies. Each point represents real data transformed by square root divided by 20 of the actual count at that time period. (From Robinson et al., 2018)

discussed in more detail in ► Sect. 28.3 below). Another important early study validated known SNPs associated with rheumatoid arthritis using a validated EHR algorithm (Kurreeman et al., 2011). This study demonstrated the effect sizes from the EHR algorithms and from prior research studies were similar.

Another advance highlighted first in early EHR studies was the **phenome-wide association study (PheWAS; Fig. 28.3b)**, which is discussed in ► Sect. 28.4.3 below. That the first systematic “PheWAS” was performed in EHRs was enabled by the broad collection of phenotypes found in EHRs that is essentially unrelated to an *a priori* research hypothesis (Denny, Ritchie, Basford, et al., 2010). PheWAS approaches have been applied in observational cohorts as well (Millard et al., 2015; Sarah A Pendergrass et al., 2013).

An important development in the use of EHRs for precision medicine was the National Human Genome Research Institute-funded **Electronic Medical Records and Genomics**

**(eMERGE) network**, which began in 2007. eMERGE had the explicit goal of exploring the capabilities of EHRs for genomic discovery. The initial eMERGE network had five sites and has been renewed twice, now in its third iteration, with 10 sites. In subsequent iterations, eMERGE has grown from a primary focus of discovery to also include implementation of genomic medicine (Rasmussen-Torvik et al., 2014). The first novel discovery out of eMERGE was in 2011 by identifying variants in *FOXE1* associated with autoimmune hypothyroidism (some of the results from this study are shown in ► Fig. 28.3) (Denny et al., 2011). Since then, eMERGE sites have investigated nearly 100 different phenotypes, many with novel discoveries (Crawford et al., 2014).

### 28.3 Finding Research-Grade Phenotypes in EHRs

A characteristic of EHR phenotypes is the combination of multiple modalities of the

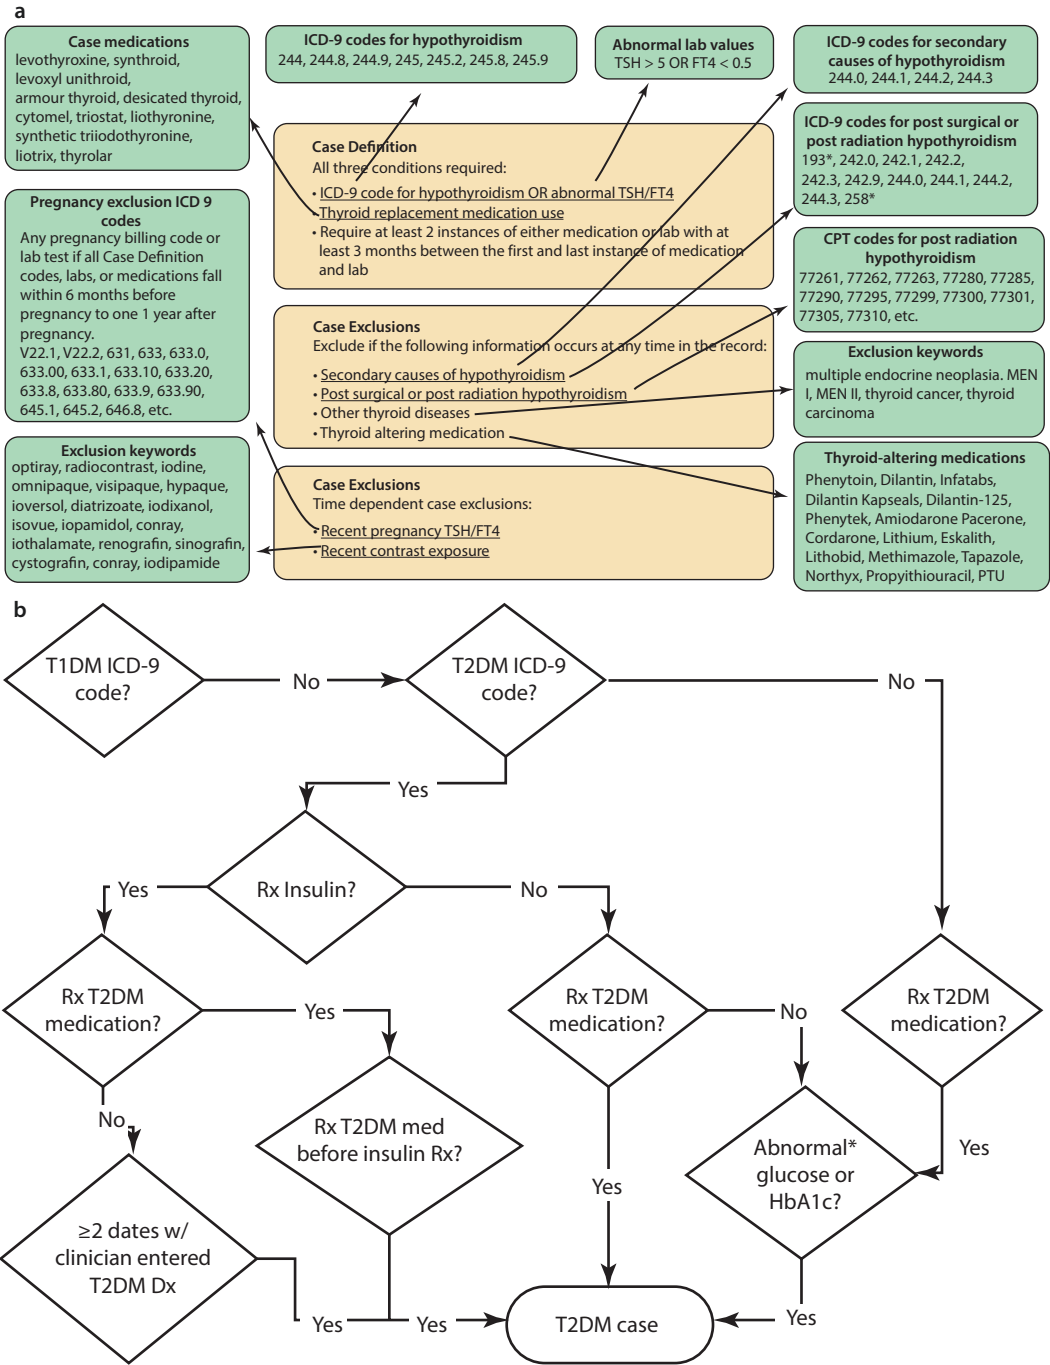

**Fig. 28.3** Example GWAS and PheWAS using EHR data. **a** Manhattan plot from a GWAS of autoimmune hypothyroidism performed in the eMERGE Network. This GWAS identified variants in *FOXE1* as a risk factor for autoimmune hypothyroidisms, a novel finding at the time. **b** PheWAS of the variant identified in panel

A. This PheWAS identified autoimmune thyroid disease associated with this variant and highlighted other conditions, like atrial flutter, that are inversely associated with hypothyroidism. (With permission from Denny et al. 2011 © Elsevier)

EHR information to identify high-quality research grade phenotypes. Most frequently, they include billing codes, medications, laboratory results, and some sort of text processing or natural language processing. Example phenotypes for autoimmune hypothyroidism and type 2 diabetes are shown in **Fig. 28.4**.

Both of these were validated at more than one site and demonstrated successful genomic discovery or replication (Denny et al., 2011; Kho et al., 2012). Clearly, sufficient sample size (and consequently statistical power) is needed to identify associations. Thus, the eMERGE network has found it necessary to run pheno-

**Fig. 28.4** EHR phenotype algorithms for Autoimmune Hypothyroidism and Type 2 Diabetes. Details for each of these algorithms are available on <http://PheKB.org>. Each algorithm was validated by manual chart review at multiple institutions. (Figures adapted from: **a** Conway et al., (2011) and **b** Kho et al., (2012))

type algorithms across different sites to increase sample size. In doing so, eMERGE found it helpful to collaboratively develop

phenotypes across different sites given local variability in EHR systems, billing practices, and institutional practices. Algorithms from

eMERGE and other networks have been shared for use on ► [PheKB.org](https://phekb.org) (Kirby et al., 2016). Currently, PheKB houses more than 150 EHR-based algorithms.

There are many algorithmic approaches to creating high-quality phenotype algorithms. Perhaps the most common approach is through combinations of different elements via Boolean-logic, such as the algorithms depicted in ■ Fig. 28.4. Other researchers have trained machine learning algorithms using a set of reviewed cases and controls. Among the first demonstration of this approach was using the Partners Biobank to find rheumatoid arthritis patients (Kurreeman et al., 2011; Liao et al., 2010). While algorithms using machine learning often can be overfit on a particular data set, research has shown that at least some machine learning approaches in EHR data can be portable across different EHR systems (Carroll et al., 2012). This machine learning approach has also been applied to Veteran Affairs EHRs from the Million Veteran Program to find cases of acute ischemic stroke (Imran et al., 2018).

A common theme among both rule-based and machine learning approaches is incorporation of different types of data (e.g., billing codes, laboratory data, note content, and medication data) from the EHR. ■ Table 28.1 reviews the most common features used by algorithms posted in PheKB. In addition, rules requiring more than one instance of a given data type often improve algorithm performance as well. A study looking at 10 different diseases across ICD codes, clinical notes, and medications specific to diseases demonstrated that use of multiple modalities improves algorithm performance more than counting rules within a single data type (Wei et al., 2016). In this study, the average PPV of a single ICD code instance was only 0.37, but this increased to 0.84 when 2 or more instances of ICD codes were required. Requiring at least 2 different elements improved PPV to 0.91. Overall, notes were the most sensitive data type.

The overall process of defining and evaluating a phenotype algorithm is shown in ■ Fig. 28.5. In evaluating a phenotype algo-

■ **Table 28.1** Data modalities used in phenotyping algorithms available on PheKB

	Public (n = 44)	Nonpublic (n = 110)	Percent of total
ICD-9/-10 codes	39	73	73%
Medications	31	51	53%
CPT codes	23	44	44%
NLP	28	36	42%
Laboratory test results	21	37	38%
Vital signs	5	14	12%

From Robinson et al., (2018)

rithm, it has become common to compare the algorithm to manual chart review as the “gold standard”. Two typical approaches have been undertaken for this analysis (Newton et al., 2013). One is to use clinically-trained professionals to evaluate the patient records to determine whether or not the individual match the given clinical condition being assessed. The other approach is to develop a formal chart abstraction instrument that trained chart abstractors will review the chart to identify the elements to determine who it matches the case (or control) definition. This approach often proposes a set of rules for reviewers to validate in the patient record that determine if an individual meets a research-defined case definition. Regardless of the approach for chart review, the process is usually iterative: an investigator proposes an algorithm, executes it on a population, and then evaluates a set of charts. Especially if the chart review is using a trained professional instead of a chart abstraction instrument, it is best practice to include both individuals who match the algorithm

■ **Fig. 28.5** Overview of the general approach to finding a phenotype in the EHR

and those who do not match the algorithm in the chart review to avoid anchoring bias. In this review, the order of the charts would be randomized and the reviewers blinded to the algorithm's determination of case (or control) status. After review, the investigators can calculate the **positive predictive value (PPV)** as the number of true positives divided by (the number of true positives plus the number of false positives). Additionally, researchers may want to calculate a **sensitivity** (or recall). Calculating recall for common diseases may be relatively straightforward but very challenging to assess for rare diseases. Thus, many reviewers often make simplifying assumptions about requirements to be a case. For example, many researchers make the assumption that a case must have at least one relevant ICD code to be a case (Carroll et al., 2012; Liao et al., 2010). This approach provides a reasonable estimate of sensitivity.

PPV is typically viewed as the most important metric performance for a case-control study, since it is usually more important to be sure to have high-quality cases and controls for a given analysis. For instance, review of phenotype algorithm implementa-

tions on ► [PheKB.org](https://phekb.org) demonstrated that out of 145 posted implementations (as of December 2018), 79 (54%) reported PPV and 33 (23%) reported recall. The condition in which sensitivity is more important is when the variable is being used as a covariate in an analysis.

To facilitate EHR based discovery, huge data sets are needed. While the growth through the early 2000's and this decade have often been focused on single EHR systems, there is an increasing need to combine data across sides for discovery. This is important both for the needs of amassing the necessary size of this size as well as representing diversity of geography, demographics, environmental exposures, and practice habits, which can vary between institutions and geography. In short, this effort has been facilitated through use of common data representations such as the Fast Health Interoperability Resource (FHIR) and common data models (CDMs). Most frequently used common data models have been the Informatics for Integrative Biology and the Bedside (i2b2) data model, PCORNet, and the OMOP data model. These are discussed in more detail in ► Chap. 25.

## 28.4 Omic Discovery Approaches

Over the last three decades, the explosion of efficient and relatively inexpensive dense molecular measures has led to the growth of more data-driven molecular investigations of traits and diseases. The most commonly investigated currently would be genomic investigations. Some of these are also finding translation into clinical practice (discussed in ► Sect. 28.7). The research observation of genetic pleiotropy (the condition in which one gene or genetic variant impacts multiple phenotypes) combined with more dense phenotypic assessments have led to similar hypothesis-free tests of association of the phenome. Specific technologies are discussed further in ► Chaps. (9 and 26).

### 28.4.1 Genome-Wide Association Studies (GWAS)

A GWAS systematically surveys polymorphisms across the genome to find variants associated with a trait or disease. Variants for a GWAS are typically weighted toward more common SNPs that can represent a broad range of genomic variation based on linkage disequilibrium, that is the nonrandom clustering of variation in the genome based on inheritance patterns. Thus, relatively small numbers of the >3 billion base pairs in the (haploid) human genome can represent a large fraction of inherited variation in the genome. Most GWAS assay >500,000 mostly SNPs common SNPs. More recent GWAS have incorporated rare variants, such as functional genomic variants known to be associated with disease and pharmacogenomic variants.

The first GWASs (■ Fig. 28.3a) was conducted in 2005 and 2006 and discovered genetic variants associated with Age-related Macular Degeneration of ~100k SNPs (Dewan et al., 2006; Klein et al., 2005). The modern era of array-based GWAS approach with large case control populations identifying common variants influencing common disease was arguably introduced in a large scale by the 2007 by the Wellcome Trust Case Control Consortium, which successfully iden-

tified SNPs associated with 7 common diseases (Wellcome Trust Case Control Consortium, 2007). As mentioned above, the first GWAS using EHR information to define cases and controls was performed in 2010 (Denny, Ritchie, Crawford, et al., 2010; Kullo et al., 2010). Since then, the number of EHR-based GWAS and large consortia using EHR information has risen dramatically (Wei & Denny, 2015). The current inclusion of routine healthcare data in very large cohorts (see ► Sect. 28.6 below) has made reliance on healthcare data such as those from EHRs or administrative claims data now commonplace.

Since 2009, published GWAS have been curated and made available via the online GWAS Catalog, begun first by NHGRI and now hosted by EMBL-EBI (► <https://www.ebi.ac.uk/gwas/>) (MacArthur et al., 2017). By 2010, more than 500 GWASs had been performed on a wide variety of traits in common disease, and by the end of 2018, this had grown to 3675 publications reporting one of more GWASs, noting associations between 87,081 SNPs and phenotypes (Green, Guyer, & National Human Genome Research Institute, 2011; MacArthur et al., 2017).

### 28.4.2 Genomic Sequencing

The rapidly falling cost of genomic sequencing (to several hundred for a research whole exome and less than \$1000 for a whole genome as of the end of 2018) is leading to a dramatic growth in use of genetic sequencing. The primary added benefit of genomic sequencing to precision medicine at the current time is a better and more detailed assessment of rare and very rare variants through a more comprehensive coverage of the genome. Sequencing approaches have enabled the discovery of novel variants for common disease and have been especially impactful for the uncovering of variants in rare disease. Sequencing is routinely used now clinically to aid cancer care or diagnose rare genetic diseases. In research, sequencing is rapidly expanding our ability to discover associations with rare conditions. The NIH's Undiagnosed Disease Network, for instance, routinely

employs whole exome sequencing (WES) or whole genome sequencing (WGS) to diagnose individuals. As a notable win for sequencing, the UDN has been able to diagnose 35% of individuals referred into their network, 74% of which were made with the addition of genomic sequencing to comprehensive clinical phenotyping (Splinter et al., 2018). In addition, they have defined 31 new syndromes through their comprehensive clinical and molecular assessments of undiagnosed patients.

### 28.4.3 Phenome-Wide Association Studies (PheWAS)

Growth of EHR based cohorts provided rich and diverse phenotype data to complement biologic data. Whereas GWASs provided a way to assess genomic accession associations in a hypothesis-free manner starting around 2005, GWAS usually assesses only one phenotype at a time. However, the growth of GWAS quickly highlighted the occurrence of genetic pleiotropy – the condition in which one gene influences multiple independent phenotypes. Thus, the rich collection of diverse phenotype information in EHRs and other growing cohorts provided the ability to simultaneously access phenotype associations in the same scanning hypothesis free manner as GWAS. The first PheWAS EHR-based aggregated billing codes into 744 PheWAS “cases” (Denny, Ritchie, Basford, et al., 2010). Each case was linked to a control group. After identification of case and control groups, a PheWAS (■ Fig. 28.3b) is essentially a pairwise test of all phenotypes against an independent variable, such as a genetic variant or laboratory value. For a genetic variant, PheWAS is analogous to genetic association tests performed in a GWAS, with a typical approach employing a logistic regression adjusted for demographic and genetic variables, such as genetic ancestry. The first PheWAS tested seven known SNP-disease associations, replicating four and suggested a couple of new associations. Newer approaches to PheWAS have leveraged increased density of phenotypes from the EHR, which current methods mapping

ICD9 and ICD10 codes into >1800 phenotype case groups. A 2013 study shows that this approach was able to replicate 66% of adequately-powered SNP-phenotype pairs, and also identified several new associations that were replicated (Denny et al., 2013). A catalog of some of the PheWAS associations found to date is available at ► <http://phewascatalog.org>. A PheWAS of all phenotypes available in the UK Biobank has also been performed (► <http://www.nealelab.is/uk-biobank>).

PheWAS can essentially be performed on any broad collection of phenotypes. Researchers have used raw unaggregated ICD codes, other aggregation systems of ICD codes, or phenotypes collected from observational cohorts (Hebring et al., 2013; Pathak, Kiefer, Bielinski, & Chute, 2012; S A Pendergrass et al., 2011). The disadvantage to using more granular ICD codes is the increased number of hypotheses being tested, which hinders the statistical power to detect a result. Lack of ICD code aggregation can also introduce variability in coding practices that decreases sample size for a given phenotype, such as the number of specific diagnostic codes available to represent common conditions and their complications, such as diabetes mellitus subtypes (e.g., with specific codes for controlled or uncontrolled glucose status and its resulting cardiovascular, renal, or neurological complications) or gout (e.g., chronic or acute, with or without tophi, etc).

PheWAS can quickly highlight potential pleiotropy of a given genetic variant or other independent variable by analyzing for associations with multiple phenotypes within a single population, one can test the independence of the potential pleiotropic findings with subsequent conditioned analyses. Other advantages of PheWAS is that they are quick to perform and easily implemented through existing R packages (► <https://github.com/PheWAS/PheWAS>) or iteration through common statistical packages. A disadvantage of PheWAS is that its phenotypes can be coarse and can have both lower sensitivity and PPV than custom phenotype algorithms as discussed in ► Sect. 28.3. Fortunately, these types of bias typically biased towards the null. Associations

found via PheWAS can require refinement and subsequent validation.

#### 28.4.4 Other Omic Investigations

In addition to genomics, the growth of a number of other omic approaches are providing greater insight into an individual's environment, endophenotypes, and molecular measures. Some of these include the microbiome, proteome, metabolome, and other bioassays. Additional dense phenotypic and environmental assessments include dense measures of the environment and personal sensor-based technologies, such as consumer activity monitors. Publicly available datasets providing detailed measures of pollution, the built environment, weather patterns, availability of quality food or greenspace, and sociodemographic factors are available for linkage via geolocation, linked via smartphones and other devices that continuously track geolocation. These devices can also measure activity and heart rate to provide greater insight into a person's habits and physiological factors. Today, the clinical impact of many of these measures is not yet known. However, their growing ubiquity through both research and commercial interests are enabling deeper investigation into their clinical impact. They are also being included in large research cohorts (see ► Sect. 28.6).

### 28.5 Approaches to Using Dense Genomic and Phenomic Data for Discovery

#### 28.5.1 Combining Genotypes and Phenotypes as Risk Scores

Most genetic variants discovered via GWAS have had relatively mild effect sizes for their phenotype of interest. However, the size of modern GWAS, now involving hundreds of thousands of individuals for more common traits, have allowed identification of many independent genetic loci, sometimes reaching into the hundreds of distinct loci (Locke et al.,

2015; Okada et al., 2014; Wood et al., 2014). Collectively, these genetic variants can explain a much larger percentage of the variance in disease risk than the individual risk variants, even when the effect sizes of many of the individual variants may be rather small (e.g., having odds ratios of  $\sim 1.01$ ). As a tool, researchers have aggregated genetic risk variants into a calculated score (called a “genetic risk score”, **GRS**, or “polygenic risk score”, **PRS**), typically as a sum of the presence of the variant multiplied by a weight, often taken from a regression analysis. These risk scores need to account linkage disequilibrium to find independent loci and may also produce a weighted model using penalized regression. A simple approach can be given as:

$$GRS = \sum_{i=1}^k w_i N_i$$

where  $w_i$  is the weight for the variant (e.g., the log odds ratio from a logistic regression) and  $N_i$  is the number of risk alleles for that variant (typically, 0, 1, or 2). The clinical advantage of a GRS is that it provides a way to evaluate the aggregate risk of an individual having a given disease that takes into account many typically small risk factors.

For instance, consider breast cancer genetic testing. It has long been recognized that variants in *BRCA1* and *BRCA2* confer significant increased risk of breast cancer to carriers of these mutations. While pathogenic variants in these genes do confer a large risk of breast cancer (lifetime risk of 45–65%), the vast majority of breast cancer is not related to these variants, since they are present in <1% of the general population (Torkamani, Wineinger, & Topol, 2018). However, common SNPs from a large breast cancer GWAS published in 2017 represents about 41% of the familial risk of breast cancer (Michailidou et al., 2017). Studies with cardiovascular diseases have found similar results and potential clinical utility for PRS. In a study looking at 5 prospectively-followed cardiovascular cohorts with genetic testing found that polygenic risk scores and lifestyle factors were independently associated with incident cardiovascular events (Khera et al., 2016). Moreover, their study

identified that patients with high genetic risk of cardiovascular disease but healthy lifestyles were at similar risk to those with unhealthy lifestyles but low genetic risk. Importantly, healthy lifestyles decreased cardiovascular risk at any genetic risk threshold, suggesting the importance of potential preventative lifestyle modifications and therapies in those individuals at high genetic risk.

A more recently introduced approach is to do a similar process with phenotypes in a **phenotype risk score (PheRS)** (Bastarache et al., 2018). In the initial demonstration of PheRS, ICD codes were mapped to phecodes and summed weighted based on the inverse log of the frequency of the phecode in the EHR:

$$PheRS = \sum_{p=1}^m w_p x_{i,p}$$

where:

$x_{i,p} = 1$  if individual  $i$  has phenotype  $p$ , or 0 otherwise

$$w_p = \log \frac{N}{n_p}$$

where  $n_p$  is the number of individuals with phenotype  $p$ . By aggregating phenotypes in a similar way as genotypes, a combined score can increase the sensitivity to detect the phenotypic impact of a genetic variant. For example, the PheRS for cystic fibrosis includes component phenotypes such as bronchiectasis, pneumonia, infertility, and asthma. The disease code itself (“cystic fibrosis”) is not part of the PheRS. Based on EHR weighting, bronchiectasis has a much higher weight than asthma since asthma is much more common. This approach was used in an initial demonstration exercise looking at ~1200 Mendelian diseases that could be tested in an EHR population. In this study, PheRS was able to identify diagnosed genetic diseases in the EHR using the component phenotypes of disease and was also able to be used to identify novel pathogenic variants for undiagnosed conditions.

## 28.5.2 Mendelian Randomization

**Mendelian randomization (MR)** is a technique used to provide evidence for the causality of a biomarker on a disease state in conditions in which randomized controlled trials are difficult or too expensive to pursue. For example, low density lipoprotein (LDL) and high-density lipoprotein (HDL) levels have long been associated with myocardial infarctions in observational cohorts, but it is unclear whether they are markers or causal: perhaps these levels are a marker of diet, activity level, or other unknown factors. It is essentially impossible (and probably unethical) to perform a randomized control trial that alters someone’s LDL or HDL levels in isolation. However, a number of genetic variants have been found that alter LDL and HDL levels. Since alleles are randomly distributed to ova or sperm during meiosis, studying the impact of biomarker-influencing alleles provides a naturally occurring randomization of the risk factor. Genetic variants are generally not associated with behavioral, social, and some physiological factors – reducing confounding. Thus, by studying the impact on the clinical outcome of the variants associated with the biomarker, one can assert causality of the biomarker to the outcome of the variant. MR has proven a powerful tool in recent years (■ Fig. 28.6). MR studies have demonstrated clear associations between LDL and triglyceride levels and cardiovascular disease while casting doubt on the role of HDL in protecting against cardiovascular disease (Holmes et al., 2015; Voight et al., 2012). The latter is particularly interesting as cholesteryl ester transfer protein (CETP) inhibitors, medications targeted to raise HDL, have so far not been successful at reducing mortality (Mohammadpour & Akhlaghi, 2013).

By providing an approach to assess causality, MR can also provide an approach to investigate potential drug effects. An MR approach demonstrated that the lipid-lowering agent ezetimibe would reduce cardiovascular disease (by studying the clinical impact of

**Fig. 28.6** Mendelian Randomization (MR) vs. Randomized Controlled Trials (RCT). MI myocardial infarction, *LDL* low density lipoprotein levels. \*Allele could represent a single SNP or group of SNPs (e.g., combined via a genetic risk score)

genetic variants mimicking its effect) prior to a randomized controlled trial demonstrated this effect (Cannon et al., 2015; Myocardial Infarction Genetics Consortium Investigators et al., 2014). Similarly, MR has been used to show that diabetes is a potential concern for PCSK9 inhibitors and combined with PheWAS to highlight potential unanticipated side effects (Jerome et al., 2018; Schmidt et al., 2017).

### 28.5.3 Using Dense Data-Driven Measures to “Redefine” Disease

There is increasing enthusiasm that precision medicine will lead to new ways of defining disease and selecting treatments that will identify more rational therapeutic choices, improve our understanding of prognosis, and result in more effective disease screening. One example is cystic fibrosis pharmacotherapy, for which medications have been developed to target defects corresponding with specific genetic variants (O’Reilly & Elphick, 2013). These targeted therapies have dramatic influence on the disease course. There is a hope that similar approaches could be found for many common diseases aiding in drug selection and risk stratification for diseases such as depression, diabetes, hypertension, heart disease, and many other common diseases. Recent studies using clinical and molecular information have suggested subtypes of type 2 diabetes, heart failure, and autism (Ahmad et al., 2014; Doshi-Velez, Ge, & Kohane, 2014; Li et al., 2015); however, the clinical impact of such

subtypes is unclear. Two examples of where targeted treatment for disease is currently being utilized in practice are pharmacogenomics and oncology, which are discussed in more detail in ► Sect. 28.7.

### 28.5.4 Use of Machine Learning and Artificial Intelligence to Advance Precision Medicine

The focus of this section is largely on the application of these methods to advance precision medicine. Other discussions on machine learning and artificial intelligence appear in ► Chap. 9.

Machine learning falls into two major classes of approaches: supervised and unsupervised, with the ability to apply many different algorithms. **Supervised machine learning** approaches tasks use a gold standard set as input to learn classifiers designed to optimally mimic the training set. **Unsupervised machine learning** learn patterns from the data without labeled training sets. Machine learning has the potential to augment any classification task, and has long been used with clinical data. Machine learning has been used for many tasks in EHRs (such as in natural language processing (Jiang et al., 2011; Y. Wu et al., 2017)) and in bioinformatics, such as aiding in interpretation of genetic variants (Kircher et al., 2014). Some of these use cases are referenced above, such as the learning of phenotype classifiers using EHR data and labeled cases or controls (Carroll, Eyer, & Denny, 2011; Liao et al., 2010; Lin et al., 2015; Peissig et al., 2014).

Recent areas of exploration in machine learning have seen a rapid rise in deep learning approaches. These take massive datasets and multi-layered neural networks to learn patterns in data that have proven superior to other machine learning techniques. They typically require very large data sets that have previously been unavailable in healthcare or biomedical research. However, the recent rapid growth of available EHR, genomic, and imaging data sources is enabling a new potential for machine learning to be applied to these data sets as well. Recent examples include training algorithms to identify malignant skin lesions and diabetic retinopathy from retinal scan (Esteva et al., 2017; Gulshan et al., 2016). These algorithms can present with performance that equals that of trained physicians at times. A challenge of these approaches is that they required huge data sets: the Gulshan et al. algorithm which used nearly 130,000 labeled retinal digital images to train its diabetic retinopathy algorithm (Gulshan et al., 2016). The growing availability of large-scale public biomedical data through cohorts such as those mentioned in ► Sect. 28.6 represent an important opportunity to accelerate such research. In addition, a number of for-profit companies, such as Alphabet, IBM, and many startups, have formed partnerships with diverse clinical entities from individual healthcare systems to the United Kingdom's National Health Service (Saria, Butte, & Sheikh, 2018).

## 28.6 Large Cohorts to Advance Precision Medicine Discovery

Clinical care since the 1960s has been dramatically influenced by observational cohort studies. Studies such as the Framingham Heart Study, the Nurses Health Study, or National Health and Nutrition Examination Survey (NHANES) have produced dramatic insights that have fundamentally changed our understanding of modifiable risk factors for many diseases. For instance, the Framingham Heart Study taught us that blood pressure, cholesterol, smoking, and activity contribute

to cardiovascular disease risk. Its initial discoveries were derived from detailed longitudinal assessment of just under 5000 individuals. Most of these epidemiological cohorts have largely focused on answering exposure- or disease-focused questions. Two developments beginning in the early 2000s have brought new data resources to advanced discovery in more disease-neutral fashion. One has been the growth of large national-scale cohorts containing diverse phenotypic information connected with biosamples, and the other has been the growth of incorporation of routinely collected healthcare data linked to biological specimens. Example cohorts include the UK Biobank, the Million Veteran Program, the *All of Us* Research Program, and the China Kadoorie Biobank (► Table 28.2). Collectively, these cohorts will enroll millions of individuals across the world for longitudinal assessment of healthcare outcomes analyzed against molecular and environmental exposures. Each of these cohorts includes both participant-generated survey data and healthcare-derived data linked with biospecimens. Several of these cohorts also include the ability to recontact individuals. Collectively, these multiple complementary avenues of phenotype assessment augment passive phenotype collection (e.g., with EHR and claims-type data) with participant-provided information and the potential for reassessment with deeper phenotyping along topics of interest. Within *All of Us*, the participant provided survey information and the in-person research protocol physical measures are both being incorporated into the OMOP Common Data Model to simplify comparison of these data modalities. Digital engagement through email or websites or the collection of healthcare information enable cost-efficient follow-up for healthcare outcomes over long periods of time. Some of these larger resources are also pioneering newer models of researcher access that facilitate broad researcher communities to access the environments. An important aspect for these cohorts is the diversity of its participants, which is discussed in the next section.

### 28.6.1 Need for Diversity, and Role of Precision Medicine in Health Disparities

Health disparities are abundant in health care. The same concerns can be said for precision medicine, for which variabilities in health insurance coverage, access to care, and financial situations may alter availability and accessibility for precision therapies (Bentley, Callier, & Rotimi, 2017). However, it is also true that precision medicine has the potential to identify and help alleviate some health disparities. Since genetic variants vary by ancestry, genetic testing has the opportunity to identify those most at risk for adverse events based not just on ancestry but on actual carriage of variants. Moreover, drugs traditionally have not been tested in all diverse populations and risk factors may not always be identified reach population. For instance, individuals of Asian ancestry are at much greater risk for severe skin reactions such as

Stevens-Johnson syndrome from antiepileptics such as carbamazepine (Phillips et al., 2018). Similarly, it has been noted that carriage of *CYP2C19* loss of function of alleles is much more common in individuals of Pacific Island descent (Kaneko et al., 1999). Since diverse ancestries are often not tested in large numbers in clinical trials, the increased risks in diverse populations are not necessarily noticed. However, genomic testing would identify those at greater risk of adverse events thus identifying the opportunities to optimize care. The specific association of clopidogrel and reduced efficacy in individuals of Pacific Island descent was a subject of a lawsuit (A. H. Wu, White, Oh, & Burchard, 2015).

Unfortunately, the vast majority of individuals who have been genotyped or sequenced to date are of European ancestry. For instance, a 2016 study noted that 81 percent of all individuals who had undergone GWAS at that time were of European ancestry, and only ~4% represented African, Hispanic, or native

ancestries (Popejoy & Fullerton, 2016). Those latter populations represent about one-third of the current US population. A lack of diversity in genetic testing results in a lack of knowledge of the genetic architecture for diverse populations. For instance, variance in warfarin sensitivity vary by ancestry such that the variants needed to accurately guide prescribing for European and African ancestry are different (Perera et al., 2013; Ramirez et al., 2012). Moreover, it is known that individuals of African ancestry typically require higher doses of warfarin. However, most of the warfarin pharmacovariants that have been identified actually increase sensitivity to warfarin rather than reducing it.

The lack of diversity genotype populations affects not only our ability to adequately treat individuals with diverse ancestries, it also hinders discovery. For instance, the discovery of rare *PCSK9* loss-of-function variants as a drug target for cholesterol and cardiovascular disease was discovered in African Americans (Cohen, Boerwinkle, Mosley, & Hobbs, 2006). These loss of function variants led to production of monoclonal antibodies against PCSK9 that dramatically reduce cholesterol levels – and will treat individuals of essentially any ancestry (Sabatine et al., 2017).

## 28.7 Implementation of Precision Medicine in Clinical Practice

Currently, most efforts in precision medicine implementation focus on genomics. This comes in three main flavors: germline genomic changes to better tailor drug prescribing, diagnosing genetic disease, and identification of somatic variants to guide cancer therapy. A number of networks have been funded by the NIH to support these integration of genomic medicine into clinical care. They include the Implementing Genomics Into Practice (IGNITE) network, Electronic Medical Records and Genomics (eMERGE) Network, Clinical Sequencing Evidence-Generating Research (CSER) Network,

the Pharmacogenomics Research Network (PGRN), and the Newborn Sequencing In Genomic medicine and public Health (NSIGHT) Network (■ Table 28.3).

**Cancer genomic testing** Perhaps the most widespread use of precision medicine currently is for somatic variation to target cancer therapies. Cancer therapies have long recognized the contribution of genetic variation to prognosis, starting with clinical karyotyping. One of the earliest applications of truly targeted therapy started with identification of the Philadelphia chromosome/translocation, which generates a fusion gene product BCR-ABL1. BCR-ABL1 results in the tyrosine kinase Abl being constitutively activated and is a marker for acute lymphoblastic leukemia and chronic myeloid leukemia. It's particular relevance to targeted therapy was noted in the 1990s when imatinib was identified through high throughput screening assays of tyrosine kinase inhibitors. Randomized controlled trials demonstrated a survival benefit on patients with chronic myelogenous leukemia (CML), thus leading to targeted therapies for individuals positive for this translocation.

The use of genetic changes to guide cancer therapy are proliferating rapidly. The growth of next generation sequencing of cancer patients has resulted in discovery of a number of mutations that have been successfully targeted for therapeutics. Examples include variants in *BRAF* for melanoma; *EGFR*, *ALK*, *ROS1*, and others for lung cancer; and many others. Hallmarks of genetically-focused therapies are applicability to smaller populations and a potential for fewer side effects compared to traditional chemotherapy. However, they also tend to be more expensive (Tannock & Hickman, 2016).

Given the focused care and workout for cancer patients, typical treatment for these individuals with cancers that have available genetically-targeted therapies is to clinically sequence tumor samples. These reports typically come in the form of PDFs; however, this is not a major impediment to accurate clinical care since it is a focus work up guided by professionals very knowledgeable in the field.

*eMERGE* The Electronic Medical Records and Genomics Network, *IGNITE* Implementing Genomics into Practice

**Germline pharmacogenomics** Medications have variable efficacy and potentials for adverse effects based on three major modes of action: altered metabolism, on-target side effects, or off-target side effects, each of which can result from a **drug-genome interaction** (See ▶ Chap. 26, ▶ Sect. 26.5 for more details.). A common scenario for altered metabolism resulting in lack of efficacy would be if a drug is a **prodrug**, meaning that the drug that is administered requires activation *in vivo* (typically by enzymes) into its active form. For example, clopidogrel is a prodrug that requires activation from CYP2C19 to its active form 2-oxoclopidogrel (Scott et al., 2013). Thus, people with poor metabolizing variants of CYP2C19 are more likely to experience a lack of clopidogrel efficacy and be at higher risk of myocardial infarctions, need for revascularization, stroke, and death (Delaney et al., 2012). Similarly, decreased metabolism of thiopurines (e.g., azathioprine) due to *TPMT* polymorphisms can

result in excessive bone marrow suppression (Relling et al., 2019). Second, drugs can produce adverse effects through off-target effects, such as an allergic reaction via an interaction with the immune system. Examples here include severe skin reactions from drugs such as carbamazepine and abacavir, which can be predicted by certain human leukocyte antigen variants (White et al., 2018). Third, drugs can have toxicity from on-target effects, such as increased sensitivity to warfarin resulting in an increased risk of bleeding with higher dose.

Germline pharmacogenomics holds the promise of tailoring medications to an individual's makeup to enable the “right drug for the right person” based on understanding of these effects. Unlike cancer genetic testing, pharmacogenetics requires a provider to potentially alter drug prescribing based on understanding of one's genotype. To allow for pharmacogenetics to work, the system must be able to intercept a drug order and provide

guidance. Drug-genome interactions could be accepted either by a computerized system of decision support (see ► Chap. 24) or via a human mechanism, e.g., via pharmacists. For decision support to work, the EHR requires a structured understanding of one's genotype, a clinical decision support system that can support action ability based on both a drug order and genotype.

Pharmacogenomic testing can be ordered in either a preemptive or reactive fashion. In a preemptive fashion, an individual has pharmacogenetic testing prior to drug prescribing. Then, when a medication would be prescribed that may be altered by one's genetic makeup, the system can intercept the order and recommend a genetically-tailored medication at the time of the prescribing event, such as the decision support alert in ■ Fig. 28.7. This sort of genetic testing has been deployed at Vanderbilt, University of Chicago, and Indiana's INGENIOUS trial (Eadon et al., 2016; O'Donnell et al., 2012; Pulley et al., 2012). Further investigation of this approach is underway within the IGNITE Network.

Reactive pharmacogenetic testing is the more common approach to genetic testing and involves testing an individual when there is a specific indication for that test. Research has shown that having genetic testing available at the time of the prescribing event results

in a higher frequency of genetically-tailored prescriptions (Peterson et al., 2016). Many genetic tests can take several days or more to receive results back for actionability, which may require a provider to recontact a patient to make a therapy change.

#### Genomics for disease diagnosis and risk assessment

Clinical genetic testing has often occurred within the presence of specialized clinic visits with geneticists or genetic counselors, most commonly for prenatal screening or diagnosis of suspected genetic disease. These types of interactions typically require very little direct informatics support and results can be delivered effectively via send-out paper lab results. However, newer approaches underlying broaden understanding of individual disease risks based on genetics require greater intervention from informatics systems. While clinical use of genetic testing for common disease risk (such as through PRS as discussed above in ► Sect. 28.5.1) is uncommon in clinical care now, the explosion of genetic knowledge envisions a day in which people could clinically implement genetic risk to enhance their understanding of their degree of genetic risk for a disease. Understandings of genetic risk for disease is already implied through resource through direct-to-consumer genetic testing, discussed in the next section.

#### Drug-Genome Advisor

**Intermediate Metabolizer - clopidogrel (Plavix) - Rare Risk Allele**  
**Substitution recommended due to increased cardiovascular risks**

**If not otherwise contraindicated:**

- Prescribe prasugrel (Effient) 10 mg daily
  - Prasugrel should not be given to patients:**
    - history of stroke or transient ischemic attack
    - $\geq 75$  years of age [Current patient age: 51]
    - with body weight  $< 60$  kg [Current patient weight: 59.0 kg as of 10/12/2012]
- Prescribe ticagrelor (Brilinta) 90 mg twice daily
  - Ticagrelor should not be given to patients:**
    - history of severe hepatic impairment
    - intracranial bleed
- Continue with clopidogrel (Plavix) prescription
  - Primary override reason:**
    - Contraindicated for prasugrel or ticagrelor
    - Potential side effects
    - Provider/Patient opts for clopidogrel
    - Cost

## 28.8 Sequencing Early in Life

One crucial complication in the search for genomic explanations for any given disease or phenotype is the impact of environmental interactions. Over time, every person on earth is exposed to environmental factors that may differ based not only on a factory that disposes of industrial waste near a drinking water supply or the traffic on the street they grew up on, but also by the foods they eat, the climates in which they live, and the infections they have harbored. Those external variables, hard to control for and sometimes even to know, can have major effects on the downstream products and activities of one's genomic fingerprint. Early in life, however, those effects are less pronounced. Of course, the impact of the in-utero environment on the well-being of the developing fetus is well established. But a genetic defect is much more likely to be the cause in a newborn with an unidentified disease than in an adult patient who has undergone a lifetime of environmental insults. In this vein, a number of initiatives have been established across the US to offer clinical sequencing services for young patients, including programs at Children's Hospital of Philadelphia, Duke University, Partners Healthcare, the Baylor College of Medicine, and the Medical College of Wisconsin. More controversial on paper, and not yet being performed in practice, is prenatal genome sequencing. Ethicists are exploring the potential implications of this possible direction (Donley, Hull, & Berkman, 2012).

Addressing the time and resources needed to perform genome interpretation, one striking success story was achieved at Children's Mercy Hospitals and Clinics in Kansas City, MO (Saunders et al., 2012). Investigators used an Illumina HiSeq 2500 machine and an internally-developed automated analysis pipeline to perform whole-genome sequencing and make a differential diagnosis for genetic disorders in under 50 h. The diagnoses in question are among the ~3500 known monogenetic disorders that have been characterized. In this case, WGS is not being used to identify novel, previously unknown mutations. Rather, it is shortening the path to diagnosis to just over 2 days instead of the more traditional 4–6 weeks as a battery of tests were performed sequentially.

We offer one final example in which genome sequencing was used as a last resort in a medical odyssey to identify the cause of a mysterious bowel condition in a 4-year-old boy named Nicholas Volker (Worthey et al., 2011). Having ruled out every diagnosis they could conceive of, doctors resorted to exome sequencing, leading to the identification of 16,124 mutations, of which 1527 were novel. A causal mutation was discovered in the gene *XIAP*. This gene was already known to play a role in XLP, or X-linked lymphoproliferative syndrome and retrospective review showed that colitis had been observed in 2 XLP patients in the past. Based on these findings, a cord blood transplant was performed, and 2 years later, Nic's intestinal issues had not returned. News coverage of this story by the Milwaukee Journal Sentinel was awarded a Pulitzer Prize for explanatory reporting (Journal Sentinel wins Pulitzer Prize for "One in a Billion" DNA series, n.d.).

## 28.9 Direct to Consumer Genetics

In the wake of the human genome project and the commoditization of genotypic data, a number of companies were founded to provide consumers with their own genetic information directly. These direct-to-consumer (DTC) genomic companies began making the services broadly available when deCODE genetics launched the deCODEme service in November 2007, followed a few days later by 23andMe. Navigenics was launched the following spring. These companies offered consumers the opportunity to provide a saliva specimen or buccal swab through the mail, and in exchange to receive genotypic information for a range of known genetic markers. Different companies emphasized different aspects of genetic testing. Navigenics focused on known disease risk markers, while 23andMe was much broader, including disease markers but also ancestry information and "recreational" genetic information, for example earwax type and the ability to smell a distinct odor in urine after eating asparagus. Navigenics offered free genetic counseling as part of their service, while 23andMe and deCODEme provided referrals to genetic

counselors. A study of concordance between these three services found >99.6% agreement among them, but in some cases the predicted relative risks differed in magnitude or even direction (Imai, Kricka, & Fortina, 2011). This disagreement is likely due to differences in the specific SNPs and the reference population used to calculate risk.

From the companies' perspectives, their customers offer a rich resource of genomic data for potential research and data mining. 23andMe created a research initiative called 23andWe through which they enlist customers "to collaborate with us on cutting-edge genetic research." (23andWe: The First Annual Update – 23andMe Blog, n.d.) They invite users to fill out questionnaires and then use the phenotypic information to perform genome-wide analysis studies. This approach enabled researchers at the company to replicate a number of known associations, and to discover a number of novel associations, recreational though they may be, for curly hair, freckling, sunlight-induced sneezing, and the ability to smell a metabolite in urine after eating asparagus (Tung et al., 2011). deCODE, purchased by Amgen in 2012, boasts a large number of medically significant genetic discoveries to have come out of their volunteer registry of 160,000 Icelanders, more than half of the adult population of that country (SCIENCE | deCODE genetics, n.d.). Navigenics was purchased by Life Technologies (now part of Thermo Fisher Scientific Inc.) in 2012 and no longer offers their Health Compass genetic testing service.

## 28.10 Conclusion

Physicians have always sought to provide care personalized to the individual. The current era of large and deep data about individual patients is ushering in the promise of precision medicine that tailors care to the individual based on factors not previously observable by the clinician, such as genomic data, predictive patterns derived from mining clinical data, or dense sensors tracking activity and heart rate at density previously not possible. For precision medicine to become a reality, we will need informatics, to enable both its discovery and

implementation. The irony of the ability to personalize care based on an individual's makeup is that it requires huge data sets of many individuals densely phenotyped to have statistical power to make predictions for rare variants, diseases, and outcomes. Thus, precision medicine requires that we have large data sets that are shareable and available for research. We will also need to effectively enroll diverse populations and ensure that the data includes both molecular data and social behavioral determinants of health. In addition, the ability to make accurate decisions for the individual patient requires implementation in the EHR, as the amount of data required to make decisions is vast and changing quickly.

PheKB: a catalog and workflow for creating electronic phenotype algorithms for transportability. *Journal of the American Medical Informatics Association*, 23(6), 1046–1052. <https://doi.org/10.1093/jamia/ocv202>. Introduces the Phenotype KnowledgeBase website, which contains phenotype algorithms and related comments, plus implementation and validation data, for finding cases and controls for genomic analysis from EHR data. The paper includes some summary tables and experiences from the first several years of uploaded EHR phenotype algorithms.

Newton, K. M., Peissig, P. L., Kho, A. N., Bielinski, S. J., Berg, R. L., Choudhary, V., ... Denny, J. C. (2013). Validation of electronic medical record-based phenotyping algorithms: results and lessons learned from the eMERGE network. *Journal of the American Medical Informatics Association*, 20(e1), e147–54. <https://doi.org/10.1136/amiajnl-2012-000896>.

This paper provides best practices and lessons learned from the Electronics Medical Records and Genomics (eMERGE) Network for how research-grade phenotypes are found from EHR data. This paper includes phenotype algorithm design, creation, and validation process, as well as some experiences regarding what worked well and what did not.

Pulley, J. M., Denny, J. C., Peterson, J. F., Bernard, G. R., Vnencak-Jones, C. L., Ramirez, A. H., ... Roden, D. M. (2012). Operational implementation of prospective genotyping for personalized medicine: the design of the Vanderbilt PREDICT project. *Clinical Pharmacology and Therapeutics*, 92(1), 87–95. <https://doi.org/10.1038/clpt.2011.371>.

This paper describes one of the first prospective implementations of pharmacogenomics. Patients were selected based on their risk for potentially needing a medication affected by pharmacogenes. They were tested on a multiplexed platform, and then medication recommendations were provided through computer-based provider order entry decision support. The first implementation was CYP2C19 and clopidogrel (an antiplatelet medication), but because the platform tested multiple pharmacovariants, drug-genome interactions could be added over time.

Wellcome Trust Case Control Consortium. (2007).

Genome-wide association study of 14,000 cases of seven common diseases and 3,000 shared controls. *Nature*, 447(7145), 661–678. <https://doi.org/10.1038/nature05911>. This was one of the first large scale genome-wide association studies, which found common genetic variants influencing seven common diseases. One interesting component, discovered loci for type 2 diabetes, was in FTO, whose effect on diabetes risk is largely mediated through adiposity. This shows the importance of considering phenotypes along the causal pathway when performing GWAS.

## ? Questions for Discussion

1. Design a study to assess the genomic influences of a disease or drug response phenotype using EHR data. Who would be your cases and controls? What features would define each case and control, and how would you validate that the algorithms you picked for cases and controls were indeed finding the patients you wanted to find?
2. Research studies traditionally have not returned their research results to study subjects. However, genetic studies are on the forefront of changing paradigms in this space. What do you think about the implications of returning results to patients? How would you feel if you were a subject in a research study? Would you want results back or not?
3. What are the implications of returning results of actionable genetic variants (such as those causing breast and ovarian cancer) found incidentally during research studies or clinical testing purposes?
4. What are some ways in which precision medicine may improve health disparities between different populations? In what ways might precision medicine worsen them? How can researchers promote research that ameliorates this risk?
5. What are some requirements for a health system or a physician in the context of pharmacogenomic testing?
6. Given that genomics do not generally change over the lifetime, how can a patient take their genomic test results from one institution to another? What technological and non-technological solutions could be employed to allow a patient to take their genetic results with them?
7. Discuss the strengths and weaknesses of EHRs for precision medicine studies of diseases, drug responses, and exposures. What kinds of exposures and health outcomes does an EHR excel at capturing and where would traditional survey or in-person assessment measures perform better?

## Learning Objectives

After reading this chapter, you should know the answers to these questions:

- Why is the development and use of IT in healthcare so much slower than in other industries?
- How has public policy promoted the adoption and use of health IT?
- How does health IT support national agendas and priorities for health and health care?
- Why is it important to measure the value of health IT in terms of improvements in care quality and savings in costs?
- How can public policies safeguard patient privacy in an era of electronic health information?
- What are the main policy issues related to exchanging health information among health care organizations?
- What are the major tradeoffs for regulating electronic health records in the same way that other medical devices are regulated to ensure patient safety?
- What policies are needed to encourage clinicians to redesign their care practices to exploit better the capabilities of health IT?
- How does the U.S. approach to health IT policy compare with those of other countries?

## 29.1 Public Policy and Health Informatics

For decades after most industries had adopted IT as part of their core business and operational processes, clinical care in the U.S. remained largely in the paper world. Most developed countries adopted health IT sooner, especially in primary care. International leaders have included Denmark, Sweden and the Netherlands. However, health systems leaders in the U.S. have recognized that public policy played a role in the pace and nature of their health systems' adoption and use of IT, and that changes in policy had the potential to accelerate change.

The influence of policy can be found throughout a health care system. Policies shape the structure of health care delivery organizations and the markets for medical products. Directly or indirectly, policies influence the behaviors of all health care stakeholders including patients, providers, health plans, and researchers. Public policy changes can enhance or set back health care delivery through incentives, requirements, and restrictions.

In recent years, policy interventions have influenced health IT in major ways. In 2004, U.S. President George W. Bush established the Office of the National Coordinator for Health IT.<sup>1</sup> In 2009, during the Obama Administration, the U.S. Congress allocated approximately \$30 billion to support providers' **meaningful use** of health IT. In 2015, the Medicare Access and CHIP Reauthorization Act (MACRA) absorbed the meaningful use program as part of a larger effort to harmonize how the federal government pays health-care providers, called the Quality Payment Program (QPP). In 2016, the twenty-first Century Cures Act included provisions to improve patient access to their digital medical data and allow them to use the data in applications of their choice, which may accelerate innovation. Notably, healthcare information technology has been one of the few relatively non-partisan topics. Governments of many other countries have also spent significant public funds on health IT and are considering related policy issues.

In this chapter, we review some of the key policy goals relevant to informatics and discuss how researchers and policymakers are trying to address them. We discuss how health IT policy goals have changed substantially in recent years, from a focus on accelerating adoption to a greater emphasis on interoperability and fostering innovation. Protecting privacy of patients' health information, ensuring health IT products are safe for patients, and improving medical practice

1 [▶ http://www.healthit.gov/newsroom/about-onc](http://www.healthit.gov/newsroom/about-onc) (Accessed 12/9/2012).

workflows remain persistent challenges and of interest to policy.

While informatics research has been occurring for several decades, research in health IT policy is still relatively new. As stakeholders look to health IT to help address the major cost and quality problems in national health care systems, we expect the issues discussed in this chapter to become more important to policymakers and researchers in the fields of health policy and informatics.

## 29.2 How Health IT Supports National Health Goals: Promise and Evidence

Health IT is not an end in itself. Like all technology, it is simply a tool for achieving larger clinical, social and policy goals, such as improving health outcomes, improving the quality of care, and reducing costs. Health IT has the potential to have a tremendous impact on these goals.

Policymakers, however, are interested not only in the promise of health IT but also the reality. Like most software products, early versions of health IT products tend to have many problems, such as bugs, poor usability, and difficulties integrating with other products. Only after the technology matures is it possible to realize a larger portion of the promised benefits. Policymakers may be reluctant to invest public funds, which are raised primarily in the form of taxes, on technologies that have not been shown in empirical studies to produce benefits.

Many studies have demonstrated empirical benefits of health IT, especially CPOE (see ► Chap. 14) and some types of CDS (see ► Chap. 24) (Jones et al. 2014). Recent studies of HIE (see ► Chaps. 15 and 18) have also found some beneficial effects (Menachemi et al. 2018). However, substantial gaps in evidence exist. For example, many studies come from a small number of academic medical centers or geographical communities, and it is unknown if the benefits in terms of quality, safety and efficiency are being realized in other settings. Some have described this phe-

nomenon as a health IT “productivity paradox” because of some observers’ assessment that the benefits of IT have so far not justified the investment (Jones et al. 2012). Lessons from other industries suggest that the substantial benefits of IT will eventually be realized but will require more than just improvements in the technology itself. Care processes will likely also need to be redesigned so that users can take advantage of the technology’s potential. New best practices may be needed for different care settings. And additional studies will likely also be needed to demonstrate benefits that may exist but are difficult to detect, especially in non-academic settings that do not have the expertise or incentives to conduct robust evaluation studies (see ► Chap. 13).

Despite the limits of the empirical evidence, policymakers have invested substantial sums in health IT hoping that the technology will realize its promised benefits and support national health goals. Further empirical studies will help to identify where health IT has been successful and what factors have made these investments effective, as well as to identify gaps that may benefit from further policy efforts. This section presents an overview of both the promise and the evidence of how health IT supports policy goals.

### 29.2.1 Improving Care Quality and Health Outcomes

As informatics professionals understand intuitively, health IT has enormous potential to improve care quality and health outcomes, which are, of course, central policy goals (► Table 29.1). Just as computers have revolutionized many other industries, from banking to baseball, information technology is beginning to revolutionize health care through innovative applications. Policymakers in the U.S. appear to recognize this potential as demonstrated by the multiple pieces of state and federal legislation passed in recent years related to health IT. This activity began with a focus on encouraging adoption and has shifted to improving interoperability, patient

**Table 29.1** The promise of health IT (selected functionality)

Health IT functionality	Expected effect on care quality	Expected effect on cost
Electronic health record (EHR) with clinical decisions support (CDS)	Improved clinical decisions, fewer medication and diagnostic errors, timelier follow up	Fewer unnecessary tests
Health information exchange (HIE)	Improved clinical decisions	Reduced burden of information gathering, reduced duplicate testing
Patient decision aids	More personalized treatment	Fewer procedures
Telehealth and personal health records (PHR)	More timely and accessible interactions with clinicians	Fewer office visits
E-prescribing	Fewer errors	Reduced costs from errors

access to records, and innovation. Many other countries also specifically encourage adoption and use of health IT to improve health care quality.

Electronic health records (EHRs; ► Chap. 14) probably represent the form of health IT that has been evaluated most extensively and are now widely adopted in hospitals and clinics. EHRs with CPOE and clinical decision support (CDS; ► Chap. 24) have been extensively studied and evaluated in terms of quality, safety, and efficiency benefits, with most studies finding positive results. For example, one study found EHRs with medication-related CDS can reduce the number of adverse drug events from 30% to 84% (Ammenwerth et al. 2008). A study that examined EHR use in several hospitals in Texas found that there are reduced rates of inpatient mortality, complications, and length of stay when EHRs are

used (Amarasingham et al. 2009). Studies like these have supported the promotion of EHRs, medication-related CDS, and e-prescribing and are now widely, but not universally, adopted. Other functionalities, such as electronic patient decision aids, may have enormous potential to improve quality, safety and efficiency, but have not been evaluated as extensively and are not widely adopted (Friedberg et al. 2013).

Another component of health IT that may substantially improve quality of care is clinical data exchange, which is the ability to exchange health information among health care organizations and patients (see ► Chaps. 15 and 18). There is a great need for this kind of capability. In the U.S., the typical Medicare beneficiary visits seven different physicians in four different offices per year on average, and many patients with chronic conditions see more than 16 physicians per year (Pham et al. 2007). Not surprisingly, in such a fragmented system, information is often missing. One study shows that primary care doctors reported missing information in more than 13% of visits and other studies suggest much higher rates of missing data, affecting as much as 81% of visits (Smith et al. 2005; van Walraven et al. 2008; Tang et al. 1994). A study in one community found that there may be a need to exchange data among local medical groups in as many as 50% of patient visits (Rudin et al. 2011). Recent empirical studies have shown that real-world implementations of electronic clinical data exchange systems result in fewer duplicated procedures, reduced use of imaging, lower costs, and improved patient safety (Menachemi et al. 2018). However, these studies were concentrated in a small number of HIEs and some were restricted to a single vendor; it is not clear to what extent the results will generalize to other contexts.

Researchers and policymakers agree that improving the quality of health care must involve making it more patient-centric, and health IT will likely be crucial to achieving that goal on a large scale. For example, **personal health records (PHRs)** and patient portals were promoted by federal requirements in the US and are increasingly available – one

recent survey found that roughly half of older adults have accessed a PHR (Malani 2018). PHRs give patients access to their clinical data (see ► Chap. 11), facilitate communication between patients and providers, and provide relevant and customized educational materials so that patients can take a more active role in their care (Tang et al. 2006; Halamka et al. 2008; Wells et al. 2014). PHRs may also incorporate patient decision-aids to help them to make critical health care decisions, considering their personal preferences (Fowler et al. 2011; Friedberg et al. 2013). **Telehealth** technologies, which enable patients to interact with clinicians over the Internet (see ► Chap. 20), may make health care more patient-centric by allowing patients to receive some of their care without having to go physically to the doctor's office. Few empirical studies to date have shown that these technologies result in improvements in care quality or health outcomes (Milani et al. 2017).

A concern of policymakers is that there is an emerging “digital divide” in health IT, in which disadvantaged groups who might benefit most have less access to health IT than more affluent groups. One empiric study of this issue found that minority groups were less likely to access web-based PHRs and, in general, minorities and disadvantaged groups have less web access than other groups (Yamin et al. 2011). On the other hand, adoption rates of mobile platforms do not show as much of a divide and PHRs are increasingly accessible via these platforms. Still, policies may be necessary to ensure the technology is designed and implemented with minorities in mind to prevent disparities in health care from getting worse and to ensure that the improvements in care quality enabled by health IT are shared by all.

The digital divide has also been suggested to exist among hospitals. One study found that although EHRs are widely adopted among hospitals, critical access hospitals lagged in adoption of performance measurement and patient engagement functions, suggesting an “advanced use” digital divide (Adler-Milstein et al. 2017). However, even if critical access hospitals are slower to adopt advanced functionalities, that may not indi-

cate a permanent divide but rather a typical technology diffusion curve in which some organizations adopt faster than others.

Unfortunately, health IT also has the potential to facilitate harmful unintended side effects (Bloomrosen et al. 2011). In one study involving a pediatric intensive care unit in Pittsburgh, patient mortality increased in patients transferred in after computerized physician order entry (CPOE) was installed (Han et al. 2005). The study found that certain aspects of the ordering system and some of the implementation decisions, restricted clinicians' ability to work efficiently, causing delays in treatment, which was especially deleterious because of the urgent nature of the children's conditions. Implementation decisions involving configuration of the system and changes in workflows appear to have been the major contributors to the increase in mortality—the same EHR product was installed in another hospital without such adverse impacts on mortality (Beccaro et al. 2006). Considering the volume of health IT studies, there are relatively few empirical assessments of adverse effects. Nonetheless, questions about the need to regulate the safety of EHRs are being debated. Balancing the need to protect patients from unintended harm is the concern, further discussed later in this chapter, that over-regulation may impede innovation. Most researchers tend to believe that if health IT systems are well-designed and implemented with close attention to the needs of the users, these kinds of unintended consequences can be avoided and health IT systems will result in tremendous improvements in quality of care (Berg 1999). Researchers have developed guides to help organizations implement health IT in a way that minimizes safety risks and improves patient safety (Sittig et al. 2014). In addition to unintended consequences on patients' health, IT has also been shown to be a source of physician professional dissatisfaction (Sinsky et al. 2017).

## 29.2.2 Reducing Costs

In addition to improving quality, health IT is expected to reduce costs of care substantially

(Table 29.1). Policies that promoted the use of health IT were informed by projections based on models showing large potential savings for many forms of health IT. One study by the RAND Corporation estimated that EHRs could save more than \$81 billion per year (Hillestad et al. 2005). Another study estimated that electronic clinical data exchange has the potential to save \$77.8 billion per year (Walker et al. 2005). Many of these savings were expected to come from reductions in redundant tests and use of generic drugs, as well as reductions in adverse drug events and other errors that EHRs might prevent (Bates et al. 1998; Wang et al. 2003). Telehealth and PHRs were also projected to result in billions of dollars in savings (Kaelber and Pan 2008; Cusack et al. 2008).

One weakness of these projections is that they relied on expert opinions for some point estimates because, other than several studies showing that EHRs reduce costs by reducing medical errors, few studies have tried to examine empirically the effect of health IT on costs (Tierney et al. 1987, 1993). Also, some of the projections have been criticized because they estimate potential savings rather than actual measured savings (Congressional Budget Office 2008). However, the projections do not include several types of savings that may result from providing better preventive care and care coordination, which would reduce the need for patients' use of high cost procedures in hospitals and emergency rooms. They also do not include potential reductions in costs that may result from decision aids for patients, which may, for example, reduce the number of unnecessary surgeries (O'Connor et al. 2009). And they do not include other innovations such as the impact of small changes in EHR displays. For example, one study found that when the fees associated with laboratory tests were shown to clinicians when they ordered the test, rates of test ordering decreased by more than 8% (Feldman et al. 2013). The actual savings, therefore, may be much greater than the projections suggest. As described above, realizing these savings will likely require more than simply adopting the technology – it will also require redesigning

healthcare workflows to make greater use of the technology, and developing and spreading best practices.

### 29.2.3 Using Health IT to Measure Quality of Care

---

All health care stakeholders agree that a health care system should deliver high quality care. But how does one measure care quality? Current methods of quality measurement rely largely on administrative claims submitted by providers to insurers. These data may be useful for certain quality measurements such as for assessing a primary care physician's mammography screening rates, but they lack important clinical details, such as the results of laboratory tests. They also do not represent a comprehensive picture of the care that is delivered, assess the appropriateness of most medical procedures, or determine if a patient's quality of life has improved after treatment. Also, most patients in the U.S. switch insurance companies every few years, limiting the ability of any one insurer to measure quality improvements over longer periods of time, which is required to assess accurately the treatment of many medical conditions.

Increasingly, clinical data available through EHRs are used for quality measurement (Ancker et al. 2015). Clinical data are much more comprehensive than administrative claims, and methods for measuring clinical quality using these data are growing. In the U.S., there is growing policy interest in creating such measures as shown in the National Quality Strategy and other reports (AHRQ 2017). This approach has been used in the United Kingdom (U.K.) where nearly 200 quality measures have regularly been assessed, with up to 25% of payment for general practitioners based on performance on these measures (Roland and Olesen 2016). While initially popular, U.K. physicians have become increasingly disenchanted with the administrative requirements of the program. There is growing support for developing patient-reported **outcome measurements** which may be integrated in PHRs, or obtained

through other mechanisms and integrated with the patient’s clinical data (Lavallee et al. 2016).

However, using electronic clinical data to generate quality measures is also associated with problems. Studies have found that clinical data in EHRs are often incomplete, inaccurate, and may not be comparable across different EHRs (Chan et al. 2010; Colin et al. 2018). Existing measures also tend to focus more on adherence to care processes rather than patient outcomes (Burstin et al. 2016). More research is needed to develop and standardize meaningful quality measures that would be worth the burden of reporting them.

### 29.2.4 Holding Providers Accountable for Cost and Quality

Currently, in the U.S., most care is delivered using a fee-for-service payment system, in which providers are paid for every procedure or patient visit. Under this payment method, providers have incentives to provide more care rather than less, which contributes to over-treatment (Lyu et al. 2017). It is therefore not surprising to find that in the U.S., costs are high and rising, nearly double those of many other industrial nations, and quality of care is mixed (Squires 2015). As Fig. 29.1 shows,

■ Fig. 29.1 Health care expenditures and life expectancy in the United States and ten other developed countries. (From Fuchs and Milstein (2011), with permission © Massachusetts Medical Society)

the U.S. spends more money per capita on health care than any other country by a wide margin. Yet, many studies suggest that the U.S. is far from the world's leader in overall care quality (Squires 2015). A seminal study by McGlynn et al. in 2003 found that patients in the U.S. received recommended care only about half of the time across a broad array of quality measures (McGlynn et al. 2003). An updated version in 2016 found that those results had not changed much (Levine et al. 2016).

Policymakers are trying to replace the fee-for-service payment method with other methods that would hold providers accountable for the care they deliver. These policies create incentives for healthcare providers to constrain costs and may therefore motivate greater use of health IT tools to achieve this goal. In the U.S., one of the proposed mechanisms for accomplishing this is through Accountable Care Organizations (ACOs). As specified in the Affordable Care Act of 2010,<sup>2</sup> an ACO is a group of providers who are held accountable, to some extent, for both the cost and the quality of a designated group of patients (Berwick 2011; McClellan et al. 2010). ACOs are still a work in progress, but early indications suggest that they may reduce some costs (McWilliams et al. 2018). The concept of ACOs depends on having an electronic health information infrastructure in place, including widespread use of EHRs, because health IT would enable ACOs to improve quality, reduce costs, and measure their performance. Without prior federal incentives for health IT adoption, these policies to aim to change incentives may not have been feasible.

Many other countries have experimented with paying providers for quality and outcomes, or holding providers responsible for costs, although few have done both at the same time to a high degree. Health IT systems are critical for many of these efforts. Few policymakers or researchers believe providers can

be held accountable to a substantial degree for the care they delivery without a robust health IT infrastructure.

## 29.2.5 Informatics Research

Although EHRs have become widespread, many health IT capabilities are still emerging, or standards have not yet been defined. New applications will still require additional research and development. For example, we are still in the early stages of understanding how to design applications for team care (► Chap. 17), remote patient monitoring (► Chaps. 20 and 21), online disease management (► Chaps. 11 and 19), clinical decision-making (► Chap. 24), alerts and reminders (► Chap. 24), public health and disease surveillance (► Chap. 18), clinical trial recruiting (► Chap. 27), and evaluations of the impact of technologies on care and costs (► Chap. 13). One concern is that most provider organizations, and increasingly even academic medical centers, are now using software applications made by private vendors, and innovating with them can be more challenging than with homegrown products. Private vendors may not be investing enough resources in research to produce transformational innovations (Shortliffe 2012). It will be essential to identify “sandboxes” in which new and innovative IT approaches can be developed and tested. More interactions between industry and academia may be a good way to accelerate progress (Rudin et al. 2016).

Federal funding plays a major role in supporting this kind of upstream informatics research to help to incubate these new technologies but is decreasing in recent years. Because the benefits of such research will accrue to everyone who uses the health care system, the investment of public funds is justified. Few private companies have taken the risk of doing this kind of experimental research to date in part because many health IT companies have been relatively small and were focused on adding the functionalities that are needed to meet federal certification requirements. More recently, some health IT

2 ► <http://www.healthcare.gov/law/index.html> (Accessed 12/9/2012).

companies have become larger but they have not sponsored much research. It is too early to know what impact private companies will have on health IT innovation, but historically, most of the innovation in health informatics has occurred at universities and other government-funded research organizations affiliated with academic medical centers.

### 29.3 Beyond Adoption: Policy for Optimizing and Innovating with Health IT

Many governments around the world have previously implemented policies to accelerate the adoption of health IT. The U.K. achieved near universal adoption of EHRs because it devoted substantial resources to the effort early on and has a national health care system which directly manages most of the health care providers in the country (Cresswell and Sheikh 2009; Ashworth and Millett 2008). Most other industrialized nations had achieved high levels of adoption in primary care by the early 2000s (Jha et al. 2008). Countries that achieved particularly high levels of adoption in non-hospital settings include Denmark, the Netherlands, Sweden, Hong Kong, Singapore, Australia, and New Zealand. Similar to the U.K., these countries devoted national resources for this effort. Levels of adoption in hospitals, however, lagged in many countries.

In the U.S., after years of slow adoption of health IT relative to other developed countries, the federal government began to address this issue in 2004 by establishing the Office of the National Coordinator for Health IT (ONC). This office is located within the U.S. Department of Health and Human Services and tasked with “promoting development of a nationwide Health IT infrastructure that allows for electronic use and exchange of information.” The importance of this office grew considerably in 2009 when Congress passed legislation that is considered a major landmark in the history of health IT policy: the Health Information Technology

for Economic and Clinical Health (HITECH) Act.<sup>3</sup> This legislation authorized \$27 billion in stimulus funds to be paid to health care providers who demonstrate “meaningful use” of electronic health records as defined by specific criteria (Blumenthal 2010). Although there is debate as to the extent to which HITECH accelerated EHR adoption in ambulatory clinics, EHR adoption increased dramatically among hospitals and clinics in the U.S. after these incentives were put in place (Menemeyer et al. 2016). Today, over 90% of hospitals and clinics have adopted some form of EHR, but there is large variation in adoption of specific EHR capabilities (HealthIT 2016).

Now that EHRs have become widely adopted, policymakers in many countries are shifting focus toward optimizing the technology and fostering innovation to achieve greater impact. In the U.S., policy efforts are now trying to improve interoperability and health information exchange among providers and patients and facilitate innovation by making health information accessible to third party applications using **application programming interfaces (APIs)**. U.S. policy has also incorporated many health IT efforts into a larger program that affects how Center for Medicare and Medicare Services (CMS) pays health providers for services. This section describes some of these efforts.

#### 29.3.1 Health Information Exchange

All countries have challenges sharing clinical data among providers (see ► Chap. 15). For many years, U.S. policy promoted data exchange through the formation of regional health information exchanges (HIEs). These organizations provided a variety of services including aggregating EHR data from local health care providers to create aggregate longitudinal patient records, automating the

3 ► <https://www.healthit.gov/topic/laws-regulation-and-policy/health-it-legislation> (Accessed 10/16/2018).

delivery of laboratory results, integrating with pharmacies to facilitate e-prescribing, and facilitating public health and quality reporting. Although some HIEs are well-established, the number of these organizations has been declining and many of the remaining ones may not be financially viable (Adler-Milstein et al. 2016).

Why is it so difficult to establish an HIE? Part of the problem is that EHR products did not always use the same technical data standards and are not interoperable. Recently developed technical and semantic standards have made considerable progress in making the standards robust (Health Level Seven International 2019). However, additional custom programming is still required to integrate EHRs with HIEs. HIEs face many other challenges including: recruiting providers who are reluctant to share data with competing medical groups, privacy and security concerns, legal issues, HIE-related fees, training clinicians to use the HIE, and the lack of a business case (► Chap. 15). The business case problem is perhaps the most pressing – for a business to thrive, key stakeholders must be willing to pay for the product or service. In HIE, the primary financial beneficiaries are employers and insurers, but they have been reluctant to pay for the exchange services (Walker et al. 2005). While regional HIEs have faltered, EHR vendor-based networks have emerged as an alternative, but the extent to which they will succeed in the long term is uncertain. These networks may be limited to one vendor or involve a consortium of vendors. Currently, the most prominent vendor-based networks are Epic CareEverywhere, CareQuality, and the CommonWell Health Alliance.

Policymakers have recognized that for data exchange to be comprehensive, these networks as well as regional HIEs will need to interact and share data. To address this concern, there are plans to establish a “trusted exchange framework” that facilitates this interaction (HealthIT 2018). Policymakers have also identified **information blocking** on the part of vendors and providers as a concern and plan to issue regulations to prevent it.

Some have proposed a different approach to data exchange in which patients can aggregate and control access to their complete health records (Szolovits et al. 1994). The history and details of this model are explained in ► Chap. 15. There has been an increase in interest in this approach recently. However, it is too early to tell if it will become widely adopted.

No country to date has completely solved the problem of clinical data exchange. In every country that attempts to foster data exchange, the hardest issues appear to be socio-political rather than technical, and there is clear agreement that health IT policy is particularly important to address these problems, especially in establishing standards. The U.K. has set up a “spine” which allows summary care documents to be widely exchanged (Greenhalgh et al. 2010). However, the overall program has encountered major political difficulties, and has been largely dismantled. Canada has established a program called Canada Health Infoway, which has emphasized setting up an infrastructure for data exchange (Rozenblum et al. 2011). While that effort has been somewhat successful, relatively little in the way of clinical data is being exchanged to date, in part because the adoption rate of electronic health records remains low. In Scandinavia, there has been substantial concern about the privacy aspects of data exchange, especially in Sweden, though data exchange is taking place in Denmark and its use is growing.

### 29.3.2 Patient Portals and Telehealth

Although EHRs have become widely adopted, other forms of health IT are still lagging. To encourage more patient-centric care, many countries are trying to foster the adoption of Patient Portals and Telehealth (see ► Chaps. 11 and 20). In the U.S., federal incentives promoted patient portals, and adoption rates are growing. To promote telehealth, policymakers are exploring the possibility of reimbursing for telehealth care, which would probably

improve adoption of this technology considerably (Mehrotra et al. 2016). Even though many states have passed “parity laws” that require commercial insurers to reimburse for telehealth visits, most healthcare encounters are still in-person.

### 29.3.3 Application Programming Interfaces

---

To accelerate innovation, policymakers in the U.S. have begun to promote Application Programming Interfaces (APIs) for EHR data. APIs are software mechanisms that allow different applications to connect to one another and share information. All modern software utilizes APIs for purposes ranging from communication with a computer’s operating system to querying a website for the latest news stories. In healthcare, one use of APIs is to allow patients to more easily download their latest medical data into an application of their choosing, such as an application on their smartphone that helps them organize and understand their health data. Another use of APIs is to allow providers to install third party applications for use within their EHRs. If patients and providers can pick and choose applications, a new market of innovative applications may arise to take advantage of these data. Standardization of APIs across EHRs is critical because otherwise application developers will be required to spend effort customizing their product to integrate with every EHR vendor. In the U.S., new policies will require EHR vendors to support APIs as a condition for certification and for receiving certain payments (Leventhal 2018).

## 29.4 Policies to Ensure Safety of Health IT

---

As adoption of health IT accelerates and new innovations are developed, it is important to be vigilant about, and to reduce, the risk of unintended harmful side effects related to health IT use. Harm could arise from deficiencies in many areas when designing and deploy-

ing complex systems, including poor usability, inadequate testing and quality assurance, software flaws, poor implementation decisions, inattention to workflow design, or inadequate training. Policymakers have funded development of frameworks and guidelines to help implement and use health IT in a way that addresses safety concerns (Sittig and Singh 2012).

### 29.4.1 Should Health IT Be Regulated as Medical Devices?

---

One policy option for reducing the likelihood of health IT-related medical errors is to create regulations that require health IT products to adhere to strict principles of safe design and be tested and certified (see also ► Chap. 12) (Shuren et al. 2018). This is how many medical devices are regulated by the U.S. Food and Drug Administration.<sup>4</sup> While this approach may ensure some degree of patient safety, the regulatory burden will increase the price of health IT systems, raise barriers of entry for new companies, and could stifle innovation. Also, even with regulations, health IT products might still have safety issues because software products can be used in many ways, unlike other medical devices that have more limited utility.

There is an active debate about the appropriate types of regulation for medical apps for use by patients. Currently estimates have found more than 150,000 health apps available for download, but analysts have found that few have demonstrated clinical utility (Singh et al. 2016). The FDA does not regulate most apps but has recently begun a pilot “precertification” program for digital health which will provide information about vendors’ software quality control processes but does not involve evaluations of outcomes (Bates et al. 2018; Lee and Kesselheim 2018). This is controversial, and some feel it does not go far enough (Bates et al. 2018).

---

4 ► <http://www.fda.gov/> (Accessed 12/10/12).

### 29.4.2 Alternative Ways to Improve Patient Safety

---

There are many other policy options to support patient safety (Committee on Patient Safety and Health Information Technology; Institute of Medicine 2011). Policies may fund training programs to educate clinicians in how to use health IT safely and alert them to common mistakes. Policies might encourage providers to report problems with software, including usability issues and bugs, so that vendors can fix them quickly. Policies might also help to establish programs in which users can rate health IT products. Finally, funding research into the science of patient safety would improve our knowledge of how to design better products and identify risks of errors (Shekelle et al. 2011).

## 29.5 Policies to Ensure Privacy and Security of Electronic Health Information

---

It is almost impossible to have a conversation about digital medical records without discussing issues of privacy and security. Although the topic of privacy arose in the discussion of ethics in ► Chap. 12, it also has policy implications and warrants mention here. As healthcare has become digitized, there has been an increase in security events (Liu et al. 2015). Protecting privacy and security are clearly important policy goals.

### 29.5.1 Regulating Privacy

---

The Health Insurance Portability and Accountability Act (HIPAA) of 1996<sup>5</sup> and subsequent regulations created a legal category of “protected health information” which was defined to encompass most forms

of clinical data. **Covered entities** which include providers and insurers are legally required under this law to safeguard electronic health information and would face fines if they did not.

Many states have additional privacy laws regarding data exchange (e.g., mental health and HIV status). The effectiveness of these privacy-protective laws has not been rigorously evaluated. They can inadvertently reduce privacy protection, particularly when exchanging data across state lines, and have been showed to slow the adoption of EHRs (Miller and Tucker 2009; Harmonizing State Privacy Law Collaborative 2009).

In other countries, privacy also has received a good deal of debate. Most recently, the European General Data Protection Regulation (GDPR) went into effect in 2018 and goes beyond healthcare in scope by encouraging “privacy by design” for all software products that store personal data (Haug 2018). Governments are still trying to find the best policies to protect privacy of medical records without slowing the adoption of health IT.

### 29.5.2 Security

---

Now that healthcare entities are mostly digital, they are increasingly targeted by cyberattacks, which may aim to steal patient data, demand money in return for unlocking a system, or make a political statement. HIPAA includes security policies that require health providers and other covered entities to implement various safeguards, and if data are breached, the federal government may charge a fine. The recent increase in cyberattacks on hospital and other healthcare stakeholders suggest that these regulations may not be adequate, and policymakers are considering additional moves. Security concerns exist in all countries. For example, the UK’s National Health Service recently experienced a cyberattack that crippled many hospitals and required many clinics to close down completely (Clarke and Youngstein 2017).

---

5 ► <http://www.hhs.gov/ocr/privacy/index.html> (Accessed 12/9/2012).

### 29.5.3 Record Matching and Linking

For health IT to be effective, an essential prerequisite is that patients must be matched to their health data, and electronic records for the same patient must be linked together. If patients' identity attributes are used (e.g., name, address, date of birth), matching and linking errors often occur because many patients share attributes, attributes change over time, and clerical errors are common. Many countries have adopted a **unique health identifier (UHI)** to facilitate these processes. However, in response to concerns of privacy advocates, the U.S. congress prohibited use of HHS to expend federal dollars to support development of a UHI. There is little evidence that suggests UHIs pose an increased risk of privacy violations and, in fact, not having a UHI may be even more risky because many other kinds of personal data may be collected and used instead (Greenberg et al. 2009). But UHIs require substantial federal resources to implement and may not address all matching and linking issues. Currently, some estimates suggest that errors in linking records shared across providers in the U.S. can be as high as 50%.

Policymakers are therefore interested in alternative approaches, which include improving linking algorithms to better match identity attributes (e.g., name, address, date of birth), defining standards for the identity attributes, using biometrics-based methods, and allowing patients to participate more directly in the process, such as by verifying their phone number with their mobile phone or managing their data on their smartphone (Rudin et al. 2018). There are advantages and disadvantages to every approach, and it is likely that multiple approaches will be needed to substantially reduce matching and linking errors (Pew 2018). Policymakers may play a critical role in overseeing progress and supporting research to develop and more rigorously evaluate solutions.

### 29.6 The Growing Importance of Public Policy in Informatics

Public policy is becoming increasingly important to the field of informatics. Policies affect everything from what research projects receive funding to whether a physician in a solo practice allows her patients to access their medical records online. Many of the health IT policy issues we discuss in this chapter are just beginning to attract attention from policymakers, and further research is needed to understand the best role for policy. It is likely that new policy issues will emerge as technology capabilities become more advanced. For example, artificial intelligence may help with many clinical applications, but policies may be needed to ensure it is applied safely and to ensure accountability.

Traditionally, most informatics research has focused on the development of new technologies and how they integrate into clinical practice. Relatively few studies provide advice to policymakers on health IT policy issues, even though policies have enormous consequences for informatics research and practice. We hope that researchers and policymakers will recognize that technology and policy issues affect each other, and it is necessary to use both perspectives to understand how information technology can be used to improve health care.

research study discusses a successful early attempt to use APIs within a live EHR and emerging technical standards to implement patient- and provide-facing apps.

Clarke, R., & Youngstein, T. (2017). Cyberattack on Britain's National Health Service – a wake-up call for modern medicine. *New England Journal of Medicine*, 377(5), 409–411. <https://doi.org/10.1056/NEJMp1706754>. This brief perspective describes a harrowing cyber attack on the U.K.'s healthcare system and offers suggestion to help improve preparedness.

Jones, S. S., Heaton, P. S., Rudin, R. S., & Schneider, E. C. (2012). Unraveling the IT productivity paradox – lessons for health care. *New England Journal of Medicine*, 366(24), 2243–2245. This brief perspective addresses the contentious issue of why few studies have been able to show that health IT produces an improvement in economic productivity. It makes its case by pointing out that the IT industry had the same problem in the 1980s and 1990s but managed to overcome these difficulties through better measurement of productivity, improved management of technology, and better usability.

Sinsky, C., Colligan, L., Li, L., Prgomet, M., Reynolds, S., Goeders, L., et al. (2016). Allocation of physician time in ambulatory practice: A time and motion study in 4 specialties. *Annals of Internal Medicine*, 165(11), 753–760. <https://doi.org/10.7326/M16-0961>. This study reported direct observation of 57 U.S. physicians and found they spend almost 50% of their time on EHR and desk work, which was much more than time on direct clinical face time with patients. Other work by some of the same authors have identified EHRs as a source of professional dissatisfaction and burnout.

Sittig, D. F., & Singh, H. (2012). Electronic health records and national patient-safety goals. *New England Journal of Medicine*, 367(19), 1854–1860. <https://doi.org/10.1056/NEJMs1205420>. This article proposes a 3-phased approach to implementing EHRs in a way that improves safety: address safety concerns unique to EHR technology, mitigate safety concerns arising from failure to use EHRs appropriately, and use EHRs to monitor and improve patient safety.

## ? Questions for Discussion

1. What are the key barriers to effective use of EHRs and exchange of health information? Which of these challenges are amenable to public policy decisions?
2. What are the key barriers to innovation in health IT? What can be done to accelerate innovation?
3. What might be some of the tradeoffs of using administrative claims data compared with using clinical data from health IT systems for care quality analysis?
4. What might be some of the tradeoffs of promoting health IT by paying for use compared with paying for quality?
5. Should health IT be regulated the same way as devices are regulated to protect patient safety? Why or why not?
6. If research finds strong evidence of a digital divide in health IT, what policy actions should be taken?
7. What kinds of health IT functionality are needed to support accountable care organizations and patient-centered medical homes?

and Robert M. Wachter*

## Contents

- 30.1 The Present and Its Evolution from the Past – 988**
- 30.2 Looking to the Future – 994**
- References – 1016**

**Learning Objectives**

After reading this chapter, you should know the answers to these questions:

- What does the past evolution of the field of biomedical informatics tell us about its future trajectory?
- How will data science methods influence biomedical informatics research
- What roles will electronic health records and artificial intelligence play in health care of the future?

**30.1 The Present and Its Evolution from the Past**

Every good look forward should start with a look back to provide perspective regarding the past and an assessment of the pace of change, thereby helping us to anticipate a trajectory for

the future. This book first appeared in 1990 at a time when the field was much younger (the word *informatics* had come into common use only in the previous decade) and was still being defined. Thus that early edition, and the ones that followed (in 2000, 2006, and 2014) offer a glimpse of what topics appeared over time, which ones faded away, and how even the terminology evolved (as it will no doubt continue to do in the future). Consider, for example, the list of chapter titles from the 1990 edition (Table 30.1). The first edition was titled *Medical Informatics: Computer Applications in Medical Care*, reflecting the field’s original roots in clinical medicine. In those days, the field was called medical informatics (see Chap. 1) and the first edition was focused largely on clinical application areas, such as electronic health records, nursing systems, laboratory systems, radiology system, and education systems.

The next decade was revolutionary, however, and it had a profound effect on informatics. During the 1990s, the Human Genome Project made it clear that much of what needed to be accomplished in human biology and genetics could not be achieved with the use of the computational methods available or introduced at that time. Many of the informatics techniques that had been developed in the clinical world became relevant to genomics research, where investigators coined the term *bioinformatics* for their computational explorations. Thus, the field of informatics began to broaden to span both basic and applied clinical sciences. In an effort to acknowledge this evolution, the second edition of this book was renamed, with “medical care” giving way to “health care” (to acknowledge the field’s growing role in prevention and public health) and the addition of “biomedicine” (to embrace the role of informatics in human biology research) (■ Table 30.1). In addition, a new chapter on bioinformatics was added to the edition when it appeared in 2000. Similarly, the second edition took a broader view to consider topics such as standards, ethics, integrated delivery networks, and public health. Bibliographic retrieval expanded to be information retrieval, and there were changes in emphasis in several other chapters as well.

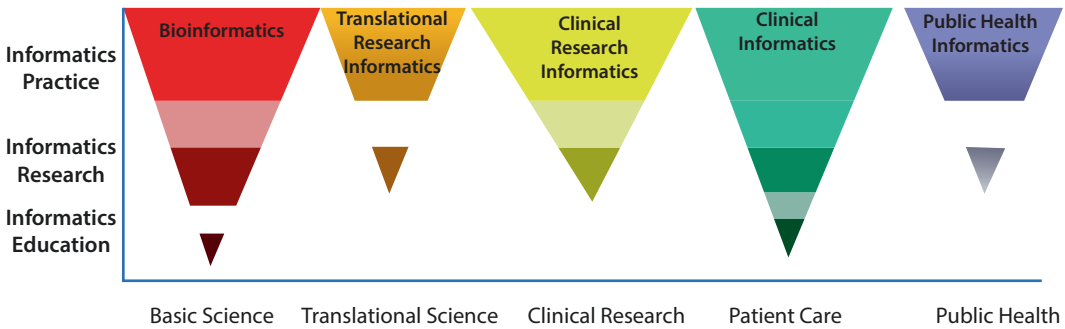

In an attempt to acknowledge and emphasize the shared methods that applied in both the human life sciences and in clinical medicine and health, the academic discipline began to change its name from “medical informatics” to “biomedical informatics”. Several departments were renamed or created with this new name for the field. Hence, when the third edition of this book appeared in 2006, it adopted the title *Biomedical Informatics*, discarding the more limited “medical informatics” focus. Although several chapters were simply updated and some were deleted, others were divided into two components (e.g., the Imaging Systems chapter from the second edition was divided into a methodologic chapter on imaging/structural informatics plus an application chapter on Imaging Systems in Radiology) (■ Table 30.1). Furthermore, totally new chapters were drawn from other fields, including cognitive science, natural language processing, and consumer-

facing systems. In addition, chapter authorship evolved substantially as new topics were introduced and authors from earlier editions brought on coauthors whose expertise complemented their own.

The book title remained unchanged in the fourth edition in 2014 (and in this edition), but changes to the chapter titles provide more detail to what was evolving (■ Table 30.1). The fourth edition introduced several new topics, including telehealth, translational bioinformatics, and clinical research informatics. And the current edition has added new chapters in the areas of human-computer interaction, mHealth, and precision medicine.

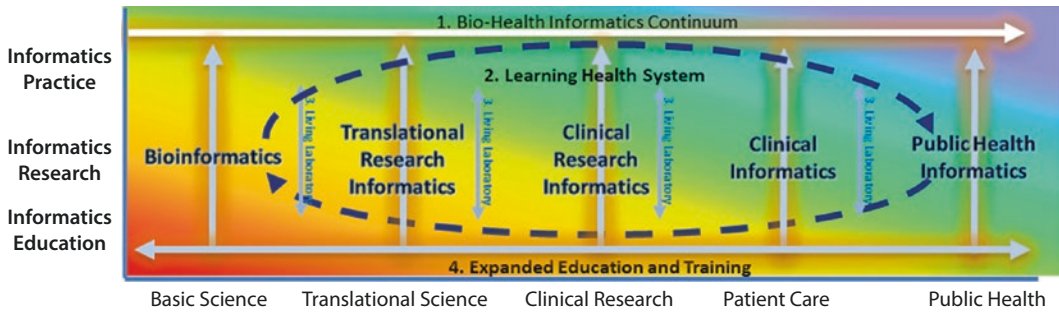

Thus, a review of the titles and tables of contents of the five editions of this book, spanning 30 years with 20 chapters at the outset evolving to 30 chapters now, provides a thumbnail view of the evolution of the field as a whole. So, what evolution can we observe and what does it tell us about where we are headed? We see a field that started with a strong focus on computer programming for clinical medicine and ancillary services. The field grew to embrace research areas related to medicine and health, ranging from molecular to biologic systems to organisms, and beyond to populations. And, as with any emerging discipline, biomedical informatics began to differentiate its activities into practice (the lion’s share), research (not just biomedical research informatics, but research on informatics in its own right), and education. Connections among these three types of activities and overlap across domains were often scant, as shown in ■ Fig. 30.1. Four trends, described throughout this book, have blurred many of the distinctions (■ Fig. 30.2).

First, the broader field of biomedicine itself has begun to blur the distinctions among its traditional areas of research domains. This is evident in the emergence of the “translational science” philosophy, with clear recognition that each scientific endeavor builds on the discoveries made at some other, usually smaller scale. One culmination of this trend is *precision medicine* (see ► Chap. 28), in which discoveries at the genomic level are translated into knowledge that supports decisions for patients and populations.

**Fig. 30.1** Prior state of biomedical informatics domains and activities. Clinical informatics was the earliest and continues to be the largest domain, as reflected in this book, with other domains following in time. The advent of the Human Genome Project led to rapid expansion of the application of bioinformatics. Research in each domain

followed practice, depicted here as more or less semi-transparent connections. Education in informatics, both for research and practice, began in the clinical domain, especially with nursing informatics, to be followed by nascent bioinformatics training programs. Connections between the education and research varied

**Fig. 30.2** Today, biomedical informatics is becoming a continuum, with fewer distinctions among domains and activities. This mirrors the continuum of biomedicine, with its recognition of the translational nature ranging from basic science public health (1), exemplified by precision medicine which draws on genomic knowledge to directly improve care of the individual patient. Increased clinical informatics activity has resulted in increased availability of clinical data, which informs research to produce better evidence to guide practice, resulting in a “learning health system” (2). Users of

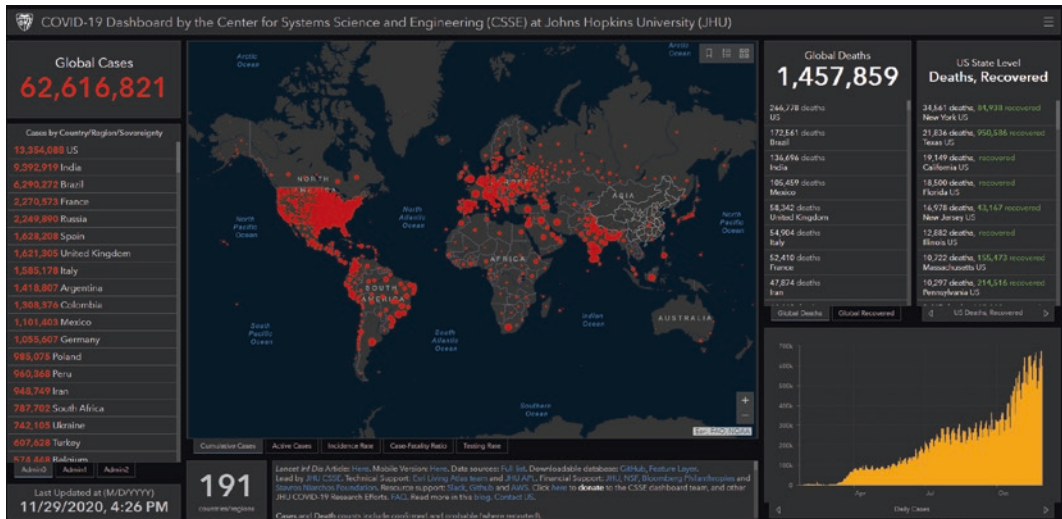

informatics applications in research and practice settings are increasingly seen as research subjects in “living laboratories” (3) for guiding the improvement of the tools they use and learning new ways to apply informatics methods. Finally, education and training in informatics is increasingly leaving the classroom and moving to practice sites for observation and learning and as settings for experimenting with new solutions (4). (<https://systems.jhu.edu/research/public-health/2019-ncov-map-faqs/>). Copyright 2020, Johns Hopkins University. All rights reserved)

Second, the *learning health system* (► Chaps. 1 and 17) is making use of large-scale data collected from patients and populations to frame research questions that are answered in the laboratory. Knowledge discovered there is then returned to the point of care to support evidence-based diagnostic, preventive and therapeutic decisions.

Third, informatics research is moving from the computer lab out to where potential users of informatics tools are actually working. Harnessing tools from cognitive science and mixed methods evaluation, the biological lab-

oratory, the clinic, and the hospital are becoming *living informatics laboratories* for testing informatics ideas and observing their impact.

Fourth, the connections between informatics education and informatics practice are being strengthened. As electronic health records have become ubiquitous in clinical practice, computing devices and information technologies have become virtually the only tools used by every health care provider. Therefore, the importance of rigorous training in the use of these tools has increased. *Informatics training programs* are now able to train their students with the

**Fig. 30.3** An example of the application of informatics to increase availability of large data sets and to facilitate their processing for public consumption. Depicted is a COVID-19 dashboard developed at the Johns Hopkins University Center for Systems Science and Engineering

living laboratories by studying how research and patient care systems are being used and can be improved. The long tradition of formal informatics training in nursing programs is now being adopted in clinical medicine, which has recently added clinical informatics as a board-certified subspecialty through the American Board of Medical Specialties (ABMS).

## 30.2 Looking to the Future

Given the general trends we have outlined, what can we expect in terms of specific advances for the field? For that, we invited seven visionaries to share their predictions for the directions we, or least should, be moving. We chose innovative thinkers who could provide insights on the future of biomedical informatics from a variety of perspectives: bioinformatics (Tarczy-Hornoch), industry (Horvitz), nursing (Murphy), health policy (Blumenthal), academic informatics (Frissie), clinical medicine (Wachter), and federal government (Brennan). Individually, they provide perspectives on government efforts, policy changes, research advances, and clinical practice. Together, they weave a rich tapestry that presages how bio-

informatics is likely to influence the twenty-first century. As it happens, shortly after these pieces were written, events have unfolded to put these predictions to the test. Writing in early 2020, we are referring of course of the COVID-19 pandemic. The chapters in this book were largely written in the preceding year or two. Some have been updated to discuss the current situation (e.g., see ► Chap. 18), but no textbook can keep current with the rapidly unfolding events of this current natural disaster. The level of public interest in biomedical information, ranging from virology and immunology, to pharmacology and epidemiology, has risen to unprecedented levels. Up-to-the-minute data are being provided with great volume, variety and velocity (the hallmarks of “big data – see ► Chap. 13) through government, academic and news media sources for popular consumption (► Fig. 30.3).<sup>1</sup> All of this requires rapid development and delivery of informatics solutions on an unprecedented scale, along with approaches for confirming the veracity of data.

<sup>1</sup> ► <https://www.arcgis.com/apps/opsdashboard/index.html#/bda7594740fd40299423467b48e9ecf6> (accessed 2/13/2021).

The lessons and predictions discussed by our guest visionaries can be applied directly to the care of patients with suspected or confirmed COVID-19. For example, Tarczy-Hornoch (► Box 30.1) describes correlation of genomic and functional data with clinical outcomes data. Thanks to adoption and interoperability of electronic health records (► Chaps. 14 and 15), sufficient data are becoming available to provide an understanding of risk factors for disease severity as well as benefits risks of putative treatments much more rapidly than could be achieved with formal human subject studies (Xu et al. 2020). Horvitz (► Box 30.2) provides an inventory of the methods drawn from the field of artificial intelligence (see ► Chaps. 1 and 24) that stand ready to use these data to infer answers to such pressing questions through machine learning. He also describes supplemental methods for “machine teaching” that can be brought to bear when some data remain sparse (Feijóo et al. 2020). Murphy (► Box 30.3) describes the advantages of tele-visits for improving access to care; the social distancing required for helping to control the pandemic provides additional incentive for care at a distance, even for those who otherwise have sufficient access to in-person care. Fortunately, the technology of tele-visits (► Chap. 20) has progressed to the point where healthcare institutions have been able to make the necessary transition with an ease that would not have been possible 10 years earlier (Hong et al. 2020). Blumenthal (► Box 30.4) enumerates issues related to safety of information systems and the government’s role in developing policies that address privacy concerns (► Chaps. 12 and 29). The immediate need for such policies relates to the balance between individual rights and the protection of the public, as software developers race to create patient contact tracing applications (Abeler et al. 2020) and patients begin to collect their own intimate, detailed data through the wearables mentioned by Frisse (see also ► Chap. 19 and Ding et al. 2020). Frisse (► Box 30.5) recognizes that with the success of informatics, and its growing impact on both science and health, the challenges and complexities involved with “doing it right”

extend beyond the protection of data privacy. Other impacts on society may be both deep and unanticipated, with the possibility that unintended consequences may exacerbate differences among how different people, with difference education, cultures, and financial means, may experience health care and manage their own health. Unintended consequences of technology have been rampant in many fields (did anyone anticipate that television would engender generations of “couch potatoes”?). Wachter, who is well known for his provocative book characterizing the “digital doctor” who is already somewhat upon us (Wachter 2017), focuses on the informatician (or *informaticist*) of the future and the impact that such individuals will have in clinical settings (► Box 30.6). He acknowledges the problems that are highlighted in his popular book, but envisions an ultimately positive future in which “the experience of being both patient and healthcare professional will be far more satisfying”, due in part to the role that informatics, and those who practice this new specialty, will play in the clinical environment. Tarczy-Hornoch, Horvitz, Murphy, Blumenthal, Frisse, and Wachter all describe ways in which clinicians’ workflow can be influenced for the better through informatics, with particular attention to their quality of life, which the pandemic has demonstrated can require as much attention, for some individuals, as do the lives of the patients they serve (Dewey et al. 2020). And of course, all of these activities are supported through access to data and literature (including the works cited here), made possible by the National Institutes of Health, with the National Library of Medicine at the fore (Zayas-Cabán et al. 2020), as well as other governmental and nongovernmental organizations. As Brennan notes in her perspective (► Box 30.7), the federal government must provide the resources for the things that only it can do (such as gathering and consolidating epidemiologic data) and collaborate with leaders in the private sector that can provide additional breadth and depth of expertise. The COVID monitoring dashboard shown in ■ Fig. 30.3 is just the tip of an iceberg of such cooperation (in this case between the Centers for Disease Control &

Prevention and Johns Hopkins University), when one considers all the work that went into obtaining the underlying data.

Today, biomedical informatics is moving out of the shadows. Instead of hearing “biomedical informatics? What’s that?”, we hear “How is biomedical informatics helping to solve this problem?” There are many answers and although they may seem specific to the current pandemic, they will remain applicable long

after the current challenges are overcome. Public recognition of the importance of informatics will lead to increased resources for research, increased interest in education and training, and new opportunities for applications in biomedicine, in preparation for the inevitable challenges we know to anticipate. The intent of this book is to prepare those who wish to understand, support and lead these changes.

### Box 30.1 A Perspective on the Future of Translational Bioinformatics and Precision Medicine

*Peter Tarczy-Hornoch*

The first part of the twenty-first century saw the establishment of the fields of translational bioinformatics (TBI) and precision medicine (PM), accompanied by the movement of this research into the early T-phases [1] of translational research (e.g. T0–T2 research focused on discovery and early application). The next decade will see the fields move into the later T-phases of broader adoption and diffusion (T3) and into evaluating the population impact in terms of health outcomes (T4). Due to shared core methodologies plus pressures on the health system, T3/T4 research will demonstrate a convergence between TBI/PM (predicting individual outcomes) and integration with more population-based approaches such as comparative effectiveness research and, more broadly, the concept of the learning healthcare system.

The earliest work in TBI and PM focused on the identification of opportunities and new approaches (T0), discovery to early health applications (T1), and assessment of value (T2). In the TBI area, T0 work focused on studies piloting the combination of both genomic data and electronic health record data for discovery (e.g. the early phase of the eMERGE project) and proof-of-concept T1 translational applications of genomic discoveries to clinical care (e.g. targeted pharmacogenomic decision-support systems). We also see an emerging body of T2 translational research that is beginning to assess the value of these new discoveries for health

practice and for the development of evidence-based guidelines. The validation of genomic discovery and demonstration of its suitability for widespread adoption (T2/T3) is just beginning. This evolution can be illustrated on the clinical T2 front by the work of the American College of Medical Genetics, which monitors new genomic discoveries to identify what secondary findings in genome and exome sequencing meet criteria for reporting [2]. Thus far only selected mutations of around 60 genes (out of over 20,000 in the genome) meet the ACMG’s rigorous criteria for clinical reporting. The clinical validation of new discoveries facilitated by TBI is a key step in the development of informatics tools that apply this knowledge to practice (e.g. decision-support tools). As an example of informatics T2 work, researchers have begun to assess the cost/benefit of genomic decision-support tools in the electronic health record [3]. The research and application of PM informatics approaches for T1 discovery and T2 application parallel those of TBI (oftentimes incorporating genomic elements as part of the input data for the development of predictive models).

In the coming decade the types and volume of data used for TBI and PM discovery and application will continue to expand and the distinctions between TBI and PM will blur even further. As the cost of genome sequencing continues to drop, increasing numbers of patients will have genotypic information available to correlate with clinical and other information, which will enable both larger scale discovery and application. In the cancer domain, for example, new single-cell sequencing approaches will provide additional granular data on a specific patient’s

clonal mutational profiles. In the metabolomics and proteomics areas, the cost of gathering these data is dropping, both at the patient and more targeted (e.g. organ) levels. The ability to begin to correlate these functional data with clinical outcome data and with response-to-therapy data will provide powerful new biological and clinical insights. These new sources of biological process data will complement new sources of phenotypic and environmental data. Text mining will enable free-text notes describing phenotype and environment (e.g. social determinants of health) to be transformed into more discrete data suitable for machine learning. Increasing availability of geocoded environmental data (e.g. climate data, pollution data, air quality data, pollen counts, etc.) will enable cross-links to patient data. With patient engagement and permission (and substantial work on standards and security), specific environmental data from the Internet of Things (e.g. lighting and temperature data in a home) may also be linked with genomic, biological and clinical data for a patient. Similarly other patient data can be integrated, such as questionnaire and survey data (patient reported outcomes and mMeasures) and data from consumer wearables (counts of steps, heart rate monitoring, sleep monitoring) as well as consumer medical devices (home glucose and blood pressure monitoring, and, recently, more experimental transdermal monitoring of metabolic processes). This increase in data about individual patients, as well as the number of patients for which these rich data are available, will greatly accelerate the T0–T1 discovery and initial clinical application phases of TBI/PM. The volume of data and potential outcomes are such that the informatics tools will become ever more important for discovery. Already health care providers struggle with information overload and with the need to be current on new medical discoveries. The anticipated complexity and volume of new findings and correlations will be such that computer-based decision-support tools will be obligatory for application of these new findings. All of these approaches will fit into the paradigm of using predictions to provide early/preventive interventions that are tailored to the unique pro-

file of the individual patient. The core methods and approaches used for analysis and discovery, and the ones used for decision support, will be fundamentally similar, whatever mix of input variables is used across the spectrum of genetic, biologic, clinical, patient provided, or environmental data. In light of this, the distinction between TBI and PM will likely vanish.

There are number of promising data analytics methods currently under development that are likely to be useful in the TBI/PM informatics area. One category is the creation of more automated model-selection and tuning methods. Without these it will be difficult to scale a number of the approaches currently being used since they are dependent on the involvement of human data scientists. Similarly, there is foundational work being done in academia and industry that is seeking better unsupervised learning approaches. These are needed because the ability to develop gold-standard training sets is now often constrained by the amount of human effort required.

Another broad category is methods that provide some explanatory power related to predictions. As one example, current machine learning approaches identify correlation but generally cannot provide insight into causation. New approaches show promise when they leverage large enough data sets to begin to infer causation. Another example is using automated tools both to develop predictive models and then to use artificial intelligence techniques to develop an explanatory model. Both these examples illustrate ways in which new methods may begin to address the concern raised by some overly opaque “black box” predictive models. A final broad category is methods that begin to leverage available data more effectively, including new AI-based image-analysis approaches, next-generation hybrid statistical and rules-based text-mining approaches, and new approaches to improve the use of temporal information in prediction algorithms (e.g. the slope and tempo of visits and laboratory values).

The rapidly rising costs of health care in the United States, without a corresponding improvement in quality, will influence the development of informatics tools for precision medicine.

Broadly this will mean that work in the TBI/PM informatics space will need to factor in the perspectives of the Quadruple Aim: (1) enhancing patient experience, (2) improving population health, (3) reducing costs, and (4) improving the work life of healthcare providers. Regarding the first of these, it will be important to ensure that predictive model-based decision-support tools are built in ways to ensure the pursuit of shared decision making involving the patient. Tools must also provide the appropriate support for ensuring that behavioral changes occur (e.g. if a model predicts the need for increased aerobic exercise, there must be methods to ensure that occurs). It will similarly be important to ensure, as data are shared and models are developed, that attention is paid to ethical, legal and social aspects of data sharing. This will help to maintain the trust of patients and to avoid unintended biases in the models (consider, for example, the recent issues with facial recognition software that works well on white males but not on women of color). The ethical lens will be particularly important to ensure that the privacy and trust of patients and public are preserved as these large scale data-intensive methods are developed and deployed. The recent academic and popular press discussions of the breeches of trust by large scale social media and other Internet companies should serve as a cautionary tale.

Regarding the next two elements in the Quadruple Aim, it will be critical that the work in TBI/PM be subject to the same kinds of assessments that we expect for other diagnostic and therapeutic interventions. Currently there are deployed tools that demonstrate a sensitivity and specificity that are far below the values that we would otherwise demand of diagnostic and screening tests. Informatics interventions have not been treated in quite the same way as laboratory tests or medications. Efforts to demonstrate value and real-world impact of TBI/PM tools will align with broader efforts to demonstrate effectiveness in the real world (e.g. Comparative Effectiveness Research). They will also form a key aspect of the Learning Healthcare System approach, since TBI/PM tools will help to assure that learning can occur from analysis of the data artifacts generated in

the care-delivery process (e.g. the electronic health record and related data).

Finally, in order to address the fourth element in the Quadruple Aim, we will need to determine how best to deploy predictive analytics tools. It will be important to preserve provider decision-making autonomy, to provide sufficient explanatory ability and rigorous validation to ensure that providers trust the results, and to diminish the information and alert overload that providers face today.

In summary, we have just begun to see TBI and PM informatics discoveries and applications have an impact on achieving the broader goals of improving health and the more focused goals of the Quadruple Aim. Over the next decade, with advances in data analytics methods and increasing sources of data regarding an increasing number of patients, we are likely to see remarkable progress in the development of more easily developed and more accurate predictive models that will allow us to intervene at the patient level. These advances will be integrated into the broader trends in health care as encapsulated in the Quadruple Aim, which will require additional research and innovation to ensure that the full potential of TBI and PM are realized.

### Box 30.2 The Future of Biomedical Informatics: Bottlenecks and Opportunities

*Eric Horvitz*

I see the rich, interdisciplinary field of biomedical informatics as the gateway to the future of health care. The concepts, methods, rich history of contributions, and the aspirations of biomedical informatics define key opportunities ahead in biomedicine—and shine light on the path to achieving true evidence-based health care.

Progress with influences of biomedical informatics on health care over the last three decades has been slower than I had hoped. However, I remain optimistic about a forthcoming biomedical informatics revolution, made possible by a confluence of advances across industry and academia. Such a revolution will accelerate discovery in biomedicine, enhance the quality of health care, and reduce the costs of health care delivery.

From my perch as an investigator and director of a worldwide system of computer science research labs, I view key opportunities ahead as hinging on (1) addressing the often underappreciated bottleneck of *translation*—moving biomedical informatics principles and prototypes into real-world practice, and (2) making progress on persisting challenges in principles and applications of artificial intelligence (AI). I am optimistic that we will make progress on both fronts and that there will be synergies among these advances.

On challenges of translation, I believe that the difficulties of transitioning ideas and implementations from academic and industry research centers into the open world of medical practice have been widely underappreciated. Numerous factors are at play, including poor understanding of how computing solutions can assist with the tasks and day-to-day needs of health care practitioners and patients, inadequate appreciation of the needs and difficulties of developing site-specific solutions, poor compute infrastructure, and a constellation of challenges with human factors, including entrenched patterns of practice and difficulties of integrat-

ing new capabilities and services into existing clinical workflows.

Multiple advances coming with the march of computer science will help to address challenges of translating ideas and methods that have been nurtured by biomedical informaticians for decades. At the base level, such advances include ongoing leaps in computing power and in storage, but also key innovations with computing principles and methods in such subdisciplines as databases, programming languages, security and privacy, human-computer interaction, visualization, and sensing and ubiquitous computing.

Faster and more effective translation of ideas and methods from biomedical informatics will also be enabled by jumps in the quality of available computing tools and infrastructure. Increases in the power and ease-of-use of cloud computing platforms are being fueled by unprecedented investments in research and development by information technology companies—companies that are competing intensely with one another for contracts with enterprises that are hungry for digital transformation and the latest in modern computing tools. Cloud computing companies are packaging in their offerings sets of development tools and constellations of specialized services. Many of these offerings are relevant to biomedical informatics efforts, including machine learning toolkits, suites for analysis and visualization of data, and computer vision, speech recognition, and natural language analysis services made available via programmatic interfaces.

Beyond developing generic platform capabilities, cloud service providers are motivated to gain understandings in key vertical markets, such as health care, finance, and defense, and have been working to custom-tailor their general platforms with tools, designs, and services for use in specific sectors. For example, there is incentive to support rising standards on schemata (e.g., Fast Healthcare Interoperability Resources (FHIR)) for storing and transferring electronic health records and on methods to ensure the privacy of patient data. There is also pressure to develop special versions of computing services for medicine, such as language

models and, more generally, natural language capabilities specialized for medical terminology, enabling more accurate understanding and analysis of medical text and speech. Competitor cloud providers have also worked to identify and provide efficient methods and tools for important vertical needs, such as the rising importance of determining DNA sequences and interpreting protein expression data. Such special needs of researchers and clinicians have led to the availability of efficient and inexpensive cloud-computing services for genomic and proteomic analyses.

Moving on to the second realm of opportunities, around harnessing advances in the constellation of technologies that we call AI, I believe that our community can do more to leverage existing methods and also to closely follow, push, and contribute to advances in AI subfields. Beyond methods available today, key developments will be required in principles and applications to realize the long-term goals of biomedical informatics. I am seeing good progress and am optimistic that the advances coming over the next decade will be deeply enabling.

On existing technologies, and focusing on the example of developing effective decision support systems, we have been very slow to leverage the visionary ideas proposed by Robert Ledley and Lee Lusted in 1959 [1]. Ledley and Lusted provided a blueprint for constructing differential diagnoses and to use decision-theoretic analyses to generate recommendations for action. Biomedical informatics investigators have been top leaders with exploring prototypes for decision support systems, and systems constructed over 60 years of research have been shown to perform at expert levels. However, real-world impact has been limited to date. A key bottleneck has been the scarcity and cost of expertise and data. I believe that harnessing advances in machine learning will be particularly critical for delivering on the vision of evidence-based clinical decision making. Machine learning techniques available today can and should be playing a more central role in health care for assisting with pattern recognition, diagnosis, and prediction of outcomes. There

are multiple opportunities to build and to integrate pipelines where data flow via machine learning to predictions and via automated decision analyses to recommendations about testing and treatment. Making key investments to build and refine effective *data-to-prediction-to-decision* pipelines will provide great value in multiple areas of medicine [2].

Opportunities ahead for biomedical informatics include leveraging recent advances in deep learning in medical applications, especially for image recognition and natural language tasks. These multilayered neural network architectures are celebrated for providing surprising boosts in classification accuracy in multiple application areas and for easing engineering overhead, as they do not require special feature engineering. The methods have been shown to perform well for recognition in the image-centric areas of pathology and radiology. Different variants of deep learning are also being explored for building predictive models from clinical data drawn from electronic health records. Beyond direct applications, deep learning methods have led to enhanced capabilities in multiple areas of AI with relevance to goals in biomedical informatics, including key advances in computer vision, speech recognition, text summarization, and language translation.

With all of the recent fanfare about deep learning, it is easy to overlook the applicability of other machine learning methods, including probabilistic graphical models, generalized additive models, and even logistic regression for serving as the heart of predictions in recommendation engines. While excitement about deep learning is appropriate, it is important to note that the methods typically require large amounts of data of the right form and that such datasets may not be available for medical applications of interest. Other approaches have proven to be as accurate for clinical applications and provide other benefits such as providing more intelligible, explainable inferences. Also, when sufficiently large corpora of data labeled with ground truth are not available, knowledge acquisition techniques, referred to broadly as *machine teaching*, can provide value. While work

is moving forward on machine teaching, existing methods and tools can be valuable in building models for prediction and classification.

I believe that it is important to note that having access to powerful machine learning procedures may be insufficient for addressing goals in biomedical informatics. Key challenges for moving ahead with developing and deploying effective decision support systems include identifying where and when such systems would provide value, collecting sufficient amounts of the right kind of data for applications, developing and integrating automated decision analyses to move from predictions to recommendations for action [2], maintaining systems over time, developing means to build and apply learned models at multiple sites, and addressing human-factors, including formulating means for achieving smooth integration of inferences and recommendations into clinical workflows, and providing explanations of inferences to clinicians [3]. Providing explanations of predictions generated by machine-learned models is a topic of rising interest [4]. I hope to see revitalized interest and similar enthusiasm extended to addressing challenges identified in biomedical informatics with the intelligibility and explanation of the advice provided by other forms of reasoning employed in decision support systems, including logical, probabilistic, and decision-theoretic inference [5].

Key opportunities in AI research for progress with developing and fielding effective decision support systems include efforts in principles and applications of *transfer learning*, *unsupervised learning*, and *causal inference*. Transfer learning refers to methods that allow for data or task competencies learned in one area to be applied to another [6]. Unsupervised and semi-supervised learning refers to methods that can be used to build models and perform tasks without having a complete set of labeled data, such as labels about the final diagnoses of patients when working with electronic health records data. Causal inference refers to methods that can be used to identify causal knowledge, versus statistical associations that are commonly inferred from data. Advances in these areas promise to provide

new sources of biomedical knowledge, and to address the challenge of data scarcity and related difficulties with the generalizability of data resources for health care applications.

On data scarcity and generalizability, an important, often underappreciated challenge in biomedical informatics is that the accuracy of diagnosis and decision support may not transfer well across institutions. In our work at Microsoft Research, we found that accuracies of a system trained on data obtained from a site can plummet when used at another location. The poor generality of datasets is based on multiple factors, including differences in patient populations—with site-specific incidence rates, covariates, and presentations of illness, site-specific capture of evidence in the electronic health record, and site-specific definitions of signs, symptoms, and lab results. As an example, we found site-specificity when my team studied the task of building models to predict the likelihood that patients being discharged from a hospital would be readmitted within 30 days. The accuracy of prediction for a model learned from a massive dataset drawn from single large urban hospital dropped when the model was applied at other hospitals. This observation of poor generalizability was behind our decision to develop a capability for performing automated, recurrent machine learning separately at each site that would rely on local data for predictions. This local train-and-test capability served as the core engine of an advisory system for readmissions management, named Readmission Manager, that was commercialized by Microsoft.

Moving forward, research on a set of methods jointly referred to as *transfer learning* may help to address challenges of data scarcity and generalizability. Transfer learning algorithms for mapping the learnings from one hospital to another show promise in medicine [6]. Such methods include *multitask learning*. Also, obtaining spanning datasets, composed of large amounts of data drawn from multiple sites, may provide effective generalization. In support of this approach, methods called *multiparty computation* have been developed that

can enable learning from multiple, privately held databases, where there is no violation of privacy among the contributing organizations.

Beyond the daily practice of health care, and uses in such applications as diagnosis and treatment, methods for learning and reasoning from data can provide the foundations for new directions in the clinical sciences via tools and analyses that identify subtle but important signals in the fusing of clinical, behavioral, environmental, genetic, and epigenetic data. I see many directions springing from applications of machine learning, reasoning, planning, and causal inference for health care delivery as well as in supporting efforts in health care policy and in the discovery of new biomedical understandings.

I remain excited about advances in biomedical informatics and see a biomedical informatics revolution on the horizon. Such a revolution will build on the glowing embers of decades of contributions and the flames of late-breaking activities that address long-term challenges and bottlenecks.

### Box 30.3 The Future of Nursing Informatics

Judy Murphy

The focus of this commentary is on the future of biomedical informatics from a nursing perspective, but it is helpful to understand the background and history of nursing's role in the field. Starting there, the focus will move to looking at nursing informatics today and then looking to the future of the field from a nursing point of view.

Nurses have contributed to the purchase, design, and implementation of health information technology (IT) since the 1970s. The term “nursing informatics” (NI) first appeared in the literature in the 1980s [1–3]. The definition of NI has evolved ever since, molded by maturation of the field and influenced by health policy. In a classic article that described its domain, NI was defined as the combination of nursing, information, and computer sciences to manage and process data into information and knowledge for use in nursing practice [4]. Nurses who worked in NI during that time were pioneers who often got into informatics practice because they were good clinicians, were involved in IT projects as educators or project team members or were just technically curious and willing to try new things. Their roles, titles, and responsibilities varied greatly.

A solid foundation for the NI profession continued to be laid over the ensuing 40 years. Today, informatics has been built into undergraduate nursing education and there are over a hundred schools offering post-graduate NI education. NI is recognized as a specialty by the American Nursing Association (ANA) and has a specialty certification [5]. NI is now described as the specialty that integrates nursing science with multiple information and analytical sciences to identify, define, manage, and communicate data, information, knowledge, and wisdom in nursing practice. NI supports nurses, consumers, patients, the interprofessional healthcare team, and other stakeholders in their decision-making in all roles and in all

settings to achieve desired health and health-care outcomes. This support is accomplished using information structures, information processes, and information technology [6].

NI continues to grow. In the most recent Health Information and Management Systems Society (HIMSS) NI Workforce Survey, 57% of respondents held a post-graduate degree in nursing or nursing informatics and 44% were specialty certified by ANA in NI or other nursing specialty. Another 32% were currently pursuing NI certification, and over half have been working in an informatics role for more than 7 years [7].

Since the HITECH Act of 2009, nursing informatics specialists have played a pivotal role in influencing the adoption of electronic health records (EHR) for meaningful use. Having the breadth and depth of healthcare knowledge and understanding clinical practice workflows, nurses help all clinicians understand the application and value of the EHR. Nurses have a perspective of the many venues of care and working with all care team members, as well as working with patients at different points in their care continuum. Nurses help the patient utilize health IT to improve engagement in their own care, take control of their own health and become an integral part of the decision-making process and care team. As patient advocates, nurses understand the power of the patient in a participatory role and how this can improve outcomes.

The type and quality of care that nurses provide to their patients will benefit immensely from the continued advancement of technology and informatics in healthcare. Although there are many ways those advancements will impact nursing, here are two areas that hold the greatest promise for nursing's future.

*Data and the Continuous Learning Health System:* Nursing research has not been as prolific as medical research, so there is a lot less known about the true impact/outcomes of nursing interventions. But now that organizations are aggregating health data electronically in an EHR and other Health IT, nurses can more easily identify practices that measurably

impact individuals by mining the data and using prescriptive, predictive and cognitive analytics to correlate actions to improved outcomes. The collection, summarization and analysis of data can be from multiple venues and sources, including social determinants and patient-generated information for personalization. Then, it's not just about impacting traditional care, but about the impact across the continuum for the individual and including public health and population health management. The learnings can be iterated back into nursing practice in months instead of years, using protocols/guidelines, documentation templates, and clinical decision support – making it easier to do the right thing and ‘hard-wiring’ new best practices – thus, creating a continuous learning health system.

*Care Coordination and Healthcare Anywhere:*

The advancement of technology has provided us the opportunity to provide care anytime/anywhere and there's little question that both patients and providers are increasingly drawn to the concept of healthcare services that are virtual. This includes “visits” using communication technologies such as email, phone and videoconference, as well as telehealth technologies for remote monitoring and management of conditions or chronic disease. Coupling this with engaged patients using portals and mobile apps creates a new ecosystem for nurses and their patients to interact. Care coordination between venues of care and across the continuum will be directly impacted in a positive way. As nurses have primary responsibility for coordinating care and helping patients navigate the complexities of the healthcare system, this will be a way for them to extend their reach to more patients and to improve the quality of the care provided to each patient. Nurses can more easily close

care gaps for preventive and disease management services, monitor patients' conditions while they live their lives and not just when they visit a healthcare facility, and provide consulting and educational services.

The future of nursing informatics has no bounds; technologies of all kinds will continue to evolve, and informatics will help nurses both integrate new technologies into their practice as well as manage the impact of new technologies on that practice. Informatics will help invent the future of nursing care transformation.

### Box 30.4 Biomedical Informatics: The Future of the Field from a Health Policy Perspective

*David Blumenthal*

Policy issues and developments in the United States will be vital to the evolution and efficacy of health information technology (HIT) in the future. This is true because health policy has made HIT a mainstream feature of the U.S. health care system and a vital tool for improving it.

Two types of health policy issues will vitally affect the future of HIT, its uses and its benefits. The first type is generic to the U.S. health care system but will indirectly affect how HIT evolves. The second type of policy issue focuses particularly on HIT.

Generic policy issues include payment reform and the push toward consumer empowerment. There is an urgent need for payment reform to address issues such as the high costs associated with the U.S. health system. HIT has the potential to be a powerful tool in health system improvement but whether that potential is exploited will depend on the needs and priorities of its users, especially health care providers. In a fee-for-service environment, where volume and revenue maximization are prioritized, purchasers of HIT will demand that it serve these purposes. The requirement to capture detailed information for billing purposes will be paramount to the design and configuration of electronic health records (EHRs) and other IT. Information systems will be used to assure that providers capture every billable service in a way that maximizes revenue collected.

Payment approaches that prioritize value will favor different HIT configurations, especially if those payment methods hold providers accountable through risk-sharing for the cost and quality of services. HIT will have to facilitate the capture and reporting of quality and cost information for the purpose of demon-

strating the value of services provided and to manage resource use continuously over a reporting period. Interoperability and exchange of health care data will become a business imperative to the extent that accountable providers must absorb the costs of services provided to their patients at other health care facilities in their communities.

HIT for value maximization will also put much greater emphasis on improving clinical decisions so as to enhance the value of services performed. In a value-oriented environment, usable and helpful decision support will achieve a priority it has never had in the current fee-for-service environment. Another priority will likely be the capability to assess the comparative performance of clinicians within organizations so as to evaluate reasons for variation in decision-making and health care outcomes.

A bipartisan interest in making health care markets more competitive and responsive to patients' needs is also motivating a push toward patient empowerment through sharing electronic data with patients and their families. This movement is reflected in legislation and regulations that encourage providers to share EHR data with individuals or their designated third parties. The Office of the National Coordinator for Health Information Technology (ONC) issued a rule in 2015 that requires certified EHRs to have standardized application programming interfaces (APIs) [1], which will facilitate access to EHR data by patients and their agents. A new ONC rule, proposed in the spring of 2018 [2], would also discourage so called information blocking.

The growing interest in data-sharing with patients is also apparent in Apple's decision to work with 13 prominent health systems [3] to accept their patients' EHR data. Large, innovative technology companies like Apple may be able to support patient empowerment by fashioning user-friendly applications that use patients' data to inform their decision-making.

The emergence of such applications will raise a host of policy issues. Finding ways to assure the safety of these consumer-facing applications will be a critical part of consumer empowerment, and constitutes a key policy agenda. To this end, the Food and Drug Administration (FDA) is making an effort to adjust its traditional regulatory approaches for the special circumstances of HIT applications.

One example of their efforts is the Accelerated Digital Clinical Ecosystem (ADviCE), a partnership between the University of California, San Francisco, several other universities and health systems, and the FDA to share best practices and data for using, integrating, and deploying health technology services and applications. ADviCE will make recommendations on the types of data needed, data sharing, transparency, and use.

Policymakers must also find ways to protect privacy of patients, either through enforceable voluntary standards or governmental regulation of emerging private organizations, like Apple, that play the role of data stewards.

Some HIT specific policy issues are also likely to influence the future development of health information technology. On this front, the increased use of EHRs has also given rise to safety challenges, as enumerated in a recent report from the Pew Charitable Trusts [4]. For example, patients may receive the incorrect dose of a medication or clinicians may select the wrong person when inputting an order. These safety issues are probably linked with the usability of EHRs, and suggest the need for improved user-centered design focused on the needs of both clinicians and patients. The

EHR certification process will likely play a role in pursuing improved safety of patient data.

To address these and other health IT safety concerns, multiple experts have proposed the establishment of a safety collaborative composed of EHR developers, hospitals, government, health practitioners, and other key organizations to work together to resolve safety problems.

Finally, policy interventions may be required to improve equity of access to benefits of HIT in rural areas and for underserved populations. Lack of connectivity and sophisticated technical support can handicap rural providers in their efforts to use advanced HIT.

With the increasing power of HIT in health care will come increased reliance on its capabilities for responding to policy challenges, both general and HIT-specific. For the most part, these challenges will stimulate evolution in HIT design that makes it even more useful and important for the future of our health care system, and its patients and providers.

**Box 30.5 Future Perspective***Mark Frisse*

As this textbook demonstrates, biomedical informatics paradigms are changing. Original paradigms of necessity were moored by an environment where data sets were small; data storage was limited; computation required massive and costly hardware; and high-bandwidth network connections were rare. Most major biomedical research was conducted in large laboratories and, with a few exceptions, computational needs were limited. Health care delivery and clinical research generally took place in hospitals and large clinics both affiliated with medical schools and endowed with talent, revenues, and capital necessary for their successful operation. Payment models and reimbursement for health care operations took place behind the scenes without excessive complexity and with few burdens on providers. Public health workers, health policy researchers and related groups had access only to selective, retrospective, and often manually-collected data and limited analytic capabilities. Informatics was a select, expensive, and time-consuming endeavor. Despite great challenges, remarkable feats were accomplished.

Recent paradigms are untethered from many early constraints. Today, data sets are massive and plentiful; data storage is inexpensive and seems unlimited; computation is ubiquitous and extends from minute sensor devices to massive cloud-based virtual machines; high-bandwidth network connections are pervasive and central to American life. The range of biomedical research activities is far broader and is constrained more by funding and talent limitations than by facilities; and computation is not only central to traditional research approaches but has extended the reach of scientific investigation dramatically through the analysis of data sets ranging from molecules to genomes. Largely because of Internet-based services, more providers and other care givers have access to information they need. Public health workers, health policy researchers and other interest groups can access large and broad data

sets collected in near real-time. Patients and their families can also access much more information and are have become truly central to health care; patients are speaking up, and our health system is listening.

Other academic disciplines, once working on the periphery of biomedical informatics, are converging and taking center stage. Social scientists explore care complexity both in delivery settings in and in the home. For example, cognitive scientists seek more effective and efficient ways of managing care tasks. Operations research professionals seek to improve patient access, scheduling, workflow analysis, capacity management, throughput, and systems science. Behavioral psychologists are studying how mobile technologies can “nudge” patients and providers into better behaviors. As a result, informatics has become even more imaginative, extensive, rigorous, broad, accessible, and inexpensive.

The accomplishments have been many, the future seems bright, and the potential for societal good is promising. But, to paraphrase novelist William Gibson, this bright future is not now nor will it quickly become evenly distributed. Both in biomedicine and in society at large, new paradigms and technologies transformed commerce, interpersonal communication, social interactions, and behaviors have upended almost every aspect of society. By integrating and analyzing the multiple data streams emerging from our personal behavior, communication, reading habits, purchasing patterns, and social interactions, data and algorithms are capable of startlingly accurate predictions that in turn can profoundly influence behavior. The velocity of these changes carries biomedical informatics – and all of society – into an uncertain future full of promise and peril.

Consider the American healthcare system. The United States has the highest per capita expenditures for health care in the world, yet, by many measures, important health care quality measures lag far behind these of other countries [1]. Despite significant advances in technology and clinical informatics, this trend continues. This may be due in part because technologies are

not capable only of reducing complexity, they are also capable of introducing additional complexity whether such complexity is warranted or not. One cannot argue against effective informatics support for prescribing decisions; biology and the clinical condition warrant extreme detail to complexity. Similarly, knowledge of total and out-of-pocket drug costs would be helpful if patients were presented with choices, but it is difficult to rationalize the hundreds (if not thousands) of different formularies imposed by health plans. One can argue that effective measurement of outcomes and care metrics is essential for demonstrably increasing quality of care, but the value of many quality metrics is uncertain and the administrative burdens imposed on clinicians who must collect these data borders on the intolerable, often coming at the expense of patient interaction. As the economist Uwe Reinhardt wrote: “I have been at many conferences at which concerned clinicians explore so-called ‘evidence-based medicine,’ replete with ‘evidence-based best-clinical-practice guidelines’ and the associated ‘clinical pathways.’ I cannot recall a conference on the topic of ‘evidence-based best administrative practices,’ (although I may have missed it.)” [2].

Consider the future role of the traditional institution-centric electronic health record. Federal incentives greatly accelerated the introduction of EHRs into hospitals and clinics and made transactions like e-Prescribing routine. Data and communications standards allow communication across different clinical systems and expand capabilities for medication management, care coordination and other clinical activities outside of hospitals and clinics. Common EHR data elements and organizational data warehouses are simplifying secondary data use for quality reporting, administration, population health, research, and other uses. Web portals, mobile communications, and patient-accessible EHRs are engaging patients and their families to a greater degree. But this rapid introduction of EHRs has been a mixed blessing. Critics claim that EHRs focus on administrative and payment at the expense of providing the cognitive support patients and clinicians desperately need. EHRs

cannot simply continue their current approach at the expense of providing the cognitive support patients and clinicians desperately need. To improve clinician morale and productivity, the urge to introduce even further unnecessary administrative burdens on care providers must be resisted.

Given the many turbulent transformations in care delivery methods, care delivery organizations, and patient-centered health technologies, many clinical informatics advances will be the realized through extension of traditional EHRs and still others will be the product of experimentation with clinical technologies address immediate consumer-directed needs and view EHR connectivity as secondary objective. Since both models will be introduced, evaluated, and adopted, one must understand how informatics can influence the evolution of many different types of clinical systems.

The ascendancy of data science has been a central theme of biomedical informatics. Broadly construed, these activities expand fundamental biomedical informatics activities through the introduction of new technologies and techniques. Findings emerging from increasingly interoperable clinical databases like i2b2, OMOP, and PCORNet further stimulate essential large-scale, collaborative data standardization and ontology development. These in turn will simplify the inclusion of a broader array of personal, environmental, and biologic computable knowledge structures. Machine learning and related disciplines arising from these activities foster discovery of previously unknown medication interactions, genetic propensities, behavioral risks, predictions, and actionable care interventions.

Social networks and other forms of informal communication are having similar impacts. In principle, these networks can gather isolated individuals sharing common concerns and can reinforce positive behaviors and combat impediments to health – social isolation, misinformation, and costs. Some forms of “digital group therapy” or “group telemedicine” may be particularly well-suited in these circumstances.

A dazzling array of new technologies must also be understood and when appropriate intro-

duced into clinical research and care delivery. The collection, integration, and analysis of new data streams produced by these devices are already being used to manage diet, weight, exercise, and even cardiac rhythm problems. Untethered from traditional EHRs, these products are producing new and valuable sources of ambiently-collected data at lower costs.

Speech and gesture recognition will simplify human-computer interaction. Ambient data collection methods simplify collection of routine data and provide additional context for documentation and interpretation. Clinician-computer interactions may be unobtrusive and allow greater focus on patients rather than computer screens. Ambient data collection – including video interpretation of clinician – patient interactions may be used to more completely summarize the clinical encounter. Image recognition technologies can diagnose skin disorders, radiographs, and some other medical images. Machine learning algorithms will reliably screen for abnormalities and complement human judgement.

We cannot fully control how innovations will be adopted, nor can we predict their societal impact. Informatics – and innovation more broadly – is a two-edged sword.

For example, clinical systems have improved care, reduced costs, and contributed to new insights through translational informatics and data science. At the same time, they have added considerably to administrative burdens and cost, and in practice, may emphasize administrative tasks over the critical cognitive work that is the foundation of clinical medicine. At the clinical and policy level, efforts to simplify programs and processes become even more important.

Similarly, social networks and telemedicine allow previously isolated individuals to reinforce possibly socially objectionable attitudes or behaviors. But these same networks can rapidly distribute and reinforce exaggerated or false claims about the efficacy of vaccinations, treatments, and scientific evidence; these prac-

tices challenge society's very idea of a common truth.

Advances in data science and analytics, when combined with sensors and devices on the person, in the home or in public spaces raise fears that “someone/something is always watching.” If data are aggregated and used by an unauthorized “data-industrial complex” working outside of socially acceptable norms, privacy rights are threatened. Better means of anonymizing data and more realistic privacy and data use policies will become even more important.

Although paradigms change, an emphasis on data, information, knowledge, and effective use remains foundational. A primary responsibility of biomedical information is to ensure that everything from data generation to knowledge generation is continually improving through greater consistency and efficiency. These improvements in turn should result in systems that more effectively address real needs and not merely automate flawed behaviors or practices. Our future depends on the extent to which we can introduce efficient means of presenting needed, reliable, and consistent information and the extent to which our efforts ensure better outcomes for individuals and society. To be effective, informatics professionals proceed based on their experience, knowledge, and values. They must, in other words, practice wisdom.

### Box 30.6 The Future of Health IT: A Clinical Perspective

*Robert M. Wachter*

About a decade ago, I hired a young clinical informaticist for a faculty position at UCSF. I told him he had an incredibly bright future, since we would soon implement a well-respected vendor-built electronic health record (EHR). I was confident that this would be exciting and important work, work that would keep him fully employed for years to come.

I didn't share with him my worry: what would his job be after the EHR was installed?

Needless to say, despite the fact that our EHR has been up and running for 6 years, he remains gainfully employed. In fact, he is busier than ever. His experience taught me something I did not understand at the time: the implementation of the EHR is merely the first step in the process of extracting value from healthcare digitization.

In fact, I have come to see the process of digitization as involving four steps:

1. Digitizing the record
2. Connecting all the digital parts ("interoperability")
3. Gaining insights from the digital data now being generated by and traversing the system
4. Taking advantage of digitization to build and/or implement new tools and approaches that deliver healthcare value (improving quality, safety, patient experience, access, and equity while also lowering costs and improving efficiency and productivity)

In the United States, the \$30 billion of incentive payments distributed by the government under the HITECH Act from 2010–2014 succeeded in achieving the first step – nearly all hospitals and 90% of physician offices now use an EHR. While we see sporadic examples of activities under Steps 2, 3, and even 4, they are by far the exception.

As we look beyond the present, let's fantasize about a future in world in which we have substantially accomplished all four steps. What might our

healthcare system look like? The answer is that the experience of being both patient and healthcare professional will be far more satisfying.

Let's turn first to the hospital. Much of the care that we currently think of as requiring hospitalization will undoubtedly be accomplished within less expensive settings (including the patient's home), aided by a variety of technologies ranging from clinical sensors to advanced audio and video capabilities. The hospital will mostly exist to care for very sick patients – the types we might today associate with being in the ICU. And the ICU will likely no longer be a walled off physical space. Rather, every hospital bed will be modular, capable of supporting ICU level care with the push of a few buttons.

Decision-making about who needs higher levels of care will not be left to the clinician's "eyeball test." Instead, clinicians' experience will be augmented by sophisticated AI-based prediction tools constantly humming in the background, alerting doctors and nurses that, say, a patient's probability of death just spiked up and thus she bears closer watching. Of course, taking advantage of all these AI-generated predictions will require cracking the tough nut of alert fatigue. This will be accomplished by markedly decreasing false positive rates, implementing advanced data visualization and other prioritization methods, and likely through the discovery of approaches that haven't yet been invented.

Patient rooms will have large video screens and sophisticated camera and audio equipment to allow for tele-visits. Patients and families will be able to review clinicians' notes, test results, and treatment recommendations, either on the big screen or on their hospital-issued tablet computer. Patients will not only have full access to their EHR but will also receive educational materials ("here's what to expect from your MRI tonight") and motivation ("Good job on your incentive spirometer today!") – provided by the technology. The dreaded nurse call button will be replaced by a voice-activated system in which a patient's request results in a nurse appearing on screen and even taking some actions (increasing the IV flow rate or adjusting

the bed, for example) remotely. If a new pill is needed, likely as not a robot will deliver it.

When the hospital doctor comes to visit the patient, the room's telemedicine capabilities will allow additional parties to participate. For example, a palliative care discussion can involve distant family members, the inpatient palliative care team, and a physician at an outside hospice. An infectious disease consult might involve a discussion between the patient, the hospitalist, and the ID consultant in real time, rather than the serial visits and imperfect communication through chart notes that marks current practice.

Speaking of notes, in both inpatient and outpatient settings physicians will no longer spend hours typing notes into the EHR. Rather, natural language processing technology will "listen" to the doctor-patient conversation via room-based microphones and create a useful note, improving itself over time as it learns each physician's individual practice style and patient population ("digital scribes"). Documentation will increasingly become the byproduct of the doctor-patient encounter, not a central focus on the physician's attention.

On the other hand, clinicians will glean far more useful information and insights from their digital tools, including the EHR. As data are entered into the patient's chart, the EHR will suggest possible diagnoses and testing approaches, and guidelines and recommended treatment approaches will be a click or a voice command away. In essence, the EHR and the electronic textbook will merge into one integrated tool.

Turning to the outpatient arena, much of the care that currently requires in-person visits will be conducted via IT-enabled home care and televisits. The care of patients with chronic diseases will be utterly transformed, with a far greater emphasis on real-time, home-based, technology-enabled decision support and disease management. The heart failure patient will begin his day by weighing himself on a digital scale and answering a few questions on the computer ("How is your breathing? How did you sleep?"). It might even know how much salt

he used in the past day (through the "Internet of Things"). The technology will integrate this information, along with streaming data on heart rate and blood pressure drawn from wearable or stick-on sensors, to offer recommendations for drug and activity adjustments. Ditto for patients with diabetes, emphysema, asthma, and the like.

Making all of this function will require a new workflow, and with it a new set of health-care professionals. Sometimes called "care traffic controllers," they will be clinicians (likely nurses with advanced training in population health and some informatics) who will monitor, via advanced digital dashboards, the status of 100, or 1000 such patients, contacting and coaching the ones who seem to be having problems. The initial contacts may be generated by AI-driven algorithms and delivered by the technology, but the care traffic controller will intervene if the patient continues to have problems. For patients continuing to do poorly, a physician will become engaged. Even then, many of these encounters will be IT-enabled remote ones.

For patients with acute medical issues, much of the care will be delivered by apps, which will also offer AI-derived recommendations for simple diagnoses and interventions. Patients who require higher levels of care will see a clinician through telemedicine or community-based urgent care. Urgent care clinics will be conveniently placed in supermarkets and pharmacies, and our eventual success in achieving complete interoperability – the patient's record always available via the cloud – will enhance the ability to view the relevant parts of the EHR and to record data that then becomes available to all subsequent practitioners.

The promise of precision medicine will finally be realized. For example, the guidelines for treating a 50-year old woman with high blood pressure or elevated cholesterol will become far more complex and customized, considering a variety of patient- and population-based risk factors and large amounts of genetic information. This same complexity also means that the clinician will depend on the computer to "know" all of these variables and

suggest the best approach. Rather than remembering the correct approach to hypercholesterolemia in middle-aged women (there will no longer be any one correct approach), the role of the clinician will become more about interpreting the computer's output (including intervening when it seems wrong), communicating the findings to the patient, and motivating the necessary behavioral change. Of course, this changed role will require a significant evolution in medical education.

In fact, the ability to analyze vast amounts of digital data will transform all clinical research. Rather than basing most of our treatment recommendations on small randomized clinical trials, many advances will come through analyses of actual clinical data, seeing which approaches are associated with better outcomes. Of course, this will require sophisticated adjustment for confounders, which should also be facilitated by the vast amounts of fully integrated digital clinical information. Individual healthcare systems will take advantage of these data as well, transforming themselves into so-called "learning healthcare systems" by mining their own data and experience to determine which approaches lead to the best outcomes.

The vision that I've described here is not around the corner – it is likely 10–15 years away. And achieving it will require not just the technology of a few large EHR vendors, but

also the contribution of companies, large and small, some built specifically to solve specific healthcare problems, others digital giants (the Apples, Googles, and Amazons of the world) taking advantage of their capabilities in areas like app development, supply chain, and AI to attack healthcare problems.

Importantly, in such a multidimensional digital world, success cannot come simply by buying pieces of technology, peeling off the bubble wrap, and dropping them into healthcare systems and workflows. It will be up to clinical informaticists to deeply understand the needs of patients, clinicians, families, and administrators, the complexities of the technologies, and the economic, regulatory, privacy, and often ethical context. Informatics professionals will be the ones making the clinical and business case for change, and working with both vendors and clinicians to ensure that these new approaches and technologies actually achieve their aims.

This is why the job of the clinician informaticist will remain highly secure for the foreseeable future. While the job of the informaticist will no longer be to implement a core enterprise EHR, he or she will be doing something more complex and likely more valuable: reimagining the work and the workflow to take advantage of evolving digital capabilities to improve healthcare value.

### Box 30.7 The Future of Biomedical Informatics from the Federal Government Perspective

*Patricia Flatley Brennan*

Advances in biomedical informatics, including computational bioinformatics, are essential to accelerating scientific discovery and assuring the health of society. Finally, after 40 years of promise, there is sufficient data and computing power to realize the visions of early biomedical informatics leaders that data-powered health could become a reality. Decades of slow but steady progress towards formalizing biomedical knowledge through effective use of language and messaging standards is now complemented by improvement in heuristics and algorithms that can translate those formalizations into actionable decisions. The attention of the field to key users has broadened to include basic science researchers and clinicians as well as patients and families.

As a major provider of health care services, as well as a key funder of health care services, supporter of biomedical and health related research, and guardian of key health quality initiatives, the United States federal government plays and will continue to play a significant role in advancing biomedical informatics over the next decade. Federal investment will lead to advances in data management and protection, new ways to draw knowledge out of health data, and delivery of better, accurate and complete health information at the point of need, anywhere. Perspectives of open science, ensuring economic advancement through research, and a recognition of the accountability of the government to the taxpayer are engendering a new commitment of openness and responsiveness to society.

The National Library of Medicine (NLM), one of the 27 institutes and centers at the National Institutes of Health, is key among the several federal agencies committed to ensuring the availability of high-quality data to characterize patient problems, account for health care resource expenditure and foster research driven by greater understanding of clinical phenomena. The NLM partners with other health relat-

ed divisions and agencies, including the Center for Disease Control and Prevention, the Center for Medicare and Medicaid, and the Agency for Health Care Research and Quality to rapidly respond to public health threats, monitor health care expenditures and quality and foster systemic interoperability. Partnerships between the NIH and with other federal agencies outside of the health sector will allow the investments in biomedical informatics to benefit from generalized investment in data curation, large scale data management and storage, privacy and network platforms.

The NLM will do for data what it has done for the literature – making them findable, accessible, interoperable and re-usable (FAIR). These attributes, linked under the rubric of the FAIR principles, provide guidance for how a federal library makes its resources available to the public. Making data FAIR requires improved curation strategies, ones that balance automated approaches with human indexing and metadata developments in a way that takes advantage of the speed of automation while preserving human talent for the most-complex cases. The Library-of-the-Future will continue to see the NLM serving as the custodian of key collections, but also increasing its reach as a connector of important information and data resources that exist outside of its boundaries. Future developments may also lead to a discovery-on-demand approach to locating and obtaining information that has not be previously archived. The NLM will invest in research that advances use of these important collections and provides novel methodologies to interrogate them.

Some agencies within the Department of Health and Human Services, such as the Office of the National Coordinator of Health Information Technology (ONC), will continue to invest in broad, societal resources to maintain the health information infrastructure. Other agencies, such as the Center for Medicare and Medicaid Services, will continue to be both data consumers (payment schemes resting on claims for health services) as well as data contributors, making their information accessible to consumers for enhanced self-monitoring and to

researchers to foster discovery informed by care. Several trans-federal initiatives are on the horizon, designed to ensure efficient investment in scalable, re-suable information resources.

The recognition across NIH of the importance linking clinical information and biological data portends expanded investment in the methods for curating and integrating information across time within a person and across people to better understand the health of individuals and populations. Rapid growth of data from research taxes existing technical capabilities and demands additional policy development and financial investment to house important data resources. The federal government fosters policies that protect patient privacy and develop the incentive structures to accelerate the adoption of effective computer systems for health care. With the rapidly growing data generating initiatives, the federal government must take a critical role in determining how to best select and preserve the full range of information. The federal government will host public discussion and dialogs that ensure the clinical information is sufficiently broad to reflect the clinical experience of all persons. It is responsible for ensuring the cross-national arrangements needed to keep scientific exchange of health data open and free-flowing.

Interagency coordination is needed to ensure that technological advances benefit health care and that health dollars leverage investment made in other sectors. The primary point of coordination is through the Networking and Information Technology Research and Development (NITRD) Program. NITRD is a trans-agency initiative designed to provide the research and development foundations for advancing information technologies, and also to deploy those technologies in the service of the country. The NIH reports its technological research and development expenditures to the President through the NITRD program. The NIH broadly, and the NLM specifically, participate in the many workgroups that focus on broad ranging topics such as computing-enabled human interaction, communication and augmentation, cybersecurity and privacy, and high capability computing infrastructure and applications.

Federal resources should be spent on those things that only the federal government should do. These investments include short and long-term research and development programs that advance the health and well-being of society, educating the workforce of the future, and protecting key assets in perpetuity. Most of this investment is likely to occur through the NLM. In the biomedical informatics arena this means investing in research to develop method that are scalable, sustainable and reproducible, creating computational approaches to data management capable of curation at scale, developing the libraries of the future that not only encompass literature and data but also the interim product of research such as protocols, ethics and human subjects agreement, as well as novel methods of documenting research activities, such as the next generation of Jupyter notebooks. Development efforts should be applied to the ever-growing amount of text-based journal articles and reports, to devise new and creative ways to expose the literature to a variety of publics. Educational programs and efforts of the future will infuse data science and advanced biomedical informatics lessons not only in the training programs of specialists, but across the biomedical research and clinical training programs, and even extending into equipping patients and lay people with access to data and information and tools to make use of those resources.

It's worthy to note two very important trends that will shape the future of the federal engagement with health information technologies. First, there will be an increase in public private partnerships to leverage knowledge in the technical and information technology sector in support of health care. Such partnership should lead to a more robust and interoperative health information environment. Second, there will be certain roles that the federal government must preserve, such as maintaining accurate and freely-accessible information resources for the public good and overseeing the development of policies that foster data sharing while protecting individual and institutional rights.

Future federal efforts will be accompanied by collaborations with industry. These collaborations could take the form of joint investments in common problems, such as data quality or cura-

tion. Other forms of partnership may emerge that engage the federal investment for research and development with accelerated pathways for technology transfer. Including industrial members on Federal Advisory Committees will provide pathways for exchange of information.

The NLM will continue to play a leadership role in maintaining accurate and freely-accessible information resources. The NLM has taken a major step towards this by migrating all of our public facing information resources onto a common, sustainable technical platform. This migration will not only enhance efficiencies but also allow for increased interoperability across our resources. A common technical platform, coupled with enhancement of terminology and vocabulary systems, will make it more feasible for intended users to traverse the information resources housed here.

In the future there will be an increasing role of the federal government in protecting and preserving information in perpetuity. The enabling legislation of the NLM directs it to collect the medical knowledge of the time and store it permanently in ways that make it accessible for a wide range of users. As the largest funder of public health and health care, the federal government indirectly shapes what constitutes health information

and how it is used and valued. The federal government has two key levers for expanding the definition of what constitutes health: investing in research to demonstrate the consideration of health data, including social and behavioral predictors, on the impact of what constitutes health is a major contribution. Additionally, because of its role as a major funder of health care through the CMS, the federal government shapes what is considered of value in health care, such as research that finds ways to incorporate the social and behavioral predictors of health into routine data collection, and then to ensure the use of this information in the diagnostic, treatment and evaluation aspects of the health care process.

The future of biomedical informatics from the federal perspective is one characterized by openness, partnerships and perpetual storage of biomedical knowledge. A vibrant research program will be needed to develop and deploy the tools needed to accomplish this vision. Thoughtful deliberation is essential to protect the privacy rights of individuals while fostering the greatest degree of sharing of data and information needed to achieve the goals enabled by data driven discovery.

## Suggested Readings

Cimino, J. J. (2019). Putting the “why” in “EHR”: Capturing and coding clinical cognition. *Journal of the American Medical Informatics Association*, 26(11), 1379–1384. Cimino identifies fundamental changes that will be needed to correct the common criticisms of today’s electronic health records to transform them from glorified billing diaries into true electronic assistants.

Mesko, B. The Medical Futurist. <https://medicalfuturist.com/magazine> (accessed June 12, 2020). Mesko’s online magazine (and other postings on the Futurist’s web site) provides a glimpse of technologies that are currently emerging or envisioned for the future, in many cases leveraging innovations in biomedical engineering or biomedical informatics.

Topol, E. (2016). *The patient will see you now: The future of medicine is in your hands*. New York: Basic Books. Topol envisions the future world that follows today’s “Gutenberg moment.” Much as the printing press took learning out of the hands of a special class that had access to manuscripts, the Internet and modern computing devices are doing the same for medicine, giving individuals control over their own health care.

Wachter, R. (2017). *The digital doctor: Hope, hype, and harm at the dawn of medicine’s computer age*. New York: McGraw-Hill Education. Offers a thoughtful critique of today’s modern application of digital technologies in health care, identifying today’s limitations but emphasizing the promise for a greatly enhanced world for both patients and physicians.

## Questions for Discussion

1. How are the advances in bioinformatics likely to affect clinical care and vice versa?
2. Identify one potential setting for an informatics “living laboratory”. Who or

what is the subject of evaluation? How would you “instrument” the setting to measure activity and performance?

3. Identify one area for informatics education and describe the living laboratory that would support training objectives.

# Supplementary Information

**Glossary – 1018**

**Name Index – 1091**

**Subject Index – 1131**

## Glossary

---

**21st Century Cures Act** A comprehensive bill that promotes and funds the acceleration of research into preventing and curing serious illnesses; accelerates drug and medical device development; attempts to address the opioid abuse crisis; and tries to improve mental health service delivery. It also includes a health IT-related provisions on interoperability, data sharing/exchange and electronic health records.

**Abductive reasoning** Can be characterized as a cyclical process of generating possible explanations or a set of hypotheses that are able to account for the available data and then each of these hypotheses is evaluated on the basis of its potential consequences. In this regard, abductive reasoning is a data-driven process that relies heavily on the domain expertise of the person.

**Accountability** Security function that ensures users are responsible for their access to and use of information based on a documented need and right to know.

**Accountable care** A descendant of managed care, accountable care is an approach to improving care and reducing costs. See: Accountable Care Organizations.

**Accountable Care Organizations (ACOs)** An organization of health care providers that agrees to be accountable for the quality, cost, and overall care of their patients. An ACO will be reimbursed on the basis of managing the care of a population of patients and are determined by quality scores and reductions in total costs of care.

**ACO** See: Accountable Care Organizations.

**Active failures** Errors that occur in an acute situation, the effects of which are immediately felt.

**Active phase** The phase of a clinical research study during which investigators collect data

from participants receiving an intervention or interventions under study. It is also common to monitor study participants for adverse events during this phase.

**Active storage** In a hierarchical data-storage scheme, the devices used to store data that have long-term validity and that must be accessed rapidly.

**Acute Physiology and Chronic Health Evaluation, Version III [APACHE III]** A scoring system for rating the disease severity for particular use in intensive care units.

**Adaptive learning** Adapting the presentation of learning content in response to continuous assessment of the learner's performance.

**Address** An indicator of location; typically a number that refers to a specific position in a computer's memory or storage device; see also: Internet Address.

**ADE** See: Adverse Drug Events.

**Admission-discharge-transfer (ADT)** The core component of a hospital information system that maintains and updates the hospital census, including bed assignments of patients.

**ADT** See: Admission-discharge-transfer.

**Advanced Cardiac Life Support** A course to train providers on the procedure and set of clinical interventions for urgent treatment of cardiovascular emergencies.

**Advanced Research Projects Agency Network (ARPANET)** A large wide-area network created in the 1960s by the U.S. Department of Defense Advanced Research Projects Agency (DARPA) for the free exchange of information among universities and research organizations; the precursor to today's Internet.

**Advanced Trauma Life Support** A training program for medical providers for the management of acute trauma cases. ATLS is developed by the American College of Surgeons.

**Adverse drug events (ADEs)** Undesired patient events, whether expected or unexpected, that are attributed to administration of a drug.

**Aggregations** In the context of information retrieval, collections of content from a variety of content types, including bibliographic, full-text, and annotated material.

**AHIMA** See: American Health Information Management Association.

**Alert message** A computer-generated warning that is generated when a record meets pre-specified criteria, often referring to a potentially dangerous situation that may require action; e.g., receipt of a new laboratory test result with an abnormal value.

**Algorithmic process** An algorithm is a well-defined procedure or sequence of steps for solving a problem. A process that follows prescribed steps is accordingly an algorithmic process.

**Alphanumeric** Descriptor of data that are represented as a string of letters and numeric digits, without spaces or punctuation.

**Amazon Mechanical Turk** Amazon's crowdsourcing website for businesses or researchers (known as Requesters) that allows hiring of remotely located "crowdworkers" to perform discrete on-demand tasks that computers are currently unable to do.

**Ambulatory medical record system (AMRS)** A clinical information system designed to support all information requirements of an outpatient clinic, including registration, appointment scheduling, billing, order entry, results reporting, and clinical documentation.

**American Health Information Management Association (AHIMA)** Professional association devoted to the discipline of health information management (HIM).

**American Heart Association** A non-profit organization dedicated to improving heart health.

**American Immunization Registry Association (AIRA)** is a membership organization that exists to promote the development and implementation of immunization information systems (IIS) as an important tool in preventing and controlling vaccine-preventable diseases. ► <https://www.immregistries.org/about-aira>.

**American Medical Informatics Association (AMIA)** Professional association dedicated to biomedical and health informatics.

**American National Standards Institute [ANSI]** A private organization that oversees voluntary consensus standards.

**American Public Health Association (APHA)** Represents a broad array of health professionals and others who care about the health of all people and all communities. It is the leading not-for-profit public health organization in the U.S. and seeks to strengthen the impact of public health professionals and provides a science-based voice in policy debates. APHA seeks to advance prevention, reduce health disparities and promote wellness. ► <http://www.apha.org/>.

**American Recovery and Reinvestment Act of 2009** Public Law 111–5, commonly referred to as the Stimulus or Recovery Act, this legislation was designed to create jobs quickly and to invest in the nation's infrastructure, education and healthcare capabilities.

**American Standard Code for Information Interchange (ASCII)** A 7-bit code for representing alphanumeric characters and other symbols.

**AMIA** See: American Medical Informatics Association.

**AMRS** See: Ambulatory medical record systems.

**Analog signal** A signal that takes on a continuous range of values.

**Analog-to-digital conversion (ADC)** Conversion of sampled values from a continuous-valued signal to a discrete-valued digital representation.

**Anchoring and adjustment** A heuristic used when estimating probability, in which a person first makes a rough approximation (the anchor), then adjusts this estimate to account for additional information.

**Annotated content** In the context of information retrieval, content that has been annotated to describe its type, subject matter, and other attributes.

**Anonymize** Applied to health data and information about a unique individual, the act of de-identifying or stripping away any and all data which could be used to identify that individual.

**ANSI** See: American National Standards Institute.

**Antibiogram** Pattern of sensitivity of a microorganism to various antibiotics.

**APACHE III** See Acute Physiology and Chronic Health Evaluation, Version III.

**Apache Open source** Web server software that was significant in facilitating the initial growth of the World Wide Web.

**Applets** Small computer programs that can be embedded in an HTML document and that will execute on the user's computer when referenced.

**Application program** A computer program that automates routine operations that store and organize data, perform analyses, facili-

tate the integration and communication of information, perform bookkeeping functions, monitor patient status, aid in education.

**Application programming interface (API)** A specification that enables distinct software modules or components to communicate with each other.

**Applications (applied) research** Systematic investigation or experimentation with the goal of applying knowledge to achieve practical ends.

**Apps** Software applications, especially ones downloaded to mobile devices.

**Archival storage** In a hierarchical data-storage scheme, the devices used to store data for long-term backup, documentary, or legal purposes.

**Arden Syntax for Medical Logic Module** A coding scheme or language that provides a canonical means for writing rules that relate specific patient situations to appropriate actions for practitioners to follow. The Arden Syntax standard is maintained by HL7.

**Argument** A word or phrase that helps complete the meaning of a predicate.

**ARPANET** See Advanced Research Projects Agency Network.

**Artificial intelligence (AI)** The branch of computer science concerned with endowing computers with the ability to simulate intelligent human behavior.

**Artificial neural network** A computer program that performs classification by taking as input a set of findings that describe a given situation, propagating calculated weights through a network of several layers of interconnected nodes, and generating as output a set of numbers, where each output corresponds to the likelihood of a particular classification that could explain the findings.

**ASCII** See: American Standard Code for Information Interchange.

**Assembler** A computer program that translates assembly-language programs into machine-language instructions.

**Assembly language** A low-level language for writing computer programs using symbolic names and addresses within the computer's memory.

**Association of American Medical Colleges (AAMC)** A non-profit organization that includes all US and Canadian medical colleges and many teaching hospitals, and supports them in their education and research mission.

**Asynchronous Transfer Mode (ATM)** A network protocol designed for sending streams of small, fixed length cells of information over very high-speed, dedicated connections, often digital optical circuits.

**Audit trail** A chronological record of all accesses and changes to data records, often used to promote accountability for use of, and access to, medical data.

**Augmented reality** Imposition of synthetic three-dimensional and text information on top of a view of the real world seen through specialized glasses worn by the learner.

**Authenticated** A process for positive and unique identification of users, implemented to control system access.

**Authorized** Within a system, a process for limiting user activities only to actions defined as appropriate based on the user's role.

**Automated indexing** The most common method of full-text indexing; words in a document are stripped of common suffixes, entered as items in the index, then assigned weights based on their ability to discriminate among documents (see vector-space model).

**Availability** In decision making, a heuristic method by which a person estimates the probability of an event based on the ease with which he can recall similar events. In security systems, a function that ensures delivery of accurate and up-to-date information to authorized users when needed.

**Averaging out at chance nodes** The process by which each chance node of a decision tree is replaced in the tree by the expected value of the event that it represents.

**Backbone links** Sections of high-capacity trunk (backbone) network that interconnect regional and local networks.

**Backbone Network** A high-speed communication network that carries major traffic between smaller networks.

**Background question** A question that asks for general information on a topic (see also: foreground question).

**Backward chaining** Also known as goal-directed reasoning. A form of inference used in rule-based systems in which the inference engine determines whether the premise (left-hand side) of a given rule is true by invoking other rules that can conclude the values of variables that currently are unknown and that are referenced in the premise of the given rule. The process continues recursively until all rules that can supply the required values have been considered.

**Bag-of-words** A language model where text is represented as a collection of words, independent of each other and disregarding word order.

**Bandwidth** The capacity for information transmission; the number of bits that can be transmitted per unit of time.

**Baseline rate: population** The prevalence of the condition under consideration in the population from which the subject was selected; individual: The frequency, rate, or degree of a condition before an intervention or other perturbation.

**Basic Local Alignment Search Tool (BLAST)** An algorithm for determining optimal genetic sequence alignments based on the observations that sections of proteins are often conserved without gaps and that there are statistical analyses of the occurrence of small subsequences within larger sequences that can be used to prune the search for matching sequences in a large database.

**Basic research** Systematic investigation or experimentation with the goal of discovering new knowledge, often by proposing new generalizations from the results of several experiments.

**Basic science** The enterprise of performing basic research.

**Bayes' theorem** An algebraic expression often used in clinical diagnosis for calculating post-test probability of a condition (a disease, for example) if the pretest probability. (prevalence) of the condition, as well as the sensitivity and specificity of the test, are known (also called Bayes' rule). Bayes' theorem also has broad applicability in other areas of biomedical informatics where probabilistic inference is pertinent, including the interpretation of data in bioinformatics.

**Bayesian diagnosis program** A computer-based system that uses Bayes' theorem to assist a user in developing and refining a differential diagnosis.

**Before-after study (aka Historically controlled study)** A study in which the evaluator attempts to draw conclusions by comparing measures made during a baseline period prior to the information resource being available and measures made after it has been implemented.

**Behaviorism** A social science framework for analyzing and modifying behavior.

**Belief network** A diagrammatic representation used to perform probabilistic inference; an influence diagram that has only chance nodes.

**Best of breed** An information technology strategy that favors the selection of individual applications based on their specific functionality rather than a single application that integrates a variety of functions.

**Best of cluster** Best of cluster became a variant of the "best of breed" strategy by selecting a single vendor for a group of similar departmental systems, such laboratory, pharmacy and radiology.

**Bibliographic content** In information retrieval, information abstracted from the original source.

**Bibliographic database** A collection of citations or pointers to the published literature.

**Binary** The condition of having only two values or alternatives.

**Biobank** A repository for biological materials that collects, processes, stores, and distributes biospecimens (usually human) for use in research.

**Biocomputation** The field encompassing the modeling and simulation of tissue, cell, and genetic behavior; see biomedical computing.

**Bioinformatics** The study of how information is represented and transmitted in biological systems, starting at the molecular level.

**Biomarker** A characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.

**Biomed Central** An independent publishing house specializing in the publication of electronic journals in biomedicine (see ► [www.biomedcentral.com](http://www.biomedcentral.com)).

**Biomedical computing** The use of computers in biology or medicine.

**Biomedical engineering** An area of engineering concerned primarily with the research and

development of biomedical instrumentation and biomedical devices.

**Biomedical informatics** The interdisciplinary field that studies and pursues the effective uses of biomedical data, information, and knowledge for scientific inquiry, problem solving, and decision making, driven by efforts to improve human health.

**Biomedical Information Science and Technology Initiative (BISTI)** An initiative launched by the NIH in 2000 to make optimal use of computer science, mathematics, and technology to address problems in biology and medicine. It includes a consortium of senior-level representatives from each of the NIH institutes and centers plus representatives of other Federal agencies concerned with biocomputing. See: ► <http://www.bisti.nih.gov>.

**Biomedical taxonomy** A formal system for naming entities in biomedicine.

**Biomolecular imaging** A discipline at the intersection of molecular biology and *in vivo* imaging, it enables the visualisation of cellular function and the follow-up of the molecular processes in living organisms without perturbing them.

**Biopsychosocial model** A model of medical care that emphasizes not only an understanding of disease processes, but also the psychological and social conditions of the patient that affect both the disease and its therapy.

**Biosample** Biological source material used in experimental assays.

**Biosurveillance** A public health activity that monitors a population for occurrence of a rare disease or increased occurrence of a common one. Also see Public Health Surveillance and Surveillance.

**Bit** The logical atomic element for all digital computers.

**Bit depth** The number of bits that represent an individual pixel in an image; the more bits, the more intensities or colors can be represented.

**Bit rate** The rate of information transfer; a function of the rate at which signals can be transmitted and the efficacy with which digital information is encoded in the signal.

**BLAST** See: Basic Local Alignment Search Tool.

**Blinding** In the context of clinical research, blinding refers to the process of obfuscating from the participant and/or investigator what study intervention a given participant is receiving. This is commonly done to reduce study biases.

**Blog** A type of Web site that provides discussion or information on specific topics.

**Blue Button** A feature of the Veteran Administration's VistA system that exports an entire patient's record in electronic form.

**Bluetooth** A standard for the short-range wireless interconnection of mobile phones, computers, and other electronic devices.

**Body** The portion of a simple electronic mail message that contains the free-text content of the message.

**Body of knowledge** An information resource that encapsulates the knowledge of a field or discipline.

**Boolean operators** The mathematical operators and, or, and not, which are used to combine index terms in information retrieval searching.

**Boolean searching** A search method in which search criteria are logically combined using and, or, and not operators.

**Bootstrap** A small set of initial instructions that is stored in read-only memory and executed each time a computer is turned on.

Execution of the bootstrap is called booting the computer. By analogy, the process of starting larger computer systems.

**Bottom-up** An algorithm for analyzing small pieces of a problem and building them up into larger components.

**Bound morpheme** A morpheme that creates a different form of a word but must always occur with another morpheme (*e.g.*, *-ed*, *-s*).

**B-pref** A method for measuring retrieval performance in which documents without relevance judgments are excluded.

**Bridge** A device that links or routes signals from one network to another.

**Broadband** A data-transmission technique in which multiple signals may be transmitted simultaneously, each modulated within an assigned frequency range.

**Browsing** Scanning a database, a list of files, or the Internet, either for a particular item or for anything that seems to be of interest.

**Bundled payments** In the healthcare context, refers to the practice of reimbursing providers based on the total expected costs of a particular episode of care. Generally occupies a “middle ground” between fee-for-service and capitation mechanisms.

**Business logic layer** A conceptual level of system architecture that insulates the applications and processing components from the underlying data and the user interfaces that access the data.

**Buttons** Graphic elements within a dialog box or user-selectable areas within an HTML document that, when activated, perform a specified function (such as invoking other HTML documents and services).

**C statistic** The area under an receiver operating characteristic (ROC) curve.

**CAD** See: Computer-aided diagnosis.

**Cadaver** An embalmed human body used for teaching anatomy through the process of dissecting tissue.

**Canonical form** A preferred string or name for a term or collection of names; the canonical form may be determined by a set of rules (*e.g.*, “all capital letters with words sorted in alphabetical order”) or may be simply chosen arbitrarily.

**Capitated payments** System of health-care reimbursement in which providers are paid a fixed amount per patient to take care of all the health-needs of a population of patients.

**Capitation** Payments to providers, typically on an annual basis, in return for which the clinicians provide all necessary care for the patient and do not submit additional fee-for-service bills.

**Cardiac output** A measure of blood volume pumped out of the left or right ventricle of the heart, expressed as liters per minute.

**Care coordinator** See: Case Manager.

**Care plan** A document that provides direction for individualized patient care.

**Cascading finite state automata (FSA)** A tagging method in natural language processing in which a series of finite state automata are employed such that the output of one FSA becomes the input for another.

**Case** Refers to the capitalization of letters in a word.

**Case manager** A person in charge of coordinating all aspects of a patient’s care.

**CCD** See: Continuity of Care Document.

**CCOW** See: Clinical Context Object Workgroup.

**CDC** See Centers for Disease Control and Prevention.

**CDE** See Common Data Element.

**CDR** See: Clinical data repository.

**CDS Hooks** A technical approach designed to invoke external CDS services from within the EHR workflow based upon a triggering event. Services may be in the form of (a) *information cards* – provide text for the user to read; (b) *suggestion cards* – provide a specific suggestion for which the EHR renders a button that the user can click to accept, with subsequent population of the change into the EHR user interface; and (c) *app link cards* – provide a link to an app.

**CDSS** See: Clinical decision-support system.

**CDW** See: Clinical data warehouse.

**Cellular imaging** Imaging methods that visualize cells.

**Center for Medicare & Medicaid Services** The Center for Medicare & Medicaid Services (CMS) is a federal agency within the United States Department of Health and Human Services that administers the Medicare program and works in partnership with state governments to administer Medicaid, the Children's Health Insurance Program, and health insurance portability standards. In addition to these programs, CMS has other responsibilities, including the administrative simplification standards from the Health Insurance Portability and Accountability Act of 1996 (HIPAA).

**Centering theory** A theory that attempts to explain what entities are indicated by referential expressions (such as pronouns) by noting how the center (focus of attention) of each sentence changes across the text.

**Centers for Disease Control and Prevention (CDC)** An agency within the US Department of Health and Human Services that provides the public with health information and promotes health through partnerships with state health departments and other organizations.

**Central computer system** A single system that handles all computer applications in an insti-

tution using a common set of databases and interfaces.

**Central processing unit (CPU)** The “brain” of the computer. The CPU executes a program stored in main memory by fetching and executing instructions in the program.

**Central Test Node (CTN)** DICOM software to foster cooperative demonstrations by the medical imaging vendors.

**Certificate** Coded authorization information that can be verified by a certification authority to grant system access.

**Challenge evaluation** An evaluation of information systems, often in the field of information retrieval or related areas, that provides a public test collection or gold standard data collection for various researchers to compare and analyze results.

**Chance node** A symbol that represents a chance event. By convention, a chance node is indicated in a decision tree by a circle.

**Character sets and encodings** Tables of numeric values that correspond to sets of printable or displayable characters. ASCII is one example of such an encoding.

**Chart parsing** A dynamic programming algorithm for structuring a sentence according to grammar by saving and reusing segments of the sentence that have been parsed.

**Chat** A synchronous mode of text-based communication.

**Check tags** In MeSH, terms that represent certain facets of medical studies, such as age, gender, human or nonhuman, and type of grant support; check tags provide additional indexing of bibliographic citations in databases such as Medline.

**CHI** See: Consumer health informatics.

**CHIN** See: Community Health Information Network.

**Chunking** A natural language processing method for determining non-recursive phrases where each phrase corresponds to a specific part of speech.

**CINAHL (or CINHL)** See: Cumulative Index to Nursing and Allied Health Literature.

**CINAHL Subject Headings** A set of terms based on MeSH, with additional domain-specific terms added, used for indexing the Cumulative Index to Nursing and Allied Health Literature (CINAHL).

**CIS** See: Clinical information system.

**Citation database** A database of citations found in scientific articles, showing the linkages among articles in the scientific literature.

**Classification** In image processing, the categorization of segmented regions of an image based on the values of measured parameters, such as area and intensity.

**Classroom Technologies** All technology used in a classroom setting including projection of two-dimensional slides or views of three-dimensional objects, electronic markup of a screen presentation, real time feedback systems such as class polling, and digital recording of a class session.

**CLIA certification** See: Clinical Laboratory Improvement Amendments of 1988 Certification.

**Client-server** Information processing interaction that distributes application processing between a local computer (the client) and a remote computer resource (the server).

**Clinical and translational research** A broad spectrum of research activities involving the translation of findings from initial laboratory-based studies into early-stage clinical studies, and subsequently, from the findings of those studies in clinical and/or population-level practice. This broad area incorporates

multiple biomedical informatics sub-domains, including both translational bioinformatics and clinical research informatics.

**Clinical Context Object Workgroup (CCOW)** A common protocol for single sign-on implementations in health care. It allows multiple applications to be linked together, so the end user only logs in and selects a patient in one application, and those actions propagate to the other applications.

**Clinical data repository (CDR)** Clinical database optimized for storage and retrieval for individual patients and used to support patient care and daily operations.

**Clinical data warehouse (CDW)** A database of clinical data obtained from primary sources such as electron health records, organized for re-use for secondary purposes.

**Clinical datum** Replaces medical datum with same definition.

**Clinical decision support** Any process that provides health-care workers and patients with situation-specific knowledge that can inform their decisions regarding health and health care.

**Clinical decision-support system (CDSS)** A computer-based system that assists physicians in making decisions about patient care.

**Clinical Document Architecture** An HL7 standard for naming and structuring clinical documents, such as reports.

**Clinical expert system** A computer program designed to provide decision support for diagnosis or therapy planning at a level of sophistication that an expert physician might provide.

**Clinical guidelines** Systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances.

**Clinical informatics** The application of biomedical informatics methods in the patient-care domain; a combination of computer science, information science, and clinical science designed to assist in the management and processing of clinical data, information, and knowledge to support clinical practice.

**Clinical information system (CIS)** The components of a health-care information system designed to support the delivery of patient care, including order communications, results reporting, care planning, and clinical documentation.

**Clinical judgment** Decision making by clinicians that incorporates professional experience and social, ethical, psychological, financial, and other factors in addition to the objective medical data.

**Clinical Laboratory Improvement Amendments of 1988 certification** Clinical Laboratory Improvement Amendments of 1988, establishing laboratory testing quality standards to ensure the accuracy, reliability and timeliness of patient test results, regardless of where the test was performed.

**Clinical modifications** A published set of changes to the International Classification of Diseases (ICD) that provides additional levels of detail necessary for statistical reporting in the United States.

**Clinical pathway** Disease-specific plan that identifies clinical goals, interventions, and expected outcomes by time period.

**Clinical Quality Language** An expression language standardized by HL7 that is used to characterize both quality measure logic and decision-support logic.

**Clinical research** The range of studies and trials in human subjects that fall into the three sub-categories: (1) Patient-oriented research: Research conducted with human subjects (or on material of human origin such as tissues, specimens and cognitive phenomena) for which an investigator (or colleague) directly

interacts with human subjects. Patient-oriented research includes: (a) mechanisms of human disease; (b) therapeutic interventions; (c) clinical trial; and (d) development of new technologies. (2) Epidemiologic and behavioral studies. (3) Outcomes research and health services research.

**Clinical research informatics (CRI)** The application of biomedical informatics methods in the clinical research domain to support all aspects of clinical research, from hypothesis generation, through study design, study execution and data collection, data analysis, and dissemination of results.

**Clinical Research Management System (CRMS)** A clinical research management system is a technology platform that supports and enables the conduct of clinical research, including clinical trials, usually through a combination of functional modules targeting the preparatory, enrollment, active, and dissemination phases of such research programs. CRMS systems are often also referred to as Clinical Trials Management Systems (CTMS), particularly when they are used to manage only clinical trials rather than various types of clinical research.

**Clinical subgroup** A subset of a population in which the members have similar characteristics and symptoms, and therefore similar likelihood of disease.

**Clinical trials** Research projects that involve the direct management of patients and are generally aimed at determining optimal modes of therapy, evaluation, or other interventions.

**Clinical-event monitors** Systems that electronically and automatically record the occurrence or changes of specific clinical events, such as blood pressure, respiratory capability, or heart rhythms.

**Clinically relevant population** The population of patients that is seen in actual practice. In the context of estimating the sensitivity and specificity of a diagnostic test, that group of patients in whom the test actually will be used.

**Closed loop** Regulation of a physiological variable, such as blood pressure, by monitoring the value of the variable and altering therapy without human intervention.

**Closed loop medication management system** A workflow process (typically supported electronically) through which medications are ordered electronically by a physician, filled by the pharmacy, delivered to the patient, administered by a nurse, and subsequently monitored for effectiveness by the physician.

**Cloud technology or computing** Cloud computing is using computing resources located in a remote location. Typically, cloud computing is provided by a separate business, and the user pays for it on per usage basis. There are variations such as private clouds, where the “cloud” is provided by the same business, but leverages methods that permit easier virtualization and expandability than traditional methods. Private clouds are popular with healthcare because of security concerns with public cloud computing.

**Clustering algorithms** A method which assigns a set of objects into groups (called clusters) so that the objects in the same cluster are more similar (in some sense or another) to each other than to those in other clusters.

**CMS** See: Center for Medicare and Medicaid Services.

**Coaching system** An intelligent tutoring system that monitors the session and intervenes only when the student requests help or makes serious mistakes.

**Cocke-Younger-Kasami (CYK)** A dynamic programming method that uses bottom-up rules for parsing grammar-free text; used only in conjunction with a grammar written in Chomsky normal form.

**Code** As a verb, to write a program. As a noun, the program itself.

**Cognitive artifacts** human-made materials, devices, and systems that extend people’s

abilities in perceiving objects, encoding and retrieving information from memory, and problem-solving.

**Cognitive engineering** An interdisciplinary approach to the development of principles, methods and tools to assess and guide the design of computerized systems to support human performance.

**Cognitive heuristics** Mental processes by which we learn, recall, or process information; rules of thumb.

**Cognitive Informatics (CI)** is an interdisciplinary field consisting of cognitive and information sciences, specifically focusing on human information processing, mechanisms and processes within the context of computing and computer applications. The focus of CI is on understanding work processes and activities within the context of human cognition and the design of interventional solutions (often engineering, computing and information technology solutions).

**Cognitive load** An excess of information that competes for few cognitive resources, creating a burden on working memory.

**Cognitive science** Area of research concerned with studying the processes by which people think and behave.

**Cognitive task analysis** The analysis of both the information-processing demands of a task and the kinds of domain-specific knowledge required performing it, used to study human performance.

**Cognitive walkthrough (CW)** An analytic method for characterizing the cognitive processes of users performing a task. The method is performed by an analyst or group of analysts “walking through” the sequence of actions necessary to achieve a goal, thereby seeking to identify potential usability problems that may impede the successful completion of a task or introduce complexity in a way that may frustrate users.

**Collaborative workspace** A virtual environment in which multiple participants can interact, synchronously or asynchronously, to perform a collaborative task.

**Color resolution** A measure of the ability to distinguish among different colors (indicated in a digital image by the number of bits per pixel). Three sets of multiple bits are required to specify the intensity of red, green, and blue components of each pixel color.

**Commodity internet** A general-purpose connection to the Internet, not configured for any particular purpose.

**Common Data Elements (CDEs)** Standards for data that stipulate the methods by which the data are collected and the controlled terminologies used to represent them. Many standard sets of CDEs have been developed, often overlapping in nature.

**Communication** Data transmission and information exchange between computers using accepted protocols via an exchange medium such as a telephone line or fiber optic cable.

**Community Health Information Network (CHIN)** A computer network developed for exchange of sharable health information among independent participant organizations in a geographic area (or community).

**Comparative effectiveness research** A form of clinical research that compares examines outcomes of two or more interventions to determine if one is statistically superior to another.

**Compiler** A program that translates a program written in a high-level programming language to a machine-language program, which can then be executed.

**Comprehensibility and control** Security function that ensures that data owners and data stewards have effective control over information confidentiality and access.

**Computational biology** The science of computer-based mathematical and statistical tech-

niques to analyze biological systems. See also bioinformatics.

**Computed check** A procedure applied to entered data that detects errors based on whether values have the correct mathematical relationship; (e.g., white blood cell differential counts, reported as percentages, must sum to 100).

**Computed tomography (CT)** An imaging modality in which X rays are projected through the body from multiple angles and the resultant absorption values are analyzed by a computer to produce cross-sectional slices.

**Computer architecture** The basic structure of a computer, including memory organization, a scheme for encoding data and instructions, and control mechanisms for performing computing operations.

**Computer memories** Store programs and data that are being used actively by a CPU.

**Computer program** A set of instructions that tells a computer which mathematical and logical operations to perform.

**Computer simulated patient** See Virtual patient.

**Computer-aided diagnosis (CAD)** Any form of diagnosis in which a computer program helps suggest or rank diagnostic considerations.

**Computer-based (or computerized) physician order entry (CPOE)** A clinical information system that allows physicians and other clinicians to record patient-specific orders for communication to other patient care team members and to other information systems (such as test orders to laboratory systems or medication orders to pharmacy systems). Sometimes called provider order entry or practitioner order entry to emphasize such systems' uses by clinicians other than physicians.

**Computer-based patient records (CPRs)** An early name for electronic health records (EHRs) dating to the early 1990s.

**Concept** A unit of thought made explicit through the representation of properties of an object or a set of common objects. An abstract idea generalized from specific instances of objects that occur in the world.

**Conceptual graph** A formal notation in which knowledge is represented through explicit relationships between concepts. Graphs can be depicted with diagrams consisting of shapes and arrows, or in a text format.

**Conceptual knowledge** Knowledge about concepts.

**Concordant test results** Test results that reflect the true patient state (true-positive and true-negative results).

**Conditional probability** The probability of an event, contingent on the occurrence of another event.

**Conditionally independent** Two events, A and B, are conditionally independent if the occurrence of one does not influence the probability of the occurrence of the other, when both events are conditioned on a third event C. Thus,  $p[A | B, C] = p[A | C]$  and  $p[B | A, C] = p[B | C]$ . The conditional probability of two conditionally independent events both occurring is the product of the individual conditional probabilities:  $p[A, B | C] = p[A | C] \times p[B | C]$ . For example, two tests for a disease are conditionally independent when the probability of the result of the second test does not depend on the result of the first test, given the disease state. For the case in which disease is present,  $p[\text{second test positive} | \text{first test positive and disease present}] = p[\text{second test positive} | \text{first test negative and disease present}] = p[\text{second test positive} | \text{disease present}]$ . More succinctly, the tests are conditionally independent if the sensitivity and specificity of one test do not depend on the result of the other test (See independent).

**Conditioned event** A chance event, the probability of which is affected by another chance event (the conditioning event).

**Conditioning event** A chance event that affects the probability of occurrence of another chance event (the conditioned event).

**Confidentiality** The ability of data owners and data stewards to control access to or release of private information.

**Consistency check** A procedure applied to entered data that detects errors based on internal inconsistencies; e.g., recognizing a problem with the recording of cancer of the prostate as the diagnosis for a female patient.

**Constructivism** Argues that humans generate knowledge and meaning from an interaction between their experiences and their ideas.

**Constructivist** Argues that humans generate knowledge and meaning from an interaction between their experiences and their ideas.

**Consumer health informatics (CHI)** Applications of medical informatics technologies that focus on patients or healthy individuals as the primary users.

**Content** In information retrieval, media developed to communicate information or knowledge.

**Content based image retrieval** Also known as query by image content (QBIC) and content-based visual information retrieval (CBVIR) is the application of computer vision techniques to the image retrieval problem, that is, the problem of searching for digital images in large databases.

**Context free grammar** A mathematical model of a set of strings whose members are defined as capable of being generated from a starting symbol, using rules in which a single symbol is expanded into one or more symbols.

**Contingency table** A  $2 \times 2$  table that shows the relative frequencies of true-positive, true-negative, false-positive, and false-negative results.

**Continuity of care** The coordination of care received by a patient over time and across multiple healthcare providers.

**Continuity of Care Document (CCD)** An HL7 standard that enables specification of the patient data that relate to one or more encounters with the healthcare system. The CCD is used for interchange of patient information (e.g., within Health Information Exchanges). The format enables all the electronic information about a patient to be aggregated within a standardized data structure that can be parsed and interpreted by a variety of information systems.

**Continuous glucose monitor (CGM)** A device that automatically tracks a diabetic patient's blood glucose levels throughout the day and night using a tiny sensor inserted under the skin.

**Continuum of care** The full spectrum of health services provided to patients, including health maintenance, primary care, acute care, critical care, rehabilitation, home care, skilled nursing care, and hospice care.

**Contract-management system** A computer system used to support managed-care contracting by estimating the costs and payments associated with potential contract terms and by comparing actual with expected payments based on contract terms.

**Contrast** The difference in light intensity between dark and light areas of an image.

**Contrast resolution** A metric for how well an imaging modality can distinguish small differences in signal intensity in different regions of the image.

**Control intervention** In the context of clinical research, a control intervention represents the intervention (e.g. placebo, standard care, etc.) given to the group of study par-

ticipants assigned to the control or comparator arm of a study. Depending on the study type, the goal is to generate data as the basis of comparison with the experimental intervention of interest in order to determine the safety, efficacy, or benefits of an experimental intervention.

**Controlled terminology** A finite, enumerated set of terms intended to convey information unambiguously.

**Copyright law** Protection of written materials and intellectual property from being copied verbatim.

**Coreference chains** Provide a compact representation for encoding the words and phrases in a text that all refer to the same entity.

**Coreference resolution** In natural language processing, the assignment of specific meaning to some indirect reference.

**Correctional Telehealth** The application of telehealth to the care of prison inmates, where physical delivery of the patient to the practitioner is impractical.

**Covered entities** Under the HIPAA Privacy Rule, a covered entity is an organization or individual that handles personal health information. Covered entities include providers, health plans, and clearinghouses.

**COVID-19** A disease that was identified in late 2019 and was declared a global pandemic on March 11, 2020. COVID-19 became an international public health emergency, affecting essentially all countries on the planet. It is characterized by contagion before symptoms, high rate of transmission between human beings, variable severity among affected individuals, and relatively high mortality rate.

**CPOE** See: Computer-based (or Computerized) Physician (or Provider) Order Entry.

**CPR (or CPRS)** See: Computer-based patient records.

**CPU** See: Central processing unit.

**CRI** See: Clinical research informatics.

**CRMS (or CRDMS)** See: Clinical Research Management System.

**Cryptographic encoding** Scheme for protecting data through authentication and authorization controls based on use of keys for encrypting and decrypting information.

**CT (or CAT)** See: Computed tomography.

**Cumulative Index to Nursing and Allied Health Literature (CINHL)** A non-NLM bibliographic database that covers nursing and allied health literature, including physical therapy, occupational therapy, laboratory technology, health education, physician assistants, and medical records.

**Curly Braces Problem** The situation that arises in Arden Syntax where the code used to enumerate the variables required by a medical logic module (MLM) cannot describe how the variables actually derive their values from data in the EHR database. Each variable definition in an MLM has {curly braces} that enclose words in natural language that indicate the meaning of the corresponding variable. The particular database query required to supply a value for the variable must be specified by the local implementer, however. The curly braces problem makes it impossible for an MLM developed at one institution to operate at another without local modification.

**Cursor** A blinking region of a display monitor, or a symbol such as an arrow, that indicates the currently active position on the screen.

**Cybersecurity** Measures that seek to protect against the criminal or unauthorized use of electronic data.

**CYK** See: Cocke-Younger-Kasami.

**Dashboard** A user-interface element that displays data produced by several computer pro-

grams simultaneously and that allows users to interact with those programs in standardized ways.

**Data buses** An electronic pathway for transferring data—for instance, between a CPU and memory.

**Data capture** The process of collecting data to be stored in an information system; it includes entry by a person using a keyboard and collection of data from sensors.

**Data Encryption Standard (DES)** A widely-used method of securing encryption that uses a private (secret) key for encryption and requires the same key for decryption (see also, public key cryptography).

**Data independence** The insulation of applications programs from changes in data-storage structures and data-access strategies.

**Data layer** A conceptual level of system architecture that isolates the data collected and stored in the enterprise from the applications and user interfaces used to access those data.

**Data Recording** The documentation of information for archival or future use through mechanisms such as handwritten text, drawings, machine-generated traces, or photographic images.

**Data science** The field of study that uses analytic, quantitative, and domain expertise for knowledge discovery, typically using “big data” which could be structured and/or unstructured.

**Database** A collection of stored data—typically organized into fields, records, and files—and an associated description (schema).

**Database management system (DBMS)** An integrated set of programs that manages access to databases.

**Data-interchange standards** Adopted formats and protocols for exchange of data between independent computer systems.

**Datum** Any single observation of fact. A medical datum generally can be regarded as the value of a specific parameter (for example, *red-blood-cell count*) for a particular object (for example, a patient) at a given point in time.

**DBMIS** See: Database Management System.

**DCMI** See: Dublin Core Metadata Initiative.

**Debugger** A system program that provides traces, memory dumps, and other tools to assist programmers in locating and eliminating errors in their programs.

**Decision analysis** A methodology for making decisions by identifying alternatives and assessing them with regard to both the likelihood of possible outcomes and the costs and benefits of those outcomes.

**Decision node** A symbol that represents a choice among actions. By convention, a decision node is represented in a decision tree by a square.

**Decision support** The process of assisting humans in making decisions, such as interpreting clinical information or choosing a diagnostic or therapeutic action. See: Clinical Decision Support.

**Decision tree** A diagrammatic representation of the outcomes associated with chance events and voluntary actions.

**Deductive reasoning** is a process of reaching specific conclusions (e.g., a diagnosis) from a hypothesis or a set of hypotheses. Deductive logic helps in building up the consequences of each hypothesis, and this kind of reasoning is customarily regarded as a common way of evaluating diagnostic hypotheses.

**De-duplicate/Deduplication** The process that matches, links, and or merges data to eliminate redundancies.

**De-identified aggregate data** Data reports that are summarized or altered slightly in a way that makes the discernment of the identity of any of the individuals whose data was used for the report impossible or so difficult as to be extremely improbable. The process of de-identifying aggregate data is known as statistical disclosure control.

**Delta check** A procedure applied to entered data that detects large and unlikely differences between the values of a new result and of the previous observations; e.g., a recorded weight that changes by 100 lb in 2 weeks.

**Demonstration study** Study that establishes a relation—which may be associational or causal—between a set of measured variables.

**Dental informatics** The application of biomedical informatics methods and techniques to problems derived from the field of dentistry. Viewed as a subarea of clinical informatics.

**Deoxyribonucleic acid (DNA)** The genetic material that is the basis for heredity. DNA is a long polymer chemical made of four basic subunits. The sequence in which these subunits occur in the polymer distinguishes one DNA molecule from another and in turn directs a cell's production of proteins and all other basic cellular processes.

**Department of Health and Human Services (DHSS)** that provides the public with health information and promotes health through partnerships with state health departments and other organizations. It is the federal agency charged with protecting the health and safety of U.S. citizens, both at home and abroad. It also oversees the development and application of programs for disease prevention and control, environmental health, and health promotion and education. ► <http://www.cdc.gov/>.

**Departmental system** A system that focus on a specific niche area in the healthcare setting, such as a laboratory, pharmacy, radiology department, etc.

**Dependency grammar** A linguistic theory of syntax that is based on dependency relations between words, where one word in the sentence is independent and other words are dependent on that word. Generally, the verb of a sentence is independent and other words are directly or indirectly dependent on the verb.

**Dependent variable (also called outcome variable)** In a correlational or experimental study, the main variable of interest or outcome variable, which is thought to be affected by or associated with the independent variables (q.v.).

**Derivational morphemes** A morpheme that changes the meaning or part of the speech of a word (e.g., *-ful* as in painful, converting a noun to an adjective).

**DES** See: Data Encryption Standard.

**Descriptive study** One-group study that seeks to measure the value of a variable in a sample of subjects. Study with no independent variable.

**Design validation** A study conducted to inform the design of an information resource, e.g., a user survey.

**DHHS** See: Department of Health and Human Services.

**Diagnosis** The process of analyzing available data to determine the pathophysiologic explanation for a patient's symptoms.

**Diagnosis-based reimbursement** Payments to providers (typically hospitals) based on the diagnosis made by a physician at the time of admission.

**Diagnosis-related group (DRG)** One of almost 500 categories based on major diagnosis, length of stay, secondary diagnosis, surgical procedure, age, and types of services required. Used to determine the fixed payment per case that Medicare will reimburse hospitals for providing care to elderly patients.

**Diagnostic decision-support system** A computer-based system that assists physicians in rendering diagnoses; a subset of clinical decision-support systems. See clinical decision support system.

**Diagnostic process** The activity of deciding which questions to ask, which tests to order, or which procedures to perform, and determining the value of the results relative to associated risks or financial costs.

**DICOM** See: Digital Image Communications in Medicine.

**Dictionary** A set of terms representing the system of concepts of a particular subject field.

**Differential diagnosis** The set of active hypotheses (possible diagnoses) that a physician develops when determining the source of a patient's problem.

**Digital computer** A computer that processes discrete values based on the binary digit or bit. Essentially all modern computers are digital, but analog computers also existed in the past.

**Digital divide** Term referring to disparity in economic access to technology between "haves" and "have-nots".

**Digital image** An image that is stored as a grid of numbers, where each picture element (pixel) in the grid represents the intensity, and possibly color, of a small area.

**Digital Image Communications in Medicine (DICOM)** A standard for electronic exchanging digital health images, such as x-rays and CT scans.

**Digital library** Organized collections of electronic content, intended for specific communities or domains.

**Digital object identifier (DOI)** A system for providing unique identifiers for published digital objects, consisting of a prefix that is

assigned by the International DOI Foundation to the publishing entity and a suffix that is assigned and maintained by the entity.

**Digital radiography (DR)** The process of producing X-ray images that are stored in digital form in computer memory, rather than on film.

**Digital signal** A signal that takes on discrete values from a specified range of values.

**Digital signal processing (DSP)** An integrated circuit designed for high-speed data manipulation and used in audio communications, image manipulation, and other data acquisition and control applications.

**Digital subscriber line (DSL)** A digital telephone service that allows high-speed network communication using conventional (twisted pair) telephone wiring.

**Digital subtraction angiography (DSA)** A radiologic technique for imaging blood vessels in which a digital image acquired before injection of contrast material is subtracted pixel by pixel from an image acquired after injection. The resulting image shows only the differences in the two images, highlighting those areas where the contrast material has accumulated.

**Direct entry** The entry of data into a computer system by the individual who personally made the observations.

**Discharge Plan** A plan that supports the transition of a patient from one care facility to home or another care facility and includes evaluation of the patient by qualified personnel, discussion with the patient or his representative, planning for homecoming or transfer to another care facility, determining whether caregiver training or other support is needed, referrals to a home care agency and/or appropriate support organizations in the community, and arranging for follow-up appointments or tests.

**Discourse** Large portions of text forming a narrative, such as paragraphs and documents.

**Discrete event simulation model** A modeling approach that assesses interactions between people, typically composed of patients that have attributes and that experience events.

**Discussion board** An on-line environment for exchanging public messages among participants.

**Discussion lists and messaging boards** Online tools for asynchronous text conversation.

**Disease** Any condition in an organism that is other than the healthy state.

**Dissemination phase** During the dissemination phase of a clinical research study, investigators analyze and report upon the data generated during the active phase.

**Distributed cognition** A view of cognition that considers groups, material artifacts, and cultures and that emphasizes the inherently social and collaborative nature of cognition.

**Distributed computer systems** A collection of independent computers that share data, programs, and other resources.

**DNA** See: Deoxyribonucleic Acid.

**DNS** See: Domain name system.

**Document structure** The organization of text into sections.

**DOI** See: Digital object identifier.

**Domain name system (DNS)** A hierarchical name-management system used to translate computer names to Internet protocol (IP) addresses.

**Doppler shift** A perceived change in frequency of a signal as the signal source moves toward or away from a signal receiver.

**Double blind** A clinical study methodology in which neither the researchers nor the subjects know to which study group a subject has been assigned.

**Double-blinded study** In the context of clinical research, a double blinded study is a study in which both the investigator and participant are blinded from the assignment of an intervention. In this scenario, a trusted third party must maintain records of such study arm assignments to inform later data analyses.

**Draft standard for trial use** A proposal for a standard developed by HL7 that is sufficiently well defined that early adopters can use the specification in the development of HIT. Ultimately, the draft standard may be refined and put to a ballot for endorsement by the members of the organization, thus creating an official standard.

**DRG** See Diagnosis-Related Groups.

**Drug repurposing** Identifying existing drugs that may be useful for indications other than those for which they were initially approved.

**Drug screening robots** A scientific instrument that can perform assays with potential drugs in a highly parallel and high throughput manner.

**Drug-genome interaction** A relationship between a drug and a gene in which the gene product affects the activity of the drug or the drug influences the transcription of the gene.

**DSA** See: Digital subtraction angiography.

**DSL** See: Digital subscriber line.

**DSP** See: Digital signal processing.

**Dublin Core Metadata Initiative (DCMI)** A standard metadata model for indexing published documents.

**Dynamic** A simulation program that models changes in patient state over time and in response to students' therapeutic decisions.

**Dynamic programming** A computationally intensive computer-science technique used, for example, to determine optimal sequence alignments in many computational biology applications.

**Dynamic transmission model** A model that divides a population into compartments (for example, uninfected, infected, recovered, dead), and for transitions between compartments are governed by differential or difference equations.

**Dynamical systems models** Models that describe and predict the interactions over time between multiple components of a phenomenon that are viewed as a system. Dynamical systems models are often used to construct "controllers," algorithms that adjust functioning of the system (an airplane, artificial pancreas, etc.) to maximize a set of optimization criteria.

**Earley parsing** A dynamic programming method for parsing context-free grammar.

**EBM** See Evidence-Based Medicine.

**EBM database** For Evidence-Based Medicine database, a highly organized collection of clinical evidence to support medical decisions based on the results of controlled clinical trials.

**Ecological momentary assessment (EMA)** A range of methods for collecting ecologically-valid self-report by enabling study participants and patients to report their experiences in real-time, in real-world settings, over time and across contexts.

**eCRF** See: Electronic Case Report Form.

**EDC** See: Electronic Data Capture.

**EDI** See: Electronic data interchange.

**EEG** See: Electroencephalography.

**EHR** See: Electronic health record.

**EIW** See: Enterprise information warehouse.

**Electroencephalography (EEG)** A method for measuring the electromagnetic fields generated by the electrical activity of the neurons using a large arrays of scalp sensors, the output of which are processed to localize the source of the electrical activity inside the brain.

**Electronic Case Report Form (eCRF)** A computational representation of paper case report forms (CRFs) used to enable EDC.

**Electronic Data Capture (EDC)** EDC is the process of capturing study-related data elements via computational mechanisms.

**Electronic Data interchange (EDI)** Electronic exchange of standard data transactions, such as claims submission and electronic funds transfer.

**Electronic Health Record (EHR)** A repository of electronically maintained information about an individual's lifetime health status and health care, stored such that it can serve the multiple legitimate users of the record. See also EMR and CPR.

**Electronic health record system** An electronic health record and the tools used to manage the information; also referred to as a computer-based patient-record system and often shortened to electronic health record.

**Electronic Medical Record (EMR)** The electronic record documenting a patient's care in a provider organization such as a hospital or a physician's office. Often used interchangeably with Electronic Health Record (EHR), although EHRs refer more typically to an individual's lifetime health status and care rather than the set of particular organizationally- based experiences.

**Electronic Medical Records and Genomics (eMERGE) network** A network of academic institutions that is exploring the capabilities of EHRs for genomic discovery and implementation.

**Electronic-long, paper-short (ELPS)** A publication method which provides on the Web site supplemental material that did not appear in the print version of the journal.

**ELPS** See: Electronic-long, paper-short.

**EMBASE** A commercial biomedical and pharmacological database from ExcerptaMedica, which provides information about medical and drug-related subjects.

**Emergent design** Study where the design or plan of research can and does change as the study progresses. Characteristic of subjectivist studies.

**Emotion detection** A natural language technique for determining the mental state of the author of a text document.

**EMPI** See: Enterprise master patient index.

**EMR (or EMRS)** See: Electronic Medical Record.

**EMTREE** A hierarchically structured, controlled vocabulary used for subject indexing, used to index EMBASE.

**Enabling technology** Any technology that improves organizational processes through its use rather than on its own. Computers, for example, are useless unless "enabled" by operation systems and applications or implemented in support of work flows that might not otherwise be possible.

**Encryption** The process of transforming information such that its meaning is hidden, with the intent of keeping it secret, such that only those who know how to decrypt it can read it; see decryption.

**Endophenotypes** An observable characteristic that is tightly linked to underlying genetics and less dependent on environmental exposures or chance.

**Enrichment analysis** A statistical method to determine whether an a priori defined set of concepts shows statistically significant overrepresentation in descriptions of a set of items (such as genes) compared to what one would expect based on their frequency in a reference distribution.

**Enrollment** during enrollment of a clinical research study, potential participants are identified and research staff determine their eligibility for participation in a study, based upon the eligibility criteria described in the study protocol. If a participant is deemed eligible to participate, there are then officially “registered” for the study. It is during this phase that in some trial designs, a process of randomization and assignment to study arms occurs.

**Enterprise information warehouse (EIW)** A data base in which data from clinical, financial and other operational sources are collected in order to be compared and contrasted across the enterprise.

**Enterprise master patient index (EMPI)** An architectural component that serves as the name authority in a health-care information system composed of multiple independent systems; the EMPI provides an index of patient names and identification numbers used by the connected information systems.

**Entrez** A search engine from the National Center for Biotechnology Information (NCBI), at the National Library of Medicine; Entrez can be used to search a variety of life sciences databases, including PubMed.

**Entry term** A synonym form for a subject heading in the Medical Subject Headings (MeSH) controlled, hierarchical vocabulary.

**Epidemiologic** Related to the field of epidemiology.

**Epidemiology** The study of the patterns, causes, and effects of health and disease conditions in defined populations.

**Epigenetics** Heritable phenotypes that are not encoded in DNA sequence.

**Epigenomics** The study of heritable phenotypes that are not encoded in the organisms DNA.

**e-prescribing** The electronic process of generating, transmitting and filling a medical prescription.

**Error analysis** In natural language processing, a process for determining the reasons for false-positive and false-negative errors.

**Escrow** Use of a trusted third party to hold cryptographic keys, computer source code, or other valuable information to protect against loss or inappropriate access.

**Ethernet** A network standard that uses a bus or star topology and regulates communication traffic using the Carrier Sense Multiple Access with Collision Detection (CSMA/CD) approach.

**Ethnography** Set of research methodologies derived primarily from social anthropology. The basis of much of the subjectivist, qualitative evaluation approaches.

**ETL** See: Extract, Transform, and Load.

**Evaluation contract** A document describing the aims of a study, the methods to be used and resources made available, usually agreed between the evaluator and key stakeholders before the study begins.

**Event-Condition-Action (ECA) rule** A rule that requires some *event* (such as the availability of a new data value in the database) to cause the *condition* (premise, or left-hand side) of the rule to be evaluated. If the condition is determined to be true, then some *action* is performed. Such rules are commonly found in active database systems and form the basis of medical logic modules.

**Evidence-based guidelines (EBM)** An approach to medical practice whereby the best possible evidence from the medical literature is incorporated in decision making. Generally such evidence is derived from controlled clinical trials.

**Exabyte**  $10^{18}$  bytes.

**Exome** The entire sequence of all genes within a genome, approximately 1–3% of the entire genome.

**Expected value** The value that is expected on average for a specified chance event or decision.

**Experimental intervention** In the context of clinical research, an experimental intervention represents the treatment or other intervention delivered to a participant assigned to the experimental arm of the study in order to determine the safety, efficacy, or benefits of that intervention.

**Experimental science** Systematic study characterized by posing hypotheses, designing experiments, performing analyses, and interpreting results to validate or disprove hypotheses and to suggest new hypotheses for study.

**Extensible markup language (XML)** A subset of the **Standard Generalized Markup Language (SGML)** from the World Wide Web Consortium (W3C), designed especially for Web documents. It allows designers to create their own custom-tailored tags, enabling the definition, transmission, validation, and interpretation of data between applications and between organizations.

**External router** A computer that resides on multiple networks and that can forward and translate message packets sent from a local or enterprise network to a regional network beyond the bounds of the organization.

**External validity** In the context of clinical research, external validity refers to the abil-

ity to generalize study results into clinical care.

**Extract, Transform, and Load (ETL)** ETL is the process by which source data is collected and manipulated so as to adhere to the structure and semantics of a receiving data construct, such as a data warehouse.

**Extrinsic evaluation** An evaluation of a component of a system based on an evaluation of the performance of the entire system.

**F measure** A measure of overall accuracy that is a combination of precision and recall.

**Factual knowledge** Knowledge of facts without necessarily having any in-depth understanding of their origin or implications.

**False negative** A negative result that occurs in a true situation. Examples include a desired entity that is missed by a search routine or a test result that appears normal when it should be abnormal.

**False positive** A positive result that occurs in a false situation. Examples include an inappropriate entity that is returned by a search routine or a test result that appears abnormal when it should be normal.

**False-negative rate (FNR)** The probability of a negative result, given that the condition under consideration is true—for example, the probability of a negative test result in a patient who has the disease under consideration.

**False-negative result (FN)** A negative result when the condition under consideration is true—for example, a negative test result in a patient who has the disease under consideration.

**False-positive rate (FPR)** The probability of a positive result, given that the condition under consideration is false—for example, the probability of a positive test result in a patient who does not have the disease under consideration.

**False-positive result (FP)** A positive result when the condition under consideration is false—for example, a positive test result in a patient who does not have the disease under consideration.

**Fast Healthcare Interoperability Resource (FHIR)** An HL7 standard for information exchange using a well-defined and limited set of resources.

**FDDI** See: Fiber Distributed Data Interface.

**Feedback** In a computer-based education program, system-generated responses, such as explanations, summaries, and references, provided to further a student's progress in learning.

**Fee-for-service** Unrestricted system of health care reimbursement in which payers pay provider for those services the provider has deemed necessary.

**Fiber Distributed Data Interface [FDDI]** A transmission standard for local area networks operating on fiberoptic cable, providing a transmission rate of 100 Mbit/s.

**Fiberoptic cable** A communication medium that uses light waves to transmit information signals.

**Fiducial** An object used in the field of view of an imaging system which appears in the image produced, for use as a point of reference or a measure.

**Field** In science, the setting, which may be multiple physical locations, where the work under study is carried out. In database design, the smallest named unit of data in a database. Fields are grouped together to form records.

**Field function study** Study of an information resource where the system is used in the context of ongoing health care. Study of a deployed system (cf. Laboratory study).

**Field user effect study** A study of the actual actions or decisions of the users of the resource.

**File** In a database, a collection of similar records.

**File format** Representation of data within a file; can refer to the method for individual characters and values (for example, ASCII or binary) or their organization within the file (for example, XML or text).

**File server** A computer that is dedicated to storing shared or private data files.

**File system** An organization of files within a database or on a mass storage device.

**Filtering algorithms** A defined procedure applied to input data to reduce the effect of noise.

**Finite state automaton** An abstract, computer-based representation of the state of some entity together with a set of actions that can transform the state. Collections of finite state automata can be used to model complex systems.

**Fire-wall** A security system intended to protect an organization's network against external threats by preventing computers in the organization's network from communicating directly with computers external to the network, and vice versa.

**Flash memory card** A portable electronic storage medium that uses a semiconductor chip with a standard physical interface; a convenient method for moving data between computers.

**Flexnerian** One of science-based acquisition of medically relevant knowledge, followed by on-the-job apprentice-style acquisition of experience, and accompanied by evolution and expansion of the curriculum to add new fields of knowledge.

**Floppy disk** An inexpensive magnetic disk that can be removed from the disk-drive unit and thereby used to transfer or archive files.

**FM** See: Frequency modulation.

**fMRI** See: Functional magnetic resonance imaging.

**FN** See: False-negative result.

**Force feedback** A user interface feature in which physical sensations are transmitted to the user to provide a tactile sensation as part of a simulated activity. See also Haptic feedback.

**Foreground question** Question that asks for general information related to a specific patient (see also background question).

**Form factor** Typically refers to the physical dimensions of a product. With computing devices, refers to the physical size of the device, often with specific reference to the display. For example, we would observe that the form factor of a desktop monitor is significantly larger than that of a tablet or smart phone, and therefore able to display more characters and larger graphics on the screen.

**Formative evaluation** An assessment of a system's behavior and capabilities conducted during the development process and used to guide future development of the system.

**Forward chaining** Also known as data-driven reasoning. A form of inference used in rule-based systems in which the inference engine uses newly acquired (or concluded) values of variables to invoke all rules that may reference one or more of those variables in their premises (left-hand side), thereby concluding new values for variables in the conclusions (right-hand side) of those rules. The process continues recursively until all rules whose premises may reference the variables whose values become known have been considered.

**FP** See: False-positive result.

**FPR** See: False-positive rate.

**Frame** An abstract representation of a concept or entity that consists of a set of attributes, called slots, each of which can have one or more values to represent knowledge about the entity or concept.

**Frame Relay** A high-speed network protocol designed for sending digital information over shared wide-area networks using variable length packets of information.

**Free morpheme** A morpheme that is a word and that does not contain another morpheme (*e.g., arm, pain*).

**Frequency modulation(FM)** A signal representation in which signal values are represented as changes in frequency rather than amplitude.

**Front-end application** A computer program that interacts with a database-management system to retrieve and save data and to accomplish user-level tasks.

**Full-text content** The complete textual information contained in a bibliographic source.

**Functional magnetic resonance imaging (fMRI)** A magnetic resonance imaging method that reveals changes in blood oxygenation that occur following neural activity.

**Functional mapping** An imaging method that relates specific sites on images to particular physiologic functions.

**Gateway** A computer that resides on multiple networks and that can forward and translate message packets sent between nodes in networks running different protocols.

**Gbps** See: Gigabits per second.

**GEM** See: Guideline Element Model.

**GenBank** A centralized repository of protein, RNA, and DNA sequences in all species, cur-

rently maintained by the National Institutes of Health.

**Gene expression microarray** Study the expression of large numbers of genes with one another and create multiple variations on a genetic theme to explore the implications of changes in genome function on human disease.

**Gene Expression Omnibus (GEO)** A centralized database of gene expression microarray datasets.

**Gene Ontology(GO)** A structured controlled vocabulary used for annotating genes and proteins with molecular function. The vocabulary contains three distinct ontologies, Molecular Function, Biological Process and Cellular Component.

**Genes** Units encoded in DNA and they are transcribed into ribonucleic acid (RNA).

**Genetic data** An overarching term used to label various collections of facts about the genomes of individuals, groups or species.

**Genetic risk score (GRS)** A calculation of the likelihood of a particular phenotype being present based on a weighed score of one or more genetic variants; also referred to as a polygenic risk score (PRS).

**Genome-Wide Association Studies (GWAS)** An examination of many common genetic variants in different individuals to see if any variant is associated with a given trait, e.g., a disease.

**Genomic medicine (also known as stratified-medicine)** The management of groups of patients with shared biological characteristics, determined through molecular diagnostic testing, to select the best therapy in order to achieve the best possible outcome for a given group.

**Genomics** The study of all of the nucleotide sequences, including structural genes, regulatory sequences, and noncoding DNA

segments, in the chromosomes of an organism.

**Genomics database** An organized collection of information from gene sequencing, protein characterization, and other genomic research.

**Genotype** The genetic makeup, as distinguished from the physical appearance, of an organism or a group of organisms.

**Genotypic** Refers to the genetic makeup of an organism.

**GEO** See: Gene Expression Omnibus.

**Geographic Information System (GIS)** A system designed to capture, store, manipulate, analyze, manage, and visually present all types of location-specific data.

**Geographic Information System (GIS)** A system designed to capture, store, manipulate, analyze, manage, and visually present all types of location-specific data.

**Gigabits per second (Gbps)** A common unit of measure for data transmission over high-speed networks.

**Gigabyte**  $2^{30}$  or 1,073,741,824 bytes.

**GIS** See: Geographic Information System.

**Global processing** Computations on the entire image, without regard to specific regional content.

**GO** See: Gene Ontology.

**Gold-standard test** The test or procedure whose result is used to determine the true state of the subject—for example, a pathology test such as a biopsy used to determine a patient's true disease state.

**Google** A commercial search engine that provides free searching of documents on the World Wide Web.

**GPS** A system for calculating precise geographical location by triangulating information obtained from satellites and/or cell towers.

**GPU** See: Graphics processing unit.

**Grammar** A mathematical model of a potentially infinite set of strings.

**Graph** In computer science, a set of *nodes* or circles connected by a set of *edges* or lines.

**Graphical user interface (GUI)** A type of environment that represents programs, files, and options by means of icons, menus, and dialog boxes on the screen.

**Graphics processing unit (GPU)** A computer hardware component that performs graphic displays and other highly parallel computations.

**Gray scale** A scheme for representing intensity in a black-and-white image. Multiple bits per pixel are used to represent intermediate levels of gray.

**Guardian Angel Proposal** A proposed structure for a lifetime, patient-centered health information system.

**GUI** See: Graphical user interface.

**Guidance** In a computer-based education program, proactive feedback, help facilities, and other tools designed to assist a student in learning the covered material.

**Guideline Element Model (GEM)** An XML specification for marking up textual documents that describe clinical practice guidelines. The guideline-related XML tags make it possible for information systems to determine the nature of the text that has been marked up and its role in the guideline specification.

**GWAS** See: Genome-Wide Association Studies.

**Haptic feedback** A user interface feature in which physical sensations are transmitted to

the user to provide a tactile sensation as part of a simulated activity.

**Haptic sensation** The sensation of touch or feel. It can be applied to a simulation of such sensation as presented within a virtual or augmented reality scenario.

**Hard disk** A magnetic disk used for data storage and typically fixed in the disk-drive unit.

**Hardware** The physical equipment of a computer system, including the central processing unit, memory, data-storage devices, workstations, terminals, and printers.

**Harmonic mean** An average of a set of weighted values in which the weights are determined by the relative importance of the contribution to the average.

**HCI** See: Human-computer interaction.

**HCO** See: Healthcare organization.

**Head word** The key word in a multi-word phrase that conveys the central meaning of the phrase. For example, a phrase containing adjectives and a noun, the noun is typically the head word.

**Header (of email)** The portion of a simple electronic mail message that contains information about the date and time of the message, the address of the sender, the addresses of the recipients, the subject, and other optional information.

**Health Evaluation and Logical Processing [HELP]** One of the first electronic health record systems, developed at LDS Hospital in Salt Lake City, Utah. Still in use today, it was innovative for its introduction of automated alerts.

**Health informatics** Used by some as a synonym for biomedical informatics, this term is increasingly used solely to refer to applied research and practice in clinical and public health informatics.

**Health information and communication technology (HICT)** The broad spectrum of hardware and software used to capture, store and transmit health information.

**Health Information exchange (HIE)** The process of moving health information electronically among disparate health care organizations for clinical care and other purposes; or an organization that is dedicated to providing health information exchange.

**Health Information Infrastructure (HII)** The set of public and private resources, including networks, databases, and policies, for collecting, storing, and transmitting health information.

**Health Information Technology (HIT)** These of computers and communications technology in healthcare and public health settings.

**Health Information Technology for Economic and Clinical Health (HITECH)** Also referred to as HITECH Act. Passed by the Congress as Title IV of the American Recovery and Reinvestment Act of 2009 (ARRA) in 2009, established four major goals that promote the use of health information technology: (1) Develop standards for the nationwide electronic exchange and use of health information; (2) Invest \$20B in incentives to encourage doctors and hospitals to use HIT to electronically exchange patients' health information; (3) Generate \$10B in savings through improvements in quality of care and care coordination, and reductions in medical errors and duplicative care and (4) Strengthen Federal privacy and security law to protect identifiable health information from misuse. Also codified the Office of the National Coordinator for Health Information Technology (ONC) within the Department of Health and Human Services.

**Health Insurance Portability and Accountability Act (HIPAA)** A law enacted in 1996 to protect health insurance coverage for workers and their families when they change or lose their jobs. An "administrative simplification" provision requires the Department of Health and Human Services to establish national

standards for electronic healthcare transactions and national identifiers for providers, health plans, and employers. It also addresses the security and privacy of health data.

**Health Level Seven (HL7)** An ad hoc standards group formed to develop standards for exchange of health care data between independent computer applications; more specifically, the health care data messaging standard developed and adopted by the HL7 standards group.

**Health literacy** A constellation of skills, including the ability to perform basic reading, math, and everyday health tasks like comprehending prescription bottles and appointment slips, required to function in the health care environment.

**Health Maintenance Organization (HMO)** A group practice or affiliation of independent practitioners that contracts with patients to provide comprehensive health care for a fixed periodic payment specified in advance.

**Health on the Net[HON]** A private organization establishing ethical standards for health information published on the World Wide Web.

**Health Record Bank (HRB)** An independent organization that provides a secure electronic repository for storing and maintaining an individual's lifetime health and medical records from multiple sources and assuring that the individual always has complete control over who accesses their information.

**Healthcare Effectiveness Data and Information Set (HEDIS)** Employers and individuals use HEDIS to measure the quality of health plans. HEDIS measures how well health plans give service to their members. HEDIS is one of health care's most widely used performance improvement tools. It is developed and maintained by the National Committee for Quality Assurance.

**Healthcare organization (HCO)** Any healthrelated organization that is involved in direct patient care.

**Healthcare team** A coordinated group of health professionals including physicians, nurses, case managers, dietitians, pharmacists, therapists, and other practitioners who collaborate in caring for a patient.

**HEDIS** See: Healthcare Effectiveness Data and Information Set.

**HELP** See Health Evaluation and Logical Processing.

**HELP sector** A decision rule encoded in the HELP system, a clinical information system that was developed by researchers at LDS Hospital in Salt Lake City.

**Helper (plug-in)** An application that are launched by a Web browser when the browser downloads a file that the browser is not able to process itself.

**Heuristic** A mental “trick” or rule of thumb; a cognitive process used in learning or problem solving.

**Heuristic evaluation (HE)** A usability inspection method, in which the system is evaluated on the basis of a small set of well-tested design principles such as visibility of system status, user control and freedom, consistency and standards, flexibility and efficiency of use.

**HICT** See: Health information and communication technology. From standard of care practices), so as to provide the basis for comparison to data sets derived from participants who have received an experimental intervention under study.

**HIE** See: Health Information Exchange.

**HIE** See: Health Information Exchange.

**Hierarchical** An arrangement between entities that conveys some superior-inferior relationship, such as parent–child, whole-part etc.

**Hierarchical Task Analysis** Task analytic approach that involves the breaking down of a task into sub-tasks and smaller constituted

parts (e.g., sub-sub-tasks). The tasks are organized according to specific goals.

**High-bandwidth** An information channel that is capable of carrying delivering data at a relatively high rate.

**Higher-level process** A complex process comprising multiple lower-level processes.

**III** See: Health Information Infrastructure.

**III** See: Health Information Infrastructure.

**Hindsight bias** The tendency to over-estimate the prior predictability of an event, once the events has already taken place. For example, if event A occurs before event B, there may be an assumption that A predicted B.

**HIPAA** See: Health Insurance Portability and Accountability Act.

**HIPAA** See: Health Insurance Portability and Accountability Act.

**HIS** See: Hospital information system.

**Historical control** In the context of clinical research, historical controls are subjects who represent the targeted population of interest for a study. Typically, their data are derived from existing resources in a retrospective manner and that represent targeted outcomes in a non-interventional state (often resulting among humans and other elements of a system, and the profession that applies theory, principles, data, and other methods to design in order to optimize human well-being and overall system performance.

**Historically controlled study** See: before-after study.

**HIT** See: Health Information Technology.

**HITECH** See: Health Information Technology for Economic and Clinical Health.

**HITECH regulations** The components of the Health Information Technology for

Economic and Clinical Health Act, passed by the Congress in 2009, which authorized financial incentives to be paid to eligible physicians and hospitals for the adoption of “meaningful use” of EHRs in the United States. The law also called for the certification of EHR technology and for educational programs to enhance its dissemination and adoption.

**HIV** See: Human immunodeficiency virus.

**HL7** See: Health Level 7.

**HMO** See: Health maintenance organization.

**Home Telehealth** The extension of telehealth services in to the home setting to support activities such as home nursing care and chronic disease management.

**HON** See: Health on the Net.

**Hospital information system (HIS)** Computer system designed to support the comprehensive information requirements of hospitals and medical centers, including patient, clinical, ancillary, and financial management.

**Hot fail over** A secondary computer system that is kept in constant synchronization with the primary system and that can take over as soon as the primary fails for any reason.

**Hounsfield number** The numeric information contained in each pixel of a CT image. It is related to the composition and nature of the tissue imaged and is used to represent the density of tissue.

**HRB** See: Health Record Bank.

**HTML** See HyperText.

**HTTP** See: HyperText Transfer Protocol.

**Human factors** The scientific discipline concerned with the understanding of interactions.

**Human Genome Project** An international undertaking, the goal of which is to deter-

mine the complete sequence of human deoxyribonucleic acid (DNA), as it is encoded in each of the 23 chromosomes.

**Human immunodeficiency virus (HIV)** A retrovirus that invades and inactivates helper T cells of the immune system and is a cause of AIDS and AIDS-related complex.

**Human-computer interaction (HCI)** Formal methods for addressing the ways in which human beings and computer programs exchange information.

**Hyper Text markup language (HTML)** The document specification language used for documents on the World Wide Web.

**Hypertext** Text linked together in a non sequential web of associations. Users can traverse highlighted portions of text to retrieve additional related information.

**HyperText Transfer Protocol (HTTP)** The client-server protocol used to access information on the World Wide Web.

**Hypothesis generation** The process of proposing a hypothesis, usually driven by some unexplained phenomenon and the derivation of a suspected underlying mechanism.

**Hypothetico-deductive approach** A method of reasoning made up of four stages (cue acquisition, hypothesis generation, cue interpretation, and hypothesis evaluation) which is used to generate and test hypotheses. In clinical medicine, an iterative approach to diagnosis in which physicians perform sequential, staged data collection, data interpretation, and hypothesis generation to determine and refine a differential diagnosis.

**Hypothetico-deductive reasoning** Reasoning by first generating and then testing a set of hypotheses to account for clinical data (i.e., reasoning from hypothesis to data).

**ICANN** See: Internet Corporation for Assigned Names and Numbers.

**ICD-9-CM** See: International Classification of Diseases, 9th Edition, Clinical Modifications.

**ICMP** See: Internet Control Message Protocol.

**Icon** In a graphical interface, a pictorial representation of an object or function.

**ICT** See: Information and communications technology.

**IDF** See: Inverse document frequency.

**IDN** See: Integrated delivery network.

**Image acquisition** The process of generating images from the modality and converting them to digital form if they are not intrinsically digital.

**Image compression** A mathematical process for removing redundant or relatively unimportant information from an electronic image such that the resulting file appears the same (lossless compression) or similar (lossy compression) when compared to the original.

**Image content representation** Makes the information in images accessible to machines for processing.

**Image database** An organized collection of clinical image files, such as x-rays, photographs, and microscopic images.

**Image enhancement** The use of global processing to improve the appearance of the image either for human use or for subsequent processing by computer.

**Image interpretation/computer reasoning** The process by which the individual viewing the image renders an impression of the medical significance of the results of imaging study, potentially aided by computer methods.

**Image management/storage** Methods for storing, transmitting, displaying, retrieving, and organizing images. The application of

methods for storing, transmitting, displaying, retrieving, and organizing images.

**Image metadata** Data about images, such as the type of image (e.g., modality), patient that was imaged, date of imaging, image features (quantitative or qualitative), and other information pertaining to the image and its contents.

**Image processing** The transformation of one or more input images, either into one or more output images, or into an abstract representation of the contents of the input images.

**Image quantitation** The process of extracting useful numerical parameters or deriving calculations from the image or from ROIs in the image.

**Image reasoning** Computerized methods that use images to formulate conclusions or answer questions that require knowledge and logical inference.

**Image rendering/visualization** A variety of techniques for creating image displays, diagrams, or animations to display images more in a different perspective from the raw images.

**Imaging informatics** A subdiscipline of medical informatics concerned with the common issues that arise in all image modalities and applications once the images are converted to digital form.

**IMIA** See: International Medical Informatics Association.

**Immersive and virtual environments** A computer-based set of sensory inputs and outputs that can give the illusion of being in a different physical environment.

**Immersive environment** A computer-based set of sensory inputs and outputs that can give the illusion of being in a different physical environment; see; Virtual Reality.

**Immersive simulated environment** A computer-based set of sensory inputs and outputs that can give the illusion of being in a different physical environment.

**Immersive simulated environment** A teaching environment in which a student manipulates tools to control simulated instruments, producing visual, pressure, and other feedback to the tool controls and instruments.

**Immunization Information System (IIS)** Confidential, population based, computerized databases that record all immunization doses administered by participating providers to persons residing within a given geopolitical area. Also known as Immunization Registries.

**Immunization Registry** Confidential, population based, computerized databases that record all immunization doses administered by participating providers to persons residing within a given geopolitical area. Also known as Immunization Information Systems.

**Implementation science** Implementation science refers to the study of socio-cultural, operational, and behavioral norms and processes surrounding the dissemination and adoption of new systems, approaches and/or knowledge.

**Inaccessibility** A property of paper records that describes the inability to access the record by more than one person or in more than one place at a time.

**Incrementalist** An approach to evaluation that tolerates ambiguity and uncertainty and allows changes from day-to-day.

**Independent** Two events, A and B, are considered independent if the occurrence of one does not influence the probability of the occurrence of the other. Thus,  $p[A | B] = p[A]$ . The probability of two independent events A and B both occurring is given by the product of the individual probabilities:  $p[A, B] = p[A] \times p[B]$ . (See conditional independence.).

**Independent variable** In a correlational or experimental study, a variable thought to determine or be associated with the value of the dependent variable (q.v.).

**Index** In information retrieval, a shorthand guide to the content that allows users to find relevant content quickly.

**Index Medicus** The printed index used to catalog the medical literature. Journal articles are indexed by author name and subject heading, then aggregated in bound volumes. The Medline database was originally constructed as an online version of the Index Medicus.

**Index test** The diagnostic test whose performance is being measured.

**Indexing** In information retrieval, the assignment to each document of specific terms that indicate the subject matter of the document and that are used in searching.

**Indirect-care** Activities of health professionals that are not directly related to patient care, such as teaching and supervising students, continuing education, and attending staff meetings.

**Inductive reasoning** Involves an inferential process from the observed data to account for the unobserved. It is a process of generating possible conclusions based on available data. For example, the fact that a patient who recently had major surgery has not had any fever for the last 3 days may lead us to conclude that he will not have fever tomorrow or in the immediate days that follow. The power of inductive reasoning lies in its ability to allow us to go beyond the limitations of our current evidence or knowledge to novel conclusions about the unknown.

**Inference engine** A computer program that reasons about a knowledge base. In the case of rule-based systems, the inference engine may perform forward chaining or backward chaining to enable the rules to infer new information about the current situation.

**Inflectional morpheme** A morpheme that creates a different form of a word without changing the meaning of the word or the part of speech (e.g., *-ed*, *-s*, *-ing* as in *activated*, *activates*, *activating*).

**Influence diagram** A belief network in which explicit decision and utility nodes are also incorporated.

**Infobutton** A context-specific link from health care application to some information resource that anticipates users' needs and provides targeted information.

**Infobutton manager Middleware** that provides a standard software interface between infobuttons in an EHR and the documents and other information resources that the infobuttons may display for the user.

**infoRAD** The information technology and computing oriented component of the very large exhibition hall at the annual meeting of the Radiological Society of North America.

**Information** Organized data from which knowledge can be derived and that accordingly provide a basis for decision making.

**Information and communications technology (ICT)** The use of computers and communications devices to accept, store, transmit, and manipulate data; the term is roughly a synonym for information technology, but it is used more often outside the United States.

**Information blocking** A practice or position that interferes with exchange or accessibility of patient data or electronic health information. This was defined by the 21st Century Cures Act.

**Information extraction** Methods that process text to capture and organize specific information in the text and also to capture and organize specific relations between the pieces of information.

**Information model** A representation of concepts, relationships, constraints, rules, and operations to specify data semantics for a chosen domain of discourse. It can provide sharable, stable, and organized structure of information requirements for the domain context.

**Information need** In information retrieval, the searchers' expression, in their own language, of the information that they desire.

**Information resource** Generic term for a computer-based system that seeks to enhance health care by providing patient-specific information directly to care providers (often used equivalently with "system").

**Information retrieval (IR)** Methods that efficiently and effectively search and obtain data, particularly text, from very large collections or databases. It is also the science and practice of identification and efficient use of recorded media. See also Search.

**Information science** The field of study concerned with issues related to the management of both paper-based and electronically stored information.

**Information theory** The theory and mathematics underlying the processes of communication.

**Information visualization** The use of computer-supported, interactive, visual representations of abstract data to amplify cognition.

**Ink-jet printer** Output device that uses a moveable head to spray liquid ink on paper; the head moves back and forth for each line of pixels.

**Input and Output** Devices, such as keyboards, pointing devices, video displays, and laser printers, that facilitate user interaction and storage or just

**Input** The data that represent state information, to be stored and processed to produce results (output).

**Inspection method** Class of usability evaluation methods in which experts appraising a system, playing the role of a user to identify potential usability and interaction issues with a system.

**Institute of Medicine** The health arm of the National Academy of Sciences, which provides unbiased, authoritative advice to decision makers and the public. Renamed the National Academy of Medicine in 2016.

**Institutional Review Board (IRB)** A committee responsible for reviewing an institution's research projects involving human subjects in order to protect their safety, rights, and welfare.

**Integrated circuit** A circuit of transistors, resistors, and capacitors constructed on a single chip and interconnected to perform a specific function.

**Integrated delivery network (IDN)** A large conglomerate health-care organization developed to provide and manage comprehensive health-care services.

**Integrated Service Digital Network (ISDN)** A digital telephone service that allows high-speed network communications using conventional (twisted pair) telephone wiring.

**Integrative model** Model for understanding a phenomenon that draws from multiple disciplines and is not necessarily based on first principles.

**Intellectual property** Software programs, knowledge bases, Internet pages, and other creative assets that require protection against copying and other unauthorized use.

**Intelligent system** See: knowledge-based system.

**Intelligent Tutor** A tutoring system that monitors the learning session and intervenes only when the student requests help or makes serious mistakes.

**Interactome** The set of all molecular interactions in a cell.

**Interface engine** Software that mediates the exchange of information among two or more systems. Typically, each system must know how to communicate with the interface engine, but not need to know the information format of the other systems.

**Intermediate effect** process of continually learning, re-learning, and exercising new knowledge, punctuated by periods of apparent decrease in mastery and declines in performance, which may be necessary for learning to take place. People at intermediate levels of expertise may perform more poorly than those at lower level of expertise on some tasks, due to the challenges of assimilating new knowledge or skills over the course of the learning process.

**Internal validity** In the context of clinical research, internal validity refers to the minimization of potential biases during the design and execution of the trial.

**International Classification of Diseases, 9th Edition, Clinical Modifications** A US extension of the World Health Organization's International Classification of Diseases, 9th Edition.

**International Medical Informatics Association (IMIA)** An international organization dedicated to advancing biomedical and health informatics; an "organization of organizations", its members are national informatics societies and organizations, such as AMIA.

**International Organization for Standards (ISO)** The international body for information and other standards.

**Internet** A worldwide collection of gateways and networks that communicate with each other using the TCP/IP protocol, collectively providing a range of services including electronic mail and World Wide Web access.

**Internet address** See Internet Protocol Address.

**Internet Control Message Protocol (ICMP)** A network-level Internet protocol that provides error correction and other information relevant to processing data packets.

**Internet Corporation for Assigned Names and Numbers (ICANN)** The organization responsible for managing Internet domain name and IP address assignments.

**Internet of Things (IoT)** A system of interconnected computing devices that can transfer data and be controlled over a network. In the consumer space, IoT technologies are most commonly found in the built environment where devices and appliances (such as lighting fixtures, security systems or thermostats) can be controlled via smartphones or smart speakers, creating “smart” homes or offices.

**Internet protocol** The protocol within TCP/IP that governs the creation and routing of data packets and their reassembly into data messages.

**Internet Protocol address** A 32-bit number that uniquely identifies a computer connected to the Internet. Also called “Internet address” or “IP address”.

**Internet service provider (ISP)** A commercial communications company that supplies fee-for-service Internet connectivity to individuals and organizations.

**Internet standards** The set of conventions and protocols all Internet participants use to enable effective data communications.

**Internet Support Group (ISG)** An on-line forum for people with similar problems, challenges or conditions to share supportive resources.

**Interoperability** The 21st Century Cures Act defines interoperability as health information technology that—(A) enables the secure exchange of electronic health information with, and use of electronic health information from, other health information technology without special effort on the part of the

user; (B) allows for complete access, exchange, and use of all electronically accessible health information for authorized use under applicable State or Federal law; and (C) does not constitute information blocking.

**Interpreter** A program that converts each statement in a high-level program to a machine-language representation and then executes the binary instruction(s).

**Interventional radiology** A subspecialty of radiology that uses imaging to guide invasive diagnostic or therapeutic procedures.

**Intrinsic evaluation** An evaluation of a component of a system that focuses only on the performance of the component. See also Extrinsic Evaluation.

**Intuitionist-pluralist or de-constructivist** A philosophical position that holds that there is no truth and that there are as many legitimate interpretations of observed phenomena as there are observers.

**Inverse document frequency (IDF)** A measure of how infrequently a term occurs in a document collection.

$$\text{IDF}_i = \log \left( \frac{\text{number of documents}}{\text{number of documents with term}} \right) + 1$$

**IOM** See: Institute of Medicine.

**IP address** See: Internet Protocol Address.

**IR** See: Information retrieval.

**IRB** See: Institutional Review Board.

**ISDN** See: Integrated Service Digital Network.

**ISG** See: Internet Support Group.

**ISO** See: International Organization for Standards.

**Iso-semantic mapping** A relationship between an entity in one dataset or model and an

entity in another dataset or model where the meaning of the two entities is identical, even if the syntax or lexical form is different.

**ISP** See: Internet service provider.

**Job** A set of tasks submitted by a user for processing by a computer system.

**Joint Commission (JC)** An independent, not-for-profit organization, The Joint Commission accredits and certifies more than 19,000 health care organizations and programs in the United States. Joint Commission accreditation and certification is recognized nationwide as a symbol of quality that reflects an organization's commitment to meeting certain performance standards. The Joint Commission was formerly known as JCAHO (the Joint Commission for the Accreditation of Healthcare Organizations).

**Just-in-time adaptive interventions (JITAs)** An intervention design that aims to provide the type of support that is most likely to be helpful in a particular context at times when users are most likely to be receptive to that support, by adapting intervention provision to an individual's changing internal and contextual state.

**Just-in-time learning** An approach to providing necessary information to a user at the moment it is needed, usually through anticipation of the need.

**Kernel** The core of the operating system that resides in memory and runs in the background to supervise and control the execution of all other programs and direct operation of the hardware.

**Key field** A field in the record of a file that uniquely identifies the record within the file.

**Key Performance Indicator (KPI)** A metric defined to be an important factor in the success of an organization. Typically, several Key Performance indicators are displayed on a Dashboard.

**Keyboard** A data-input device used to enter alphanumeric characters through typing.

**Keyword** A word or phrase that conveys special meaning or to refer to information that is relevant to such a meaning (as in an index).

**Kilobyte**  $2^{10}$  or 1024 bytes.

**Knowledge** Relationships, facts, assumptions, heuristics, and models derived through the formal or informal analysis (or interpretation) of observations and resulting information.

**Knowledge acquisition** The information-elicitation and modeling process by which developers interact with subject-matter experts to create electronic knowledge bases.

**Knowledge base** A collection of stored facts, heuristics, and models that can be used for problem solving.

**Knowledge graph** A kind of knowledge representation in which entities are encoded as nodes in a graph and relationships among entities are encoded as links between the nodes.

**Knowledge-based information** Information derived and organized from observational or experimental research.

**Knowledge-based system** A program that symbolically encodes, in a knowledge base, facts, heuristics, and models derived from experts in a field and uses that knowledge to provide problem analysis or advice that the expert might have provided if asked the same question.

**KPI** See: Key Performance Indicator.

**Laboratory function study** Study that explores important properties of an information resource in isolation from the clinical setting.

**Laboratory user effect study** An evaluation technique in which a user is observed when given a simulated task to perform.

**LAN** See: Local-area network.

**Laser printer** Output device that uses an electromechanically controlled laser beam to generate an image on a xerographic surface, which then is used to produce paper copies.

**Latency** The time required for a signal to travel between two points in a network.

**Latent failures** Enduring systemic problems that make errors possible but are less visible or not evident for some time.

**Law of proximity** Principle from Gestalt psychology that states that visual entities that are close together are perceptually grouped.

**Law of symmetry** Principle from Gestalt psychology that states that symmetric objects are more readily perceived.

**LCD** See: Liquid crystal display.

**Lean** A management strategy that focuses only on those process that are able to contribute specific and measurable value for the end customer. The LEAN concept originated with Toyota's focus on efficient manufacturing processes.

**Learning Content Management System** A software platform that allows educational content creators to host, manage, and track changes in content.

**Learning health system** A proposed model for health care in which outcomes from past and current patient care provide are systematically collected, analyzed and then fed back into decision making about best practices for future patient care.

**Learning healthcare system** See: Learning health system.

**Learning Management System** An LMS is a repository of educational content, and interface for delivering courses and content to learners, and a vehicle for faculty to track learner usage and performance.

**LED** See: Light-emitting diode.

**Lexemes** A minimal lexical unit in a language that represents different forms of the same word.

**Lexical-statistical retrieval** Retrieval based on a combination of word matching and relevance ranking.

**Lexicon** A catalogue of the words in a language, usually containing syntactic information such as parts of speech, pluralization rules, etc.

**Light-emitting diode (LED)** A semiconductor device that emits a particular frequency of light when a current is passed through it; typically used for indicator lights and computer screens because low power requirement, minimal heat generated, and durability.

**Likelihood ratio (LR)** A measure of the discriminatory power of a test. The LR is the ratio of the probability of a result when the condition under consideration is true to the probability of a result when the condition under consideration is false (for example, the probability of a result in a diseased patient to the probability of a result in a non-diseased patient). The LR for a positive test is the ratio of true-positive rate (TPR) to false-positive rate (FPR).

**Link-based** An indexing approach that gives relevance weight to web pages based on how often they are cited by other pages.

**Linux** An open source operating system based on principles of Unix and first developed by Linus Torvalds in 1991.

**Liquid crystal display (LCD)** A display technology that uses rod-shaped molecules to bend

light and alter contrast and viewing angle to produce images.

**Listserver** A distribution list for electronic mail messages.

**Literature reference database** See: bibliographic database.

**Local-area network (LAN)** A network for data communication that connects multiple nodes, all typically owned by a single institution and located within a small geographic area.

**Logical Observations, Identifiers, Names and Codes (LOINC)** A controlled terminology created for providing coded terms for observational procedures. Originally focused on laboratory tests, it has expanded to include many other diagnostic procedures.

**Logical positivist** A philosophical position that holds that there is a single truth that can be inferred from the right combination of studies.

**Logic-based** A knowledge representation method based on the use of predicates.

**LOINC** See: Logical Observations, Identifiers, Names and Codes.

**Longitudinal Care Plan** A holistic, dynamic, and integrated plan that documents important disease prevention and treatment goals and plans. A longitudinal plan is patient-centered, reflecting a patient's values and preferences, and is dependent upon bidirectional communications.

**Long-term memory** The part of memory that acquires information from short-term memory and retains it for long periods of time.

**Long-term storage** A medium for storing information that can persist over long periods without the need for a power supply to maintain data integrity.

**Lossless compression** A mathematical technique for reducing the number of bits needed

to store data while still allowing for the recreation of the original data.

**Lossy compression** A mathematical technique for reducing the number of bits needed to store data but that results in loss of information.

**Low-level processes** An elementary process that has its basis in the physical world of chemistry or physics.

**LR** See: Likelihood ratio.

**Machine code** The set of primitive instructions to a computer represented in binary code (machine language).

**Machine language** The set of primitive instructions represented in binary code (machine code).

**Machine learning** A computing technique in which information learned from data is used to improve system performance.

**Machine translation** Automatic mapping of text written in one natural language into text of another language.

**Macros** A reusable set of computer instructions, generally for a repetitive task.

**Magnetic disk** A round, flat plate of material that can accept and store magnetic charge. Data are encoded on magnetic disk as sequences of charges on concentric tracks.

**Magnetic resonance imaging (MRI)** A modality that produces images by evaluating the differential response of atomic nuclei in the body when the patient is placed in an intense magnetic field.

**Magnetic resonance spectroscopy** A noninvasive technique that is similar to magnetic resonance imaging but uses a stronger field and is used to monitor body chemistry (as in metabolism or blood flow) rather than anatomical structures.

**Magnetic tape** A long ribbon of material that can accept and store magnetic charge. Data are encoded on magnetic tape as sequences of charges along longitudinal tracks.

**Magnetoencephalography (MEG)** A method for measuring the electromagnetic fields generated by the electrical activity of the neurons using a large arrays of scalp sensors, the output of which are processed in a similar way to CT in order to localize the source of the electromagnetic and metabolic shifts occurring in the brain during trauma.

**Mailing list** A set of mailing addresses used for bulk distribution of electronic or physical mail.

**Mainframe computer system** A large, expensive, multi-user computer, typically operated and maintained by professional computing personnel. Often referred to as a “mainframe” for short.

**Malpractice** Class of litigation in health care based on negligence theory; failure of a health professional to render proper services in keeping with the standards of the community.

**Malware** Software that is specifically design to cause harm to computer systems by disrupting other programs, damaging the machine, or gaining unauthorized access to the system or the data that it contains.

**Management** The process of treating a patient (or allowing the condition to resolve on its own) once the medical diagnosis has been determined.

**Mannequin** A life size plastic human body with some or many human-like functions.

**Manual indexing** The process by which human indexers, usually using standardized terminology, assign indexing terms and attributes to documents, often following a specific protocol.

**Markov cycle** The period of time specified for a transition probability within a Markov model.

**Markov model** A mathematical model of a set of strings in which the probability of a given symbol occurring depends on the identity of the immediately preceding symbol or the two immediately preceding symbols. Processes modeled in this way are often called Markov processes.

**Markov process** A mathematical model of a set of strings in which the probability of a given symbol occurring depends on the identity of the immediately preceding symbol or the two immediately preceding symbols.

**Markup language** A document specification language that identifies and labels the components of the document’s contents.

**Massively Online Open Course (MOOC)** In a traditional MOOC, the teacher’s content is digitally recorded and made available online, freely, as a sequence of lectures with supporting learning material.

**Master patient index (MPI)** A database that is used across a healthcare organization to maintain consistent, accurate, and current demographic and essential clinical data on the patients seen and managed within its various departments.

**Mean average precision (MAP)** A method for measuring overall retrieval precision in which precision is measured at every point at which a relevant document is obtained, and the MAP measure is found by averaging these points for the whole query.

**Mean time between failures (MTBF)** The average predicted time interval between anticipated operational malfunctions of a system, based on long-term observations.

**Meaningful use** The set of standards defined by the Centers for Medicare & Medicaid

Services (CMS) Incentive Programs that governs the use of electronic health records and allows eligible providers and hospitals to earn incentive payments by meeting specific criteria. The term refers to the belief that health care providers using electronic health records in a meaningful, or effective, way will be able to improve health care quality and efficiency.

**Measurement study** Study to determine the extent and nature of the errors with which a measurement is made using a specific instrument (cf. Demonstration study).

**Measures of concordance** Measures of agreement in test performance: the true-positive and true-negative rates.

**MedBiquitous** A healthcare-specific standards consortium led by Johns Hopkins Medicine.

**Medical computer science** The subdivision of computer science that applies the methods of computing to medical topics.

**Medical computing** The application of methods of computing to medical topics (see medical computer science).

**Medical entities dictionary (MED)** A compendium of terms found in electronic medical record systems. Among the best known MEDs is that developed and maintained by the Columbia University Irving Medical Center and Columbia University. Contains in excess of 100,000 terms.

**Medical errors** Errors or mistakes, committed by health professionals, that hold the potential to result in harm to the patient.

**Medical home** A primary care practice that will maintain a comprehensive problem list to make fully informed decisions in coordinating their care.

**Medical informatics** An earlier term for the biomedical informatics discipline, medical

informatics is now viewed as the subfield of clinical informatics that deals with the management of disease and the role of physicians.

**Medical Information Bus (MIB)** A data-communication system that supports data acquisition from a variety of independent devices.

**Medical information science** The field of study concerned with issues related to the management and use of biomedical information (see also biomedical informatics).

**Medical Literature Analysis and Retrieval System (MEDLARS)** The initial electronic version of Index Medicus developed by the National Library of Medicine.

**Medical Logic Module (MLM)** A single chunk of medical reasoning or decision rule, typically encoded using the Arden Syntax.

**Medical record committees** An institutional panel charged with ensuring appropriate use of medical records within the organization.

**Medical Subject Headings (MeSH)** Some 18,000 terms used to identify the subject content of the biomedical literature. The National Library of Medicine's MeSH vocabulary has emerged as the de facto standard for biomedical indexing.

**Medication** A substance used for medical treatment, typically a medicine or drug.

**MEDLARS Online (MEDLINE)** The National Library of Medicine's electronic catalog of the biomedical literature, which includes information abstracted from journal articles, including author names, article title, journal source, publication date, abstract, and medical subject headings.

**Medline Plus** An online resource from the National Library of Medicine that contains health topics, drug information, medical dictionaries, directories, and other resources, organized for use by health care consumers.

**Megabits per second (Mbps)** A common unit of measure for specifying a rate of data transmission.

**Megabyte**  $2^{20}$  or 1,048,576 bytes.

**Member checking** In subjectivist research, the process of reflecting preliminary findings back to individuals in the setting under study, one way of confirming that the findings are truthful.

**Memorandum of understanding** A document describing a bilateral or multilateral agreement between two or more parties. It expresses a convergence of will between the parties, indicating an intended common line of action.

**Memory** Areas that are used to store programs and data. The computer's working memory comprises read-only memory (ROM) and random access memory (RAM).

**Memory sticks** A portable device that typically plugs into a computer's USB port and is capable of storing data. Also called a "thumb drive" or a "USB drive".

**Mendelian randomization (MR)** A technique used to provide evidence for the causality of a biomarker on a disease state in conditions in which randomized controlled trials are difficult or too expensive to pursue. The technique uses genetic variants that are known to associate with the biomarker as instrument variables.

**Mental images** A form of internal representation that captures perceptual information recovered from the environment.

**Mental models** A construct for describing how individuals form internal models of systems. They are designed to answer questions such as "how does it work?" or "what will happen if I take the following action?".

**Mental representations** Internal cognitive states that have a certain correspondence with the external world.

**Menu** In a user interface, a displayed list of valid commands or options from which a user may choose.

**Merck Medicus** An aggregated set of resources, including Harrison's Online, MDCConsult, and DXplain.

**Meta-analysis** A summary study that combines quantitatively the estimates from individual studies.

**Metabolomic** Pertaining to the study of small-molecule metabolites created as the end-products of specific cellular processes.

**Metadata** Literally, data about data, describing the format and meaning of a set of data.

**Metagenomics** Using DNA sequencing technology to characterize complex samples derived from an environmental sample, e.g., microbial populations. For example, the gut "microbiome" can be characterized by applying next generation sequencing of stool samples.

**Metathesaurus** One component of the Unified Medical Language System, the Metathesaurus contains linkages between terms in Medical Subject Headings (MeSH) and in dozens of controlled vocabularies.

**MIB** See Medical Information Bus.

**Microarray chips** A microchip that holds DNA probes that can recognize DNA from samples being tested.

**Microbiome** The microorganisms in a particular environment (including the body or a part of the body) or the combined genomes of those organisms.

**Microprocessor** An integrated circuit that contains all the functions of a central processing unit of a computer.

**Microsimulation models** Individual-level health state transition models that provide a means to model very complex events flexibly over time.

**MIMIC II Database** See Multiparameter Intelligent Monitoring in Intensive Care.

**Minicomputers** A class of computers that were introduced in the 1960s as a smaller alternative to mainframe computers. Minicomputers enabled smaller companies and departments within organizations (like HCOs) to implement software applications at significantly less cost than was required by mainframe computers.

**Mistake** Occurs when an inappropriate course of action reflects erroneous judgment or inference.

**Mixed-initiative dialog** A mode of interaction with a computer system in which the computer may pose questions for the user to answer, and vice versa.

**Mixed-initiative systems** An educational program in which user and program share control of the interaction. Usually, the program guides the interaction, but the student can assume control and digress when new questions arise during a study session.

**Mobile health (mHealth)** The practice of medicine and public health supported by mobile devices. Also referred to as mHealth or m-health.

**Model organism database** Organized reference databases that combine bibliographic databases, full text, and databases of sequences, structure, and function for organisms whose genomic data has been highly characterized, such as the mouse, fruit fly, and *Sarccchomyces* yeast.

**Model organism databases** Organized reference databases the combine bibliographic databases, full text, and databases of sequences, structure, and function for organisms whose genomic data has been highly characterized, such as the mouse, fruit fly, and *Sarccchomyces* yeast.

**Modem** A device used to modulate and demodulate digital signals for transmission to a remote computer over telephone lines; converts digital data to audible analog signals, and vice versa.

**Modifiers of interest** In natural language processing, a term that is used to describe or otherwise modify a named-entity that has been recognized.

**Molecular imaging** A technique for capturing images at the cellular and subcellular level by marking particular chemicals in ways that can be detected with image or radiodetection.

**Monitoring tool** The application of logical rules and conditions (e.g., range-checking, enforcement of data completion, etc.) to ensure the completeness and quality of research-related data.

**Monotonic** Describes a function that consistently increases or decreases, rather than oscillates.

**Morpheme** The smallest unit in the grammar of a language which has a meaning or a linguistic function; it can be a root of a word (e.g., *-arm*), a prefix (e.g., *re-*), or a suffix (e.g., *-it is*).

**Morphology** The study of meaningful units in language and how they combine to form words.

**Morphometrics** The quantitative study of growth and development, a research area that depends on the use of imaging methods.

**Mosaic** The first graphical web browser credited with popularizing the World Wide Web and developed at the National Center for Supercomputing Applications (NCSA) at the University of Illinois.

**Motion artifact** Visual interference caused by the difference between the frame rate of an imaging device and the motion of the object being imaged.

**Mouse** A small boxlike device that is moved on a flat surface to position a cursor on the screen of a display monitor. A user can select and mark data for entry by depressing buttons on the mouse.

**Multi-axial** A terminology system composed of several distinct, mutually exclusive term sub-sets that are combined to support post-coordination.

**Multimodal interface** A design concept which allows users to interact with computers using multiple modes of communication or tools, including speaking, clicking, or touchscreen input.

**Multiparameter Intelligent Monitoring in Intensive Care (MIMIC-II)** A publicly and freely available research database that encompasses a diverse and very large population of ICU patients. It contains high temporal resolution data including lab results, electronic documentation, and bedside monitor trends and waveforms.

**Multiprocessing** The use of multiple processors in a single computer system to increase the power of the system (see parallel processing).

**Multiprogramming** A scheme by which multiple programs simultaneously reside in the main memory of a single central processing unit.

**Multiprotocol label switching (MPLS)** A mechanism in high-performance telecommunications networks that directs data from one network node to the next based on short path labels

rather than long network addresses, avoiding complex lookups in a routing table.

**Multiuser system** A computer system that shares its resources among multiple simultaneous users.

**Mutually exclusive** State in which one, and only one, of the possible conditions is true; for example, either A or not A is true, and one of the statements is false. When using Bayes' theorem to perform medical diagnosis, we generally assume that diseases are mutually exclusive, meaning that the patient has exactly one of the diseases under consideration and not more.

**Myocardial ischemia** Reversible damage to cardiac muscle caused by decreased blood flow and resulting poor oxygenation. Such ischemia may cause chest pain or other symptoms.

**Naïve Bayesian model** The use of Bayes Theorem in a way that assumes conditional independence of variables that may in fact be linked statistically.

**NAM** See: National Academy of Medicine.

**Name** Designation of an object by a linguistic expression.

**Name authority** An entity or mechanism for controlling the identification and formulation of unique identifiers for names. In the Internet, a name authority is required to associate common domain names with their IP addresses.

**Named-entity normalization** The natural language processing method, after finding a named entity in a document, for linking (normalizing) that mention to appropriate database identifiers.

**Named-entity recognition** In language processing, a subtask of information extraction that seeks to locate and classify atomic elements in text into predefined categories.

**Name-server** In networked environments such as the Internet, a computer that converts a host name into an IP address before the message is placed on the network.

**National Academies** The collective name for the National Academy of Engineering, National Academy of Medicine and National Academy of Sciences which are private, non-profit institutions that provide expert advice on some of the most pressing challenges facing the nation and the world. The work of the National Academies helps shape sound policies, inform public opinion, and advance the pursuit of science, engineering, and medicine.

**National Academy of Medicine (NAM)** An independent organization of eminent professionals from diverse fields including health and medicine; natural, social, and behavioral sciences and more. Established in 1970 as the Institute of Medicine (IOM), and in 2016 the name was changed to the National Academy of Medicine (NAM).

**National Center for Biotechnology Information (NCBI)** Established in 1988 as a national resource for molecular biology information, the NCBI is a component of the National Library of Medicine that creates public databases, conducts research in computational biology, develops software tools for analyzing genome data, and disseminates biomedical information.

**National Committee on Quality Assurance (NCQA)** An independent 501 nonprofit organization in the United States that works to improve health care quality through the administration of evidence-based standards, measures, programs, and accreditation.

**National Guidelines Clearinghouse** A public resource, coordinated by the Agency for Health Research and Quality, that collects and distributes evidence-based clinical practice guidelines (see ► [www.guideline.gov](http://www.guideline.gov)).

**National Health Information Infra-structure (NHII)** A comprehensive knowledge-based network of interoperable systems of clinical, public health, and personal health information that is intended to improve decision-making by making health information available when and where it is needed.

**National Health Information Network (NHIN)** A set of standards, services, and policies that have been shepherded by the Office of the National Coordinator of Health Information Technology to enable secure health information exchange over the Internet.

**National Information Standards Organization (NISO)** A non-profit association accredited by the American National Standards Institute (ANSI), that identifies, develops, maintains, and publishes technical standards to manage information (see ► [www.niso.org](http://www.niso.org)).

**National Institute for Standards and Technology (NIST)** A non-regulatory federal agency within the U.S. Commerce Department's Technology Administration; its mission is to develop and promote measurement, standards, and technology to enhance productivity, facilitate trade, and improve the quality of life (see ► [www.nist.gov](http://www.nist.gov)).

**National Library of Medicine (NLM)** The government-maintained library of biomedicine that is part of the US National Institutes of Health.

**National Quality Forum** A not-for-profit organization that develops and implements national strategies for health care quality measurement and reporting.

**Nationwide Health Information Network (NwHIN)** A set of standards, services, and policies that have been shepherded by the Office of the National Coordinator of Health Information Technology to enable secure health information exchange over the Internet.

**Natural language** Unfettered spoken or written language. Free text.

**Natural language processing (NLP)** Facilitates tasks by enabling use of automated methods that represent the relevant information in the text with high validity and reliability.

**Natural language query** A question expressed in unconstrained text, from which meaning must somehow be extracted or inferred so that a suitable response can be generated.

**Naturalistic** Describes a study in which little if anything is done by the evaluator to alter the setting in which the study is carried out.

**NCBI Entrez global query** A search interface that allows searching over all data and information resources maintained by NCBI.

**NCI Thesaurus** A large ontology developed by the National Cancer Institute that describes entities related to cancer biology, clinical oncology, and cancer epidemiology.

**NCQA** See National Committee on Quality Assurance.

**Needs assessment** A study carried out to help understand the users, their context and their needs and skills, to inform the design of the information resource.

**Negative dictionary** A list of stop words used in information retrieval.

**Negative predictive value (PV<sup>-</sup>)** The probability that the condition of interest is absent if the result is negative—for example, the probability that specific a disease is absent given a negative test result.

**Negligence theory** A concept from tort law that states that providers of goods and services are expected to uphold the standards of the community, thereby facing claims of negligence if individuals are harmed by substandard goods or services.

**Nested structures** In natural language processing, a phrase or phrases that are used in place of simple words within other phrases.

**Net reclassification improvement (NRI)** In classification methods, a measure of the net fraction of reclassifications made in the correct direction, using one method over another method without the designated improvement.

**Network access provider** A company that builds and maintains high speed networks to which customers can connect, generally to access the Internet (see also Internet service provider).

**Network Operations Center (NOC)** A centralized monitoring facility for physically distributed computer and/or telecommunications facilities that allows continuous real-time reporting of the status of the connected components.

**Network protocol** The set of rules or conventions that specifies how data are prepared and transmitted over a network and that governs data communication among the nodes of a network.

**Network stack** The method within a single machine by which the responsibilities for network communications are divided into different levels, with clear interfaces between the levels, thereby making network software more modular.

**Neuroinformatics** An emerging subarea of applied biomedical informatics in which the discipline's methods are applied to the management of neurological data sets and the modeling of neural structures and function.

**Next Generation Internet Initiative** A federally funded research program in the late 1990s and early in the current decade that sought to provide technical enhancements to the Internet to support future applications that currently are infeasible or are incapable of scaling for routine use.

**Next generation sequencing methods** Technologies for performing high throughput sequencing of large quantities of DNA or RNA. Typically, these technologies determine the sequences of many millions of short segments of DNA that need to be reassembled and interpreted using bioinformatics.

**NHIN Connect** A software solution that facilitates the exchange of healthcare information at both the local and national level. CONNECT leverages eHealth Exchange standards and governance and Direct Project specifications to help drive interoperability across health information exchanges throughout the country. Initially developed by federal agencies to support specific healthcare-related missions, CONNECT is now available to all organizations as downloadable open source software.

**NHIN Direct** A set of standards and services to enable the simple, direct, and secure transport of health information between pairs of health care providers; it is a component of the Nationwide Health Information Network and it complements the Network's more sophisticated components.

**NHIN** See: National Health Information Network.

**Noise** The component of acquired data that is attributable to factors other than the underlying phenomenon being measured (for example, electromagnetic interference, inaccuracy in sensors, or poor contact between sensor and source).

**Nomenclature** A system of terms used in a scientific discipline to denote classifications and relationships among objects and processes.

**Nosocomial hospital-acquired infection** An infection acquired by a patient after admission to a hospital for a different reason.

**NQF** See: National Quality Forum.

**Nuclear magnetic resonance (NMR) spectroscopy** A spectral technique used in chemistry to characterize chemical compounds by measuring magnetic characteristics of their atomic nuclei.

**Nuclear medicine imaging** A modality for producing images by measuring the radiation emitted by a radioactive isotope that has been attached to a biologically active compound and injected into the body.

**Nursing informatics** The application of biomedical informatics methods and techniques to problems derived from the field of nursing. Viewed as a subarea of clinical informatics.

**NwHIN Direct** A set of standards and services to enable the simple, direct, and secure transport of health information between pairs of health care providers; it is a component of the Nationwide Health Information Network and it complements the Network's more sophisticated components.

**Nyquist frequency** The minimum sampling rate necessary to achieve reasonable signal quality. In general, it is twice the frequency of the highest-frequency component of interest in a signal.

**Object** Any part of the perceivable or conceivable world.

**Object Constraint Language (OCL)** A textual language for describing rules that apply to the elements a model created in the Uniform Modeling Language. OCL specifies constraints on allowable values in the model. OCL also supports queries of UML models (and of models constructed in similar languages). OCL is a standard of the Object Modeling Group (OMG), and forms the basis of the GELLO query language that may be used in conjunction with the Arden Syntax.

**Objectivist approaches** Class of evaluation approaches that make use of experimental designs and statistical analyses of quantitative data.

**Object-oriented database** A database that is structured around individual objects (concepts) that generally include relationships among those objects and, in some cases, executable code that is relevant to the management and or understanding of that object.

**Odds-ratio form** An algebraic expression for calculating the posttest odds of a disease, or other condition of interest, if the pretest odds and likelihood ratio are known (an alternative formulation of Bayes' theorem, also called the odds-likelihood form).

**Office of the National Coordinator for Health Information Technology (ONC)** An agency within the US Department of Health and Human Services that is charged with supporting the adoption of health information technology and promoting nationwide health information exchange to improve health care.

**Omics** A set of areas of study in biology that use the suffix “-ome”, used to connote breadth or completeness of the objects being studied, for example genomics or proteomics.

**-omics technologies** High throughput experimentation that exhaustively queries a certain biochemical aspect of the state of an organism. Such technologies include proteomics (protein), genomics (gene expression), metabolomics (metabolites), etc.

**On line analytic processing (OLAP)** A system that focuses on querying across multiple patients simultaneously, typically by few users for infrequent, but very complex queries, often research.

**On line transaction processing (OLTP)** A system designed for use by thousands of simultaneous users doing repetitive queries.

**Ontology** A description (like a formal specification of a program) of the concepts and relationships that can exist for an agent or a community of agents. In biomedicine, such ontologies typically specify the meanings and

hierarchical relationships among terms and concepts in a domain.

**Open access publishing (OA)** An approach to publishing where the author or research funder pays the cost of publication and the article is made freely available on the Internet.

**Open consent model** A legal mechanism by which an individual can disclose their own private health information or genetic information for research use. This mechanism is used by the Personal Genome Project to enable release of entire genomes of identified individuals.

**Open source** An approach to software development in which programmers can read, redistribute, and modify the source code for a piece of software, resulting in community development of a shared product.

**Open standards development policy** In standards group, a policy that allows anyone to become involved in discussing and defining the standard.

**OpenNotes** An international movement that urges doctors, nurses, therapists, and other clinicians to invite patients to read notes that clinicians write to describe a visit. OpenNotes provides free tools and resources to help clinicians and healthcare systems share notes with patients.

**Operating system (OS)** A program that allocates computer hardware resources to user programs and that supervises and controls the execution of all other programs.

**Optical Character Recognition (OCR)** The conversion of typed text within scanned documents to computer understandable text.

**Optical coherence tomography (OCT)** An optical signal acquisition and processing method. It captures micrometer-resolution, three-dimensional images from within optical scattering media (e.g., biological tissue).

**Optical disk** A round, flat plate of plastic or metal that is used to store information. Data are encoded through the use of a laser that marks the surface of the disc.

**Order entry** The use of a computer system for entering treatments, requests for lab tests or radiologic studies, or other interventions that the attending clinician wishes to have performed for the benefit of a patient.

**Orienting issues/questions** The initial questions or issues that evaluators seek to answer in a subjectivist study, the answers to which often in turn prompt further questions.

**Outcome data** Formal information regarding the results of interventions.

**Outcome measurements** Using metrics that assess the end result of an intervention rather than an intervening process. For example, remembering to check a patient's Hemoglobin A1C is a process measure, whereas reducing the complications of diabetes is an outcome measure.

**Outcome variable** Similar to "dependent variable," a variable that captures the end result of a health care or educational process; for example, long-term operative complication rate or mastery of a subject area.

**Outpatient** A patient seen in a clinic rather than in the hospital setting.

**Output** The results produced when a process is applied to input. Some forms of output are hardcopy documents, images displayed on video display terminals, and calculated values of variables.

**P4 medicine** P4 medicine: a term coined by Dr. Leroy Hood for healthcare that strives to be personalized, predictive, preventive and participatory.

**Packets** In networking, a variable-length message containing data plus the network addresses of the sending and receiving nodes, and other control information.

**Page** A partitioned component of a computer users' programs and data that can be kept in temporary storage and brought into main memory by the operating system as needed.

**Pager** One of the first mobile devices for electronic communication between a base station (typically a telephone, but later a computer) and an individual person. Initially restricted to receiving only numeric data (e.g., a telephone number), pagers later incorporated the ability to transmit a response (referred to as "two way pagers") as well as alpha characters so that a message of limited length could be transmitted from a small keyboard. Pagers have been gradually replaced by cellular phones because of their greater flexibility and broader geographical coverage.

**PageRank (PR) algorithm** In indexing for information retrieval on the Internet, an algorithmic scheme for giving more weight to a Web page when a large number of other pages link to it.

**Parallel processing** The use of multiple processing units running in parallel to solve a single problem (see multiprocessing).

**Parse tree** The representation of structural relationships that results when using a grammar (usually context free) to analyze a given sentence.

**Partial parsing** The analysis of structural relationships that results when using a grammar to analyze a segment of a given sentence.

**Partial-match searching** An approach to information retrieval that recognizes the inexact nature of both indexing and retrieval, and attempts to return the user content ranked by how close it comes to the user's query.

**Participant calendaring** Participant calendaring refers to the capability of a CRMS to support the tracking of participant compliance with a study schema, usually represented as a calendar of temporal events.

**Participant screening and registration** participant screening and registration refers to the capability of a CTMS to support the enrollment phase of a clinical study.

**Participants** The people or organizations who provide data for the study. According to the role of the information resource, these may include patients, friends and family, formal and informal carers, the general public, health professionals, system developers, guideline developers, students, health service managers, etc.

**Part-of-speech tags** Assignment of syntactic classes to a given sequence of words, e.g., determiner, adjective, noun and verb.

**Parts of speech** The categories to which words in a sentence are assigned in accordance with their syntactic function.

**Patent** A specific legal approach for protecting methods used in implementing or instantiating ideas (see intellectual property).

**Pathognomonic** Distinctively characteristic, and thus, uniquely identifying a condition or object (100% specific).

**Patient centered care** Clinical care that is based on personal characteristics of the patient in addition to his or her disease. Such characteristics include cultural traditions, preferences and values, family situations and lifestyles.

**Patient centered medical home** A team-based health care delivery model led by a physician, physician's assistant, or nurse practitioner that provides comprehensive, coordinated, and continuous medical care to patients with the goal of obtaining maximized health outcomes.

**Patient engagement** Participation of a patient as an active collaborator in his or her health care process.

**Patient generated health data** Health-related data that are recorded or collected directly by patients.

**Patient portal** An online application that allows individuals to view health information and otherwise interact with their physicians and hospitals.

**Patient record** The collection of information traditionally kept by a health care provider or organization about an individual's health status and health care; also referred to as the patient's chart, medical record, or health record, and originally called the "unit record".

**Patient safety** The reduction in the risk of unnecessary harm associated with health care to an acceptable minimum; also the name of a movement and specific research area.

**Patient triage** The process of allocating patients to different levels or urgency of care depending upon the complaints or symptoms displayed.

**Patient-specific information** Information derived and organized from a specific patient.

**Patient-tracking applications** Monitor patient movement in multistep processes.

**Pattern check** A procedure applied to entered data to verify that the entered data have a required pattern; e.g., the three digits, hyphen, and four digits of a local telephone number.

**Pay for performance** Payments to providers that are based on meeting pre-defined expectations for quality.

**Per diem** Payments to providers (typically hospitals) based on a single day of care.

**Perimeter definition** Specification of the boundaries of trusted access to an information system, both physically and logically.

**Personal clinical electronic communication** Web-based messaging solutions that avoid the limitations of email by keeping all interactions within a secure, online environment.

**Personal computers** A small, relatively inexpensive, single-user computer.

**Personal Digital Assistants (PDA)** A small, mobile, handheld device that provides computing and information storage and retrieval capabilities for personal or business use. PDAs can typically run third-party applications.

**Personal grid architecture** A security methodology that prevents large-scale data loss from a central repository by separately storing and encrypting each person's records. While searching across records must be sequential, reasonable response times can be achieved by massive parallelization of the search process in the cloud.

**Personal health application** Software for computers, tablet computers, or smart phones that are intended to allow individual patients to monitor their own health or to stimulate their own personal health activities.

**Personal health informatics** The area of biomedical informatics based on patient-centered care, in which people are able to access care that is coordinated and collaborative.

**Personal health record (PHR)** A collection of information about an individual's health status and health care that is maintained by the individual (rather than by a health care provider); the data may be entered directly by the patient, captured from a sensing device, or transferred from a laboratory or health care provider. It may include medical information from several independent provider organizations, and may also have health and well-being information.

**Personal Internetworked Notary and Guardian (PING)** An early personally controlled health record, later known as Indivo.

**Personalized medicine** Also often called individualized medicine, refers to a medical model in which decisions are custom-tailored to the patient based on that individual's genomic data, preferences, or other considerations. Such decisions may involve diagnosis, treat-

ment, or assessments of prognosis. Also known as precision medicine.

**Personally controlled health record (PCHR)** Similar to a PHR, the PCHR differs in the nature of the control offered to the patient, with such features as semantic tags on data elements that can be used to determine the subsets of information that can be shared with specific providers.

**Petabyte** A unit of information equal to 1000 terabytes or  $10^{15}$  bytes.

**Pharmacodynamics program (PD)** The study of how a drug works, its mechanism of action and pathway of achieving its effect, or "what the drug does to the body".

**Pharmacogenetics** The study of drug-gene relationships that are dominated by a single gene.

**Pharmacogenomic variant** A particular genetic variant that affects a drug-genome interaction.

**Pharmacokinetic program** Pharmacokinetics or PK is the study of how a drug is absorbed, distributed, metabolized and excreted by the body, or "what the body does to the drug".

**Pharmacovigilance** The pharmacological science relating to the collection, detection, assessment, monitoring, and prevention of adverse effects with pharmaceutical products.

**Phase** In the context of clinical research, study phases are used to indicate the scientific aim of a given clinical trial. There are 4 phases (Phase I, Phase II, Phase III, and Phase IV).

**Phase I (clinical trial)** Investigators evaluate a novel therapy in a small group of participants in order to assess overall safety. This safety assessment includes dosing levels in the case of non-interventional therapeutic trials, and potential side effects or adverse effects of the therapy. Often, Phase I trials of non-interventional therapies involve the use of normal volunteers who do not have the disease state targeted by the novel therapy.

**Phase II (clinical trial)** Investigators evaluate a novel therapy in a larger group of participants in order to assess the efficacy of the treatment in the targeted disease state. During this phase, assessment of overall safety is continued.

**Phase III (clinical trial)** Investigators evaluate a novel therapy in an even larger group of participants and compare its performance to a reference standard which is usually the current standard of care for the targeted disease state. This phase typically employs a randomized controlled design, and often a multi-center RCT given the numbers of variation of subjects that must be recruited to adequately test the hypothesis. In general, this is the final study phase to be performed before seeking regulatory approval for the novel therapy and broader use in standard- of-care environments.

**Phase IV (clinical trial)** Investigators study the performance and safety of a novel therapy after it has been approved and marketed. This type of study is performed in order to detect long-term outcomes and effects of the therapy. It is often called “post-market surveillance” and is, in fact, not an RCT at all, but a less formal, observational study.

**PheKB.org** A web site that houses EHR-based algorithms for determining phenotypes.

**Phenome characterization** Identification of the individual traits of an organism that characterize its phenotype.

**Phenome-wide association scan** A study that derives case and controls populations using the EMR to define clinical phenotypes and then examines the association of those phenotypes with specific genotypes.

**Phenome-wide association study (PheWAS)** A study that tests for association between a particular genetic variant and a large number of phenotypic characteristics.

**Phenotype** The observable physical characteristics of an organism, produced by the interaction of genotype with environment.

**Phenotype definition** The process of determining the set of observable descriptors that characterize an organism’s phenotype.

**Phenotype risk score (PheRS)** A calculation of the likelihood of a particular genetic variant being present based on a weighed score of one or more phenotypic characteristics.

**Phenotypic** Refers to the physical characteristics or appearance of an organism.

**Picture Archive and Communication Systems (PACS)** An integrated computer system that acquires, stores, retrieves, and displays digital images.

**Pixel** One of the small picture elements that makes up a digital image. The number of pixels per square inch determines the spatial resolution. Pixels can be associated with a single bit to indicate black and white or with multiple bits to indicate color or gray scale.

**Placebo** In the context of clinical research, a placebo is a false intervention (e.g., a mock intervention given to a participant that resembles the intervention experienced by individuals receiving the experimental intervention, except that it has no anticipated impact on the individual’s health or other indicated status), usually used in the context of a control group or intervention.

**Plain old telephone service (POTS)** The standard low speed, analog telephone service that is still used by many homes and businesses.

**Plastination** A method of embalming a part of a human body using plastic to suffuse human tissue.

**Plug-in** A software component that is added to web browsers or other programs to allow them a special functionality, such as an ability to deal with certain kinds of media (e.g., video or audio).

**Pointing device** A manual device, such as a mouse, light pen, or joy stick, that can be used

to specify an area of interest on a computer screen.

**Polygenic risk score (PRS)** See Genetic risk score.

**Population Health** is not universally defined but is a commonly used term to organize activities performed by private or public entities for assessing, managing, and improving the well-being and health outcomes of a defined group of individuals. Population may be defined by a specific geographic community or region; enrollees of a health plan; persons residing in a health systems catchment area; or an aggregation of individuals with specific conditions. Population health is based on the underlying assumption that multiple common factors impact the health and well-being of specific populations, and that focused interventions early in the causal chain of disease may save resources, and prevent morbidity and mortality.

**Population management** Health care practices that assist with a large group of people, including preventive medicine and immunization, screening for disease, and prioritization of interventions based on community needs.

**Positive predictive value (PV+)** The probability that the condition of interest is true if the result is positive—for example, the probability that a disease is present given a positive test result.

**Positron emission tomography** A tomographic imaging method that measures the uptake of various metabolic products (generally a combination of a positron-emitting tracer with a chemical such as glucose), e.g., by the functioning brain, heart, or lung.

**Postcoordination** The combination of two or more terms from one or more terminologies to create a phrase used for coding data; for example, “Acute Inflammation” and “Appendix” combined to code a patient with appendicitis. See also, precoordination.

**Posterior probability** The updated probability that the condition of interest is present after additional information has been acquired.

**Postgenomic database** A database that combines molecular and genetic information with data of clinical importance or relevance. *Online Mendelian Inheritance in Man (OMIM)* is a frequently cited example of such a database.

**Post-test probability** The updated probability that the disease or other condition under consideration is present after the test result is known (more generally, the posterior probability).

**Practice management system** The software used by physicians for scheduling, registration, billing, and receivables management in their offices. May increasingly be linked to an EHR.

**Pragmatics** The study of how contextual information affects the interpretation of the underlying meaning of the language.

**Precision** The degree of accuracy with which the value of a sampled observation matches the value of the underlying condition, or the exactness with which an operation is performed. In information retrieval, a measure of a system’s performance in retrieving relevant information (expressed as the fraction of relevant records among total records retrieved in a search).

**Precision Medicine** The application of specific diagnostic and therapeutic methods matched to an individual based on highly unique information about the individual, such as their genetic profile or properties of their tumor.

**Precoordination** A complex phrase in a terminology that can be constructed from multiple terms but is, itself, assigned a unique identifier within the terminology; for example, “Acute Inflammation of the Appendix.” See also, postcoordination.

**Predatory journal** A name given to journals that publish under the OA model and have no to minimal peer review of submitted papers.

**Predicate** The part of a sentence or clause containing a verb and stating something about the subject.

**Predicate logic** In mathematical logic, the generic term for symbolic formal systems like first-order logic, second-order logic, etc.

**Predictive value (PV)** The posttest probability that a condition is present based on the results of a test (see positive predictive value and negative predictive value).

**Preparatory phase** In the preparatory phase of a clinical research study, investigators are involved in the initial design and documentation of a study (developing a protocol document), prior to the identification and enrollment of study participants.

**President's Emergency Plan for AIDS Relief (PEPFAR)** The United States government's response to the global HIV/AIDS epidemic, and represents the largest commitment by any nation to address a single disease in history. PEPFAR is intended to save and improved millions of lives, accelerating progress toward controlling and ultimately ending the AIDS epidemic as a public health threat. PEPFAR collects and uses data in the most granular manner (disaggregated by sex, age, and at the site level) to do the right things, in the right places, and right now within the highest HIV-burdened populations and geographic locations.

**Pretest probability** The probability that the disease or other condition under consideration is present before the test result is known (more generally, the prior probability).

**Prevalence** The frequency of the condition under consideration in the population. For example, we calculate the prevalence of disease by dividing the number of diseased individuals by the number of individuals in the

population. Prevalence is the prior probability of a specific condition (or diagnosis), before any other information is available.

**Primary knowledge-based information** The original source of knowledge, generally in a peer reviewed journal article that reports on a research project's results.

**Prior probability** The probability that the condition of interest is present before additional information has been acquired. In a population, the prior probability also is called the prevalence.

**Privacy** A concept that applies to people, rather than documents, in which there is a presumed right to protect that individual from unauthorized divulging of personal data of any kind.

**Probabilistic context free grammar** A context free grammar in which the possible ways to expand a given symbol have varying probabilities rather than equal weight.

**Probabilistic relationship** Exists when the occurrence of one chance event affects the probability of the occurrence of another chance event.

**Probabilistic sensitivity analysis** An approach for understanding how the uncertainty in all (or a large number of) model parameters affects the conclusion of a decision analysis.

**Probability** Informally, a means of expressing belief in the likelihood of an event. Probability is more precisely defined mathematically in terms of its essential properties.

**Probabilistic causal network** Also known as a Bayesian network, a statistical model built of directed acyclic graph structures (nodes) that are connected through relationships (edges). The strength of each of the relationships is defined through conditional probabilities.

**Probes** Genetic markers used in genetic assays to determine the presence or absence of a particular variant.

**Problem impact study** A study carried out in the field with real users as participants and real tasks to assess the impact of the information resource on the original problem it was designed to resolve.

**Problem space** The range of possible solutions to a problem.

**Problem-based learning** Small groups of students, supported by a facilitator, learned through discussion of individual case scenarios.

**Procedural knowledge** Knowledge of how to perform a task (as opposed to factual knowledge about the world).

**Procedure** An action or intervention undertaken during the management of a patient (e.g., starting an IV line, performing surgery). Procedures may also be cognitive.

**Procedure trainer** (Also Part-task trainer). An on-screen simulation of a surgical or other procedure that is controlled using physical tools such as an endoscope. It allows repeated practice of a specific skill.

**Process integration** An organizational analysis methodology in which a series of tasks are reviewed in terms of their impact on each other rather than being reviewed separately. In a hospital setting, for example, a process integration view would look at patient registration and scheduling as an integrated workflow rather than as separate task areas. The goal is to achieve greater efficiency and effectiveness by focusing on how tasks can better work together rather than optimizing specific areas.

**Prodrug** A chemical that requires transformation *in vivo* (typically by enzymes) to produce its active drug.

**Product** An object that goes through the processes of design, manufacture, distribution, and sale.

**Prognostic scoring system** An approach to prediction of patient outcomes based on formal analysis of current variables, generally through methods that compare the patient in some way with large numbers of similar patients from the past.

**Progressive caution** The idea that reason, caution and attention to ethical issues must govern research and expanding applications in the field of biomedical informatics.

**Propositions** An expression, generally in language or other symbolic form, that can be believed, doubted, or denied or is either true or false.

**Prospective study** An experiment in which researchers, before collecting data for analysis, define study questions and hypotheses, the study population, and data to be collected.

**Prosthesis** A device that replaces a body part—e.g., artificial hip or heart.

**Protected memory** An segment of computer memory that cannot be over-written by the usual means.

**Protein Data Bank (PDB)** A centralized repository of experimentally determined three dimensional protein and nucleic acid structures.

**Proteomics** The study of the protein products produced by genes in the genome.

**Protocol** A standardized method or approach.

**Protocol analysis** In cognitive psychology, methods for gathering and interpreting data that are presumed to reveal the mental processes used during problem solving (e.g., analysis of “think-aloud” protocols).

**Protocol authoring tools** A software product used by researchers to construct a description of a study’s rationale, guidelines, endpoints, and the like. Such descriptions may be structured formally so that they can be manipulated by trial management software.

**Protocol management** Protocol management refers to the capability of a CRMS to support the preparatory phase of a clinical study.

**Provider-profiling system** Software that utilizes available data sources to report on patterns of care by one or several providers.

**Pseudo-identifier** A unique identifier substituted for the real identifier to mask the identify but can under certain circumstances allow linking back to the original person identifier if needed.

**Public health** The field that deals with monitoring and influencing trends in habits and disease in an effort to protect or enhance the health of a population, from small communities to entire countries.

**Public health informatics** An application area of biomedical informatics in which the field's methods and techniques are applied to problems drawn from the domain of public health.

**Public health informatics** The systematic application of informatics methods and tools to support public health goals and outcomes, regardless of the setting.

**Public Health Surveillance** The ongoing systematic collection, analysis, and interpretation of data (e.g., regarding agent/hazard, risk factor, exposure, health event) essential to the planning, implementation, and evaluation of public health practice, closely integrated with the timely dissemination of these data to those responsible for prevention and control. ► <http://www.aphl.org/Pages/default.aspx>. Also see Biosurveillance and Surveillance.

**Public Library of Science (PLOS)** A family of scientific journals that is published under the open-access model.

**Publication type** One of several classes of articles or books into which a new publication will fall (e.g., review articles, case reports, original research, textbook, etc.).

**Public-key cryptography** In data encryption, a method whereby two keys are used, one to encrypt the information and a second to decrypt it. Because two keys are involved, only one needs be kept secret.

**Public-private keys** A pair of sequences of characters or digits used in data encryption in which one is kept private and the other is made public. A message encrypted with the public key can only be opened by the holder of the private key, and a message signed with the private key can be verified as authentic by anyone with the public key.

**PubMed** A software environment for searching the Medline database, developed as part of the suite of search packages, known as Entrez, by the NLM's National Center for Biotechnology Information (NCBI).

**PubMed Central (PMC)** An effort by the National Library of Medicine to gather the full-text of scientific articles in a freely accessible database, enhancing the value of Medline by providing the full articles in addition to titles, authors, and abstracts.

**QRS wave** In an electrocardiogram (ECG), the portion of the wave form that represents the time it takes for depolarization of the ventricles.

**Quality assurance** A means for monitoring and maintaining the goodness of a service, product, or process.

**Quality Data Model** An information model that describes the relationships between patient data and clinical concepts in a standardized format. The model was originally proposed to enable electronic quality-performance measurement and it is now aligned with CDS standards.

**Quality management** A specific effort to let quality of care be the goal that determines changes in processes, staffing, or investments.

**Quality measurements** Numeric metrics that assess the quality of health care services. Examples of quality measures include the portion of a physician's patients who are screened for breast cancer and 30-day hospital readmission rates. These measurements have traditionally been derived from administrative claims data or paper charts but there is increasing interest in using clinical data from electronic sources.

**Quality-adjusted life year (QALY)** A measure of the value of a health outcome that reflects both longevity and morbidity; it is the expected length of life in years, adjusted to account for diminished quality of life due to physical or mental disability, pain, and so on.

**Quasi-experiments** A quasiexperiment is a non-randomized, observational study design in which conclusions are drawn from the evaluation of naturally occurring and non-controlled events or cases.

**Query** The ability to extract information from an EHR based on a set of criteria; e.g., one could query for all patients with diabetes who have missed their follow-up appointments.

**Query and Reporting Tool** Software that supports both the planned and ad-hoc extraction and aggregation of data sets from multiple data forms or equivalent data capture instruments used within a clinical trials management system.

**Query-response cycle** For a database system, the process of submitting a single request for information and receiving the results.

**Question answering (QA)** A computer-based process whereby a user submits a natural language question that is then automatically answered by returning a specific response (as opposed to returning documents).

**Question understanding** A form of natural language understanding that supports computer-based question answering.

**Radiology** The medical field that deals with the definition of health conditions through the use of visual images that reflect information from within the human body.

**Radiology Information System (RIS)** Computer-based information system that supports radiology department operations; includes management of the film library, scheduling of patient examinations, reporting of results, and billing.

**Random-access memory (RAM)** The portion of a computer's working memory that can be both read and written into. It is used to store the results of intermediate computation, and the programs and data that are currently in use (also called variable memory or core memory).

**Randomized clinical trial (RCT)** A prospective experiment in which subjects are randomly assigned to study subgroups to compare the effects of alternate treatments.

**Randomly** Without bias.

**Range check** A procedure applied to entered data that detects or prevents entry of values that are out of range; e.g., a serum potassium level of 50.0 mmol/L—the normal range for healthy individuals is 3.5–5.0 mol/L.

**Ransomware** Malicious software that blocks access to a computer system or its data until a sum of money is paid to the perpetrators.

**Read-only memory (ROM)** The portion of a computer's working memory that can be read, but not written into.

**Really simple syndication (RSS)** A form of XML that publishes a list of headlines, article titles or events encoded in a way that can be easily read by another program called a news aggregator or news reader.

**Real-time acquisition** The continuous measurement and recording of electronic signals through a direct connection with the signal source.

**Real-time feedback** This is feedback to the learner in response to each action taken by the learner. Real time feedback is particularly useful in the initial steps of learning a topic. As the learner becomes more experienced with a topic, real time feedback is often withdrawn and summative feedback is provided at the end of a session.

**Recall** In information retrieval, the ability of a system to retrieve relevant information (expressed as the ratio of relevant records retrieved to all relevant records in the database).

**Receiver** In data interchange, the program or system that receives a transmitted message.

**Receiver operating characteristic (ROC)** A graphical plot that depicts the performance of a binary classifier system as its discrimination threshold is varied.

**Records** In a data file, a group of data fields that collectively represent information about a single entity.

**Reductionist approaches** An attempt to explain phenomena by reducing them to common, and often simple, first principles.

**Reductionist biomedical model** A model of medical care that emphasizes pathophysiology and biological principles. The model assumes that diseases can be understood purely in terms of the component biological processes that are altered as a consequence of illness.

**Reference Information Model (RIM)** The data model for HL7 Version 3.0. The RIM describes the kinds of information that may be transmitted within health-care organizations, and includes *acts* that may take place (procedures, observations, interventions, and so on), relationships among acts, the manner in which health-care personnel, patients, and other entities may participate in such acts, and the roles that can be assumed by the participants (patient, provider, specimen, and so on).

**Reference resolution** In NLP, recognizing that two mentions in two different textual locations refer to the same entity.

**Reference standard** See gold standard test.

**Referential expression** A sequence of one or more words that refers to a particular person, object or event, e.g., “she,” “Dr. Jones,” or “that procedure”.

**Referral bias** In evaluation studies, a bias that is introduced when the patients entering a study are in some way atypical of the total population, generally because they have been referred to the study based on criteria that reflect some kind of bias by the referring physicians.

**Region of interest (ROI)** A selected subset of pixels within an image identified for a particular purpose.

**Regional Extension Centers (RECs)** In the context of health information technology, the 60+ state and local organizations (initially funded by ONC) to help primary care providers in their designated area adopt and use EHRs through out-reach, education, and technical assistance.

**Regional Health Information Organization (RHIO)** A community-wide, multi-stakeholder organization that utilizes information technology to make more complete patient information and decision support available to authorized users when and where needed.

**Regional network** A network that provides regional access from local organizations and individuals to the major backbone networks that interconnect regions.

**Registers** In a computer, a group of electronic switches used to store and manipulate numbers or text.

**Registry** A data system designed to record and store information about the health status of patients, often including the care that they

receive. Such collections are typically organized to include patients with a specific disease or class of diseases.

**Regular expression** A mathematical model of a set of strings, defined using characters of an alphabet and the operators concatenation, union and closure (zero or more occurrences of an expression).

**Regulated Clinical Research Information Management (RCRIM)** An HL7 workgroup that is developing standards to improve information management for preclinical and clinical research.

**Relations among named entities** The characterization of two entities in NLP with respect to the semantic nature of the relationship between them.

**Relative recall** An approach to measuring recall when it is unrealistic to enumerate all the relevant documents in a database. Thus the denominator in the calculation of recall is redefined to represent the number of relevant documents identified by multiple searches on the query topic.

**Relevance judgment** In the context of information retrieval, a judgment of which documents should be retrieved by which topics in a test collection.

**Relevance ranking** The degree to which the results are relevant to the information need specified in a query.

**Reminder message** A computer-generated warning that is generated when a record meets prespecified criteria, often referring to an action that is expected but is frequently forgotten; e.g., a message that a patient is due for an immunization.

**Remote access** Access to a system or to information therein, typically by telephone or communications network, by a user who is physically removed from the system.

**Remote Intensive Care** Use of networked communications methods to monitor patients in an intensive care unit from a distance far removed from the patients themselves. See remote monitoring.

**Remote interpretation** Evaluating tests (especially imaging studies) by having them delivered digitally to a location that may be far removed from the patient.

**Remote monitoring** The use of electronic devices to monitor the condition of a patient from a distant location. Typically used to refer to the ability to record and review patient data (such as vital signs) by a physician located in his/her office or a hospital while the patient remains at home. See also remote intensive care.

**Remote-presence health care** The use of video teleconferencing, image transmission, and other technologies that allow clinicians to evaluate and treat patients in other than face-to-face situations.

**Report generation** A mechanism by which users specify their data requests on the input screen of a program that then produces the actual query, using information stored in a database schema, often at predetermined intervals.

**Representation** A level of medical data encoding, the process by which as much detail as possible is coded.

**Representational effect** The phenomenon by which different representations of a common abstract structure can have a significant effect on reasoning and decision making.

**Representational state** A particular configuration of an information-bearing structure, such as a monitor display, a verbal utterance, or a printed label, that plays some functional role in a process within the system.

**Representativeness** A heuristic by which a person judges the chance that a condition is true based on the degree of similarity between the current situation and the ste-

reotypical situation in which the condition is true. For example, a physician might estimate the probability that a patient has a particular disease based on the degree to which the patient's symptoms matches the classic disease profile.

**Request for Proposals** A formal notification of a funding opportunity, requiring application through submission of a grant proposal.

**Research protocol** In clinical research, a prescribed plan for managing subjects that describes what actions to take under specific conditions.

**Resource Description Framework (RDF)** An emerging standard for cataloging metadata about information resources (such as Web pages) using the Extensible Markup Language (XML).

**RESTful API** A “lightweight” application programming interface that enables the transfer of data between two Web-based software systems.

**Results reporting** A software system or subsystem used to allow clinicians to access the results of laboratory, radiology, and other tests for a patient.

**Retrieval** A process by which queries are compared against an index to create results for the user who specified the query.

**Retrospective chart review** The use of past data from clinical charts (classically paper records) of selected patients in order to perform research regarding a clinical question. See also retrospective study.

**Retrospective study** A research study performed by analyzing data that were previously gathered for another purpose, such as patient care. See also retrospective chart review.

**Return on investment** A metric for the benefits of an investment, equal to the net benefits of an investment divided by its cost.

**Review of systems** The component of a typical history and physical examination in which the physician asks general questions about each of the body's major organ systems to discover problems that may not have been suggested by the patient's chief complaint.

**RFP** See: Request for Proposals.

**Ribonucleic acid (RNA)** Ribonucleic acid, a nucleic acid present in all living cells. Its principal role is to act as a messenger carrying instructions from DNA in the production of proteins.

**Rich text format (RTF)** A format developed to allow the transfer of graphics and formatted text between different applications and operating systems.

**RIM** See Reference Information Model.

**Risk attitude** A person's willingness to take risks.

**Risk-neutral** Having the characteristic of being indifferent between the expected value of a gamble and the gamble itself.

**Role-limited access** The mechanism by which an individual's access to information in a database, such as a medical record, is limited depending upon that user's job characteristics and their need to have access to the information.

**Router/switch** In networking, a device that sits on the network, receives messages, and forwards them accordingly to their intended destination.

**RS-232** A commonly used standard for serial data communication that defines the number and type of the wire connections, the voltage, and the characteristics of the signal, and thus allows data communication among electronic devices produced by different manufacturers.

**RSS feed** A bibliographic message stream that provides content from Internet sources.

**Rule engine** A software component that implements an inference engine that operates on production rules.

**Rule-based system** A kind of knowledge-based system that performs inference using production rules.

**Sampling rate** The rate at which the continuously varying values of an analog signal are measured and recorded.

**Scenario** A method of teaching that presents a clinical problem in a story format.

**Schema** In a database-management system, a machine-readable definition of the contents and organization of a database.

**Schemata** Higher-level kinds of knowledge structures.

**SCORM** Shareable Content Object Reference Model, a standard for interoperability between learning content objects.

**Script** In software systems, a keystroke-by-keystroke record of the actions performed for later reuse.

**SDO** See: Standards development organizations.

**Search** A synonym for information retrieval.

**Search** See Information retrieval.

**Search engine** A computer system that returns content from a search statement entered by a user.

**Secondary knowledge-based information** Writing that reviews, condenses, and/or synthesizes the primary literature (see primary knowledge-based information).

**Secret-key cryptography** In data encryption, a method whereby the same key is used to encrypt

and to decrypt information. Thus, the key must be kept secret, known to only the sender and intended receiver of information.

**Secure Sockets Layer (SSL)** A protocol for transmitting private documents via the Internet. It has been replaced by Transport Layer Security. By convention, URLs that require an SSL connection start with https: instead of http:

**Security** The process of protecting information from destruction or misuse, including both physical and computer-based mechanisms.

**Segmentation** In image processing, the extraction of selected regions of interest from an image using automated or manual techniques.

**Selectivity** In data collection and recording, the process that accounts for individual styles, reflecting an ongoing decision-making process, and often reflecting marked distinctions among clinicians.

**Self-experimentation** Experiments in which experimenters themselves are subjects of their research.

**Semantic analysis** The study of how symbols or signs are used to designate the meaning of words and the study of how words combine to form or fail to form meaning.

**Semantic class** In NLP, a broad class that is associated with a specific domain and includes many instances.

**Semantic grammar** A mathematical model of a set of sentences based on patterns of semantic categories, e.g., patient, doctor, medication, treatment, and diagnosis.

**Semantic network** A knowledge source in the UMLS that provides a consistent categorization of all concepts represented in the Metathesaurus in which each concept is assigned at least one semantic type.

**Semantic patterns** The study of the patterns formed by the co-occurrence of individual words in a phrase or the co-occurrence of the associated semantic types of the words.

**Semantic relations** A classification of the meaning of a linguistic relationship, e.g., “treated in 1995” signifies time while “treated in ER” signifies location.

**Semantic sense** In NLP, the distinction between individual word meaning of terms that may be in the same semantic class.

**Semantic types** The categorization of words into semantic classes according to meaning. Usually, the classes that are formed are relevant to specific domains.

**Semantic Web** A future view which envisions the Internet not only as a source of content but also as a source of intelligently linked, agent-driven, structured collections of machine-readable information.

**Semantics** The meaning of individual words and the meaning of phrases or sentences consisting of combinations of words.

**Semi structured interview** Where the investigator specifies in advance a set of topics that he would like to address but is flexible about the order in which these topics are addressed, and is open to discussion of topics not on the pre-specified list.

**Sender** In data interchange, the program or system that sends a transmitted message.

**Sensitivity (of a test)** The probability of a positive result, given that the condition under consideration is present—for example, the probability of a positive test result in a person who has the disease under consideration (also called the true-positive rate).

**Sentence boundary** In NLP, distinguishing the end of one sentence and the beginning of the next.

**Sentiment analysis** The study of how symbols or signs are used to designate the meaning of

words and the study of how words combine to form or fail to form meaning.

**Sequence alignment** An arrangement of two or more sequences (usually of DNA or RNA), highlighting their similarity. The sequences are padded with gaps (usually denoted by dashes) so that wherever possible, columns contain identical or similar characters from the sequences involved.

**Sequence database** A database that stores the nucleotide or amino acid sequences of genes (or genetic markers) and proteins respectively.

**Sequence information** Information from a database that captures the sequence of component elements in a biological structure (e.g., the sequence of amino acids in a protein or of nucleotides in a DNA segment).

**Sequential Bayes** A reasoning method based on a naïve Bayesian model, where Bayes’ rule is applied sequentially for each new piece of evidence that is provided to the system. With each application of Bayes’ rule, the posterior probability of each diagnostic possibility is used as the new prior probability for that diagnosis the next time Bayes’ rule is invoked.

**Server** A computer that shares its resources with other computers and supports the activities of many users simultaneously within an enterprise.

**Service** An intangible activity provided to consumers, generally at a price, by a (presumably) qualified individual or system.

**Service oriented architectures (SOA)** A software design framework that allows specific processing or information functions (services) to run on an independent computing platform that can be called by simple messages from another computer application. Often considered to be more flexible and efficient than more traditional data base architectures. Best known example is the Internet which is based largely on SOA design principles.

**Set-based searching** Constraining a search to include only documents in a given class or set (e.g., from a given institution or journal).

**Set-top box** A device, such as a cable box, that converts video content to analog or digital television signals.

**Shallow parsing** See partial parsing.

**Shielding** In cabling, refers to an outer layer of insulation covering an inner layer of conducting material. Shielded cable is used to reduce electronic noise and voltage spikes.

**Short-term/working memory** An emergent property of interaction with the environment; refers to the resources needed to maintain information active during cognitive activity.

**Signal processing** An area of systems engineering, electrical engineering and applied mathematics that deals with operations on or analysis of signals, or measurements of time-varying or spatially-varying physical quantities.

**Simple Mail Transport Protocol (SMTP)** The standard protocol used by networked systems, including the Internet, for packaging and distributing email so that it can be processed by a wide variety of software systems.

**Simple Object Access Protocol (SOAP)** A protocol for information exchange through the HTTP/HTTPS or SMTP transport protocol using web services and utilizing Extensible Markup Language (XML) as the format for messages.

**Simulation** A system that behaves according to a model of a process or another system; for example, simulation of a patient's response to therapeutic interventions allows a student to learn which techniques are effective without risking human life.

**Simulation center** Specialized type of learning center, though its governance may reside

in an academic department such as anesthesiology or surgery depending on the center's origin and history.

**Simultaneous access** Access to shared, computer-stored information by multiple concurrent users.

**Simultaneous controls** Use of participants in a comparative study who are not exposed to the information resource. They can be randomly allocated to access to the information resource or in some other way.

**Single nucleotide polymorphism (SNP)** A DNA sequence variation, occurring when a single nucleotide in the genome is altered. For example, a SNP might change the nucleotide sequence AAGCCTA to AAGCTTA. A variation must occur in at least 1% of the population to be considered a SNP.

**Single-photon emission computed tomography** A nuclear medicine tomographic imaging technique using gamma rays. It is very similar to conventional nuclear medicine planar imaging using a gamma camera. However, it is able to provide true 3D information. This information is typically presented as cross-sectional slices through the patient, but can be freely reformat- ted or manipulated as required.

**Single-user systems** Computers designed for use by single individuals, such as personal computers, as opposed to servers or other resources that are designed to be shared by multiple people at the same time.

**Six sigma** A management strategy that seeks to improve the quality of work processes by identifying and removing the causes of defects and minimizing the variability of those processes. Statistically, a six sigma process is one that is free of defects or errors 99.99966%, which equates to operating a process that fits six standard deviations between the mean value of the process and the specification limit of that process.

**Slip** A type of medical error that occurs when the actor selects the appropriate course of action, but it was executed inappropriately.

**Slots** In a frame-based representation, the elements that are used to define the semantic characteristics of the frame.

**SMART** See: Substitutable Medical Applications and Reusable Technologies.

**SMART on FHIR** An open, standards-based platform for medical apps to access patients' data from electronic medical records. SMART on FHIR builds on two technology efforts: the Substitutable Medical Applications, Reusable Technologies (SMART) Platforms Project and Fast Health Information Resources (FHIR).

**Smart phones** A mobile telephone that typically integrates voice calls with access to the Internet to enable both access to web sites and the ability to download email and applications that then reside on the device.

**Smartwatch** A type of wearable computer in the form of a wristwatch. Typically provides health monitoring features, ability to run simple third-party apps, and WiFi or Bluetooth connectivity, in addition to telling time.

**SMS messaging** The sending of messages using the text communication service component of phone, web or mobile communication system—Short Message Service.

**SNOMED** Systematized Nomenclature of Medicine—A set of standardized medical terms that can be processed electronically; useful for enhancing the standardized use of medical terms in clinical systems.

**SNOMED-CT** The result of the merger of an earlier version of SNOMED with the Read Clinical Terms.

**SNP** See Single nucleotide polymorphism.

**Social determinants of health** Conditions in which people live, learn, work, and play. Negative examples include: poverty, poor access to healthy foods, substandard education, unsafe neighborhoods.

**Social networking** The use of a dedicated Web site to communicate informally (on the site, by email, or via SMS messages) with other members of the site, typically by posting messages, photographs, etc.

**Sociotechnical systems** An approach to the study of work in complex settings that emphasizes the interaction between people and technology in workplaces.

**Software** Computer programs that direct the hardware how to carry out specific automated processes.

**Software development life cycle (SDLC) or software development process** A framework imposed over software development in order to better ensure a repeatable, predictable process that controls cost and improves quality of a software product.

**Software oversight committee** A groups within organizations that is constituted to oversee computer programs and to assess their safety and efficacy in the local setting.

**Software psychology** A behavioral approach to understanding and furthering software design, specifically studying human beings' interactions with systems and software. It is the intellectual predecessor to the discipline of Human-Computer interaction.

**Solid state drive (SSD)** A data storage device using integrated circuit assemblies as memory to store data persistently. SSDs have no moving mechanical components, which distinguish them from traditional electromechanical magnetic disks such as hard disk drives (HDDs) or floppy disks, which contain spinning disks and movable read/write heads.

**Spamming** The process of sending unsolicited email to large numbers of unwilling recipients, typically to sell a product or make a political statement.

**Spatial resolution** A measure of the ability to distinguish among points that are close to each other (indicated in a digital image by the number of pixels per square inch).

**Specialist Lexicon** One of three UMLS Knowledge Sources, this lexicon is intended to be a general English lexicon that includes many biomedical terms and supports natural language processing.

**Specificity (of a test)** The probability of a negative result, given that the condition under consideration is absent—for example, the probability of a negative test result in a person who does not have a disease under consideration (also called the true-negative rate).

**Spectrum bias** Systematic error in the estimate of a study parameter that results when the study population includes only selected subgroups of the clinically relevant population—for example, the systematic error in the estimates of sensitivity and specificity that results when test performance is measured in a study population consisting of only healthy volunteers and patients with advanced disease.

**Speech recognition** Translation by computer of voice input, spoken using a natural vocabulary and cadence, into appropriate natural language text, codes, and commands.

**Spelling check** A procedure that checks the spelling of individual words in entered data.

**Spirometer** An instrument for measuring the air capacity of the lungs.

**Standard of care** The community-accepted norm for management of a specified clinical problem.

**Standard order sets** Predefined lists of steps that should be taken to deal with certain recurring situations in the care of patients, typically in hospitals; e.g., orders to be followed routinely when a patient is in the post-surgical recovery room.

**Standard-gamble** A technique for utility assessment that enables an analyst to determine the utility of an outcome by comparing an individual's preference for a chance event when compared with a situation of certain outcome.

**Standards development organizations** An organization charged with developing a standard that is accepted by the community of affected individuals.

**Static** In patient simulations, a program that presents a predefined case in detail but which does not vary in its response depending on the actions taken by the learner.

**Stemming** The process of converting a word to its root form by removing common suffixes from the end.

**Stop words** In full-text indexing, a list of words that are low in semantic content (e.g., “the”, “a”, “an”) and are generally not useful as mechanisms for retrieving documents.

**Storage devices** A piece of computer equipment on which information can be stored.

**Store-and-forward** A telecommunications technique in which information is sent to an intermediate station where it is kept and sent at a later time to the final destination or to another intermediate station.

**Strict product liability** The principle that states that a product must not be harmful.

**Structural alignment** The study of methods for organizing and managing diverse sources of information about the physical organization of the body and other physical structures.

**Structural informatics** The study of methods for organizing and managing diverse sources of information about the physical organization of the body and other physical structures. Often used synonymously with “imaging informatics”.

**Structure validation** A study carried out to help understand the needs for an information resource, and demonstrate that its proposed structure makes sense to key stakeholders.

**Structured data entry** A method of human-computer interaction in which users fill in missing values by making selections from pre-defined menus. The approach discretizes user input and makes it possible for a computer system to reason directly with the data that are provided.

**Structured encounter form** A form for collecting and recording specific information during a patient visit.

**Structured interview** An interview with a schedule of questions that are always presented in the same words and in the same order.

**Structured Query Language (SQL)** A commonly used syntax for retrieving information from relational databases.

**Structured reports** A report where the content of the report has coded values for the key information in each pre-specified part of the report, enabling efficient and reliable computation on the report.

**Study arm** in the context of clinical research, a study arm represents a specific modality of an experimental intervention to which a participant is assigned, usually through a process of randomization (e.g., random assigned in a balanced manner to such an arm). Arms are used in clinical study designs where multiple variants of a given experimental intervention are under study, for example, varying the timing or dose of a given medication between arms to determine an optimal therapeutic strategy.

**Study population** The population of subjects—usually a subset of the clinically relevant population—in whom experimental outcomes (for example, the performance of a diagnostic test) are measured.

**Subheadings** In MeSH, qualifiers of subject headings that narrow the focus of a term.

**Subjectivist approaches** Class of approaches to evaluation that rely primarily on qualitative data derived from observation, interview, and analysis of documents and other artifacts. Studies under this rubric focus on description and explanation; they tend to evolve rather than be prescribed in advance.

**Sublanguage** Language of a specialized domain, such as medicine, biology, or law.

**Substitutable Medical Applications and Reusable Technologies (SMART)** A technical platform enables EHR systems to behave as “iPhone-like platforms” through an application programming interface (API) and a set of core services that support easy addition and deletion of third party apps, such that the core system is stable and the apps are substitutable.

**Summarization** A computer system that attempts to automatically summarize a larger body of content.

**Summary ROC curve** A composite ROC curve developed by using estimates from many studies.

**Summative evaluation** after the product is in use, is valuable both to justify the completed project and to learn from one’s mistakes.

**Supervised learning** An approach to machine learning in which an algorithm uses a set of inputs and corresponding outputs to try to learn a model that will enable prediction of an output when faced with a previously unseen input.

**Supervised learning technique** A method for determining how data values may sug-

gest classifications, where the possible classifications are enumerated in advance, and the performance of a system is enhanced by evaluating how well the system classifies a training set of data. Statistical regression, neural networks, and support vector machines are forms supervised learning.

**Supervised machine learning** A machine learning approach that uses a gold standard set as input to learn classifiers.

**Surveillance** The ongoing collection, analysis, interpretation, and dissemination of data on health conditions (e.g., breast cancer) and threats to health (e.g., smoking prevalence). In a computer-based medical record system, systematic review of patients' clinical data to detect and flag conditions that merit attention. Also see public health surveillance and biosurveillance.

**Symbolic-programming language** A programming language in which the program can treat itself, or material like itself, as data. Such programs can write programs (not just as character strings or texts, but as the actual data structures that the program is made of). The best known and most influential of these languages is LISP.

**Syndromic surveillance** A particular type of public health surveillance. It is an ongoing process of monitoring clinical data, generally from public health, hospital, or outpatient resources, or surrogate data indicating early illness (e.g., school or work absenteeism) with a goal of early identification of outbreaks, new conditions, health threats, or bioterrorist events.

**Synonyms** Multiple ways of expressing the same concept.

**Syntax** The grammatical structure of language describing the relations among words in a sentence.

**System programs** The operating system, compilers, and other software that are included

with a computer system and that allow users to operate the hardware.

**Systematic review** A type of journal article that reviews the literature related to a specific clinical question, analyzing the data in accordance with formal methods to assure that data are suitably compared and pooled.

**Systems biology** Research on biological networks or biochemical pathways. Often, systems biology analyses take a comprehensive approach to model biological function by taking the interactions (physical, regulatory, similarity, etc.) of a set of genes as a whole.

**Tablet** Generally refers to a personal computing device that resembles a paper tablet in size and incorporates features such as a touch screen to facilitate data entry.

**Tactile feedback** In virtual or telepresence environments, the process of providing (through technology) a sensation of touching an object that is imaginary or otherwise beyond the user's reach (see also haptic feedback).

**TCP/IP** Transmission Control Protocol/Internet Protocol—A set of standard communications protocols used for the Internet and for networks within organizations as well.

**Teleconsultation** The use of telemedicine techniques to support the interaction between two (or more) clinicians where one is providing advice to the other, typically about a specific patient's care.

**Telegraphic** In NLP, describes language that does not follow the usual rules of grammar but is compact and efficient. Clinical notes written by hand often demonstrate a "telegraphic style".

**Telehealth** The use of electronic information and telecommunications technologies to support long-distance clinical health care, patient and professional health-related education,

public health and health administration. See telemedicine.

**Telehome care** The use of communications and information technology to deliver health services and to exchange health information to and from the home (or community) when distance separates the participants.

**Tele-ICU** See remote intensive care.

**Telemedicine** A broad term used to describe the delivery of health care at a distance, increasingly but not exclusively by means of the Internet.

**Teleophthalmology** The use of telemedicine methods to deliver ophthalmology services.

**Telepresence** A technique of telemedicine in which a viewer can be physically removed from an actual surgery, viewing the abnormality through a video monitor that displays the operative field and allows the observer to participate in the procedure.

**Telepsychiatry** The use of telemedicine methods to deliver psychiatric services.

**Teleradiology** The provision of remote interpretations, increasing as a mode of delivery of radiology services.

**Telesurgery** The use of advanced telemedicine methods to allow a doctor to perform surgery on a patient even though he or she is not physically in the operating room.

**Temporal resolution** A metric for how well an imaging modality can distinguish points in time that are very close together.

**Terabyte** A unit of information equal to one million million ( $10^{12}$ ) or strictly,  $2^{40}$  bytes.

**Term** A word or phrase.

**Term** Designation of a defined concept by a linguistic expression in a special language. In

information retrieval, a word or phrase which forms part of the basis for a search request.

**Term frequency (TF)** In information retrieval, a measurement of how frequently a term occurs in a document.

**Term weighting** The assignment of metrics to terms so as to help specify their utility in retrieving documents well matched to a query.

**Terminal** A simple device that has no processing capability of its own but allows a user to access a server.

**Terminology** A set of terms representing the system of concepts of a particular subject field.

**Terminology authority** An entity or mechanism that determines the acceptable term to use for a specific entity, descriptor, or other concept.

**Terminology services** Software methods, typically based on computer-based dictionaries or language systems, that allow other systems to determine the locally acceptable term to use for a given purpose.

**Test collection** In the context of information retrieval, a collection of real-world content, a sampling of user queries, and relevance judgments that allow system-based evaluation of search systems.

**Test-interpretation bias** Systematic error in the estimates of sensitivity and specificity that results when the index and gold-standard test are not interpreted independently.

**Test-referral bias** Systematic error in the estimates of sensitivity and specificity that results when subjects with a positive index test are more likely to receive the gold-standard test.

**Tethered personal health record** An EHR portal that is provided to patients by an institution and can typically be used to manage

information only from that provider organization.

**Text generation** Methods that create coherent natural language text from structured data or from textual documents in order to satisfy a communication goal.

**Text mining** The use of large text collections (e.g., medical histories, consultation reports, articles from the literature, web-based resources) and natural language processing to allow inferences to be drawn, often in the form of associations or knowledge that were not previously apparent. See also data mining.

**Text processing** The analysis of text by computer.

**Text readability assessment and simplification** An application of NLP in which computational methods are used to assess the clarity of writing for a certain audience or to revise the exposition using simpler terminology and sentence construction.

**Text REtrieval Conference (TREC)** Organized by NIST, an annual conference on text retrieval that has provided a testbed for evaluation and a forum for presentation of results. (see ► [trec.nist.gov](http://trec.nist.gov)).

**Text summarization** Takes one or several documents as input and produces a single, coherent text that synthesizes the main points of the input documents.

**Text-comprehension** A process in which text can be described at multiple levels of realization from surface codes (e.g., words and syntax) to deeper level of semantics.

**TF\*IDF weighting** A specific approach to term weighting which combines the inverse document frequency (IDF) and term frequency (TF).

**Thesaurus** A set of subject headings or descriptors, usually with a cross-reference system for use in the organization of a collection of documents for reference and retrieval.

**Thick-client** A computer node in a network or client-server architecture that provides rich functionality independent of the central server. See also thin client.

**Thin client** A program on a local computer system that mostly provides connectivity to a larger resource over a computer network, thereby providing access to computational power that is not provided by the machine, which is local to the user.

**Think-aloud protocol** In cognitive science, the generation of a description of what a person is thinking or considering as they solve a problem.

**Thread** The smallest sequence of programmed instructions that can be managed independently by an operating system scheduler.

**Three-dimensional printing** Construction of a physical model of anatomy or other object by laying down plastic versions of a stack of cross-sectional slices through the object.

**Three-dimensional structure information** In a biological database, information regarding the three-dimensional relationships among elements in a molecular structure.

**Time-sharing networks** An historical term describing some of the earliest computer networks allowing remote access to systems.

**Time-trade-off** A common approach to utility assessment, comparing a better state of health lasting a shorter time, with a lesser state of health lasting a longer time. The time-trade-off technique provides a convenient method for valuing outcomes that accounts for gains (or losses) in both length and quality of life.

**Tokenization** The process of breaking an unstructured sequence of characters into larger units called “token,” e.g., words, numbers, dates and punctuation.

**Tokens** In language processing, the composite entities constructed from individual char-

acters, typically words, numbers, dates, or punctuation.

**Top-down** In search or analysis, the breaking down of a system to gain insight into its compositional subsystems.

**Topology** In networking, the overall connectivity of the nodes in a network.

**Touch screen** A display screen that allows users to select items by touching them on the screen.

**Track pad** A computer input device for controlling the pointer on a display screen by sliding the finger along a touch-sensitive surface: used chiefly in laptop computers. Also called a touchpad.

**Transaction set** In data transfer, the full set of information exchanged between a sender and a receiver.

**Transcription** The conversion of a recording of dictated notes into electronic text by a typist.

**Transcriptomics** The study of the set of RNA transcripts that are produced by the genome and the context (specific cells or circumstances) in which transcription occurs.

**Transition matrix** A table of numbers giving the probability of moving from one state in a Markov model into another state or the state that is reached in a finite-state machine depending on the current character of the alphabet.

**Transition probability** The probability that a person will transit from one health state to another during a specified time period.

**Translational Bioinformatics (TBI)** According to the AMIA: the development of storage, analytic, and interpretive methods to optimize the transformation of increasingly voluminous biomedical data, and genomic data,

into proactive, predictive, preventive, and participatory health.

**Translational medicine** Translational medicine: the process of transferring scientific discoveries into preventive practice and clinical care.

**Transmission control protocol/internet protocol (TCP/IP)** The standard protocols used for data transmission on the Internet and other common local and wide-area networks.

**Transport Layer Security (TLS)** A protocol that ensures the privacy of data transmitted over the Internet. It grew out of Secure Sockets Layer.

**Treatment threshold probability** The probability of disease at which the expected values of withholding or giving treatment are equal. Above the threshold treatment is recommended; below the threshold, treatment is not recommended and further testing may be warranted.

**Trigger event** In monitoring, events that cause a set of transactions to be generated.

**True negative** In assessing a situation, an instance that is classified negatively and is subsequently shown to have been correctly classified.

**True positive** In assessing a situation, an instances that is classified positively and is subsequently shown to have been correctly classified.

**True-negative rate (TNR)** The probability of a negative result, given that the condition under consideration is false—for example, the probability of a negative test result in a patient who does not have the disease under consideration (also called specificity).

**True-negative result (TN)** A negative result when the condition under consideration is false—for example, a negative test result in a

patient who does not have the disease under consideration.

**True-positive rate (TPR)** The probability of a positive result, given that the condition under consideration is true—for example, the probability of a positive test result in a patient who has the disease under consideration (also called sensitivity).

**True-positive result (TP)** A positive result when the condition under consideration is true—for example, a positive test result in a patient who has the disease under consideration.

**Turn-around-time** The period for completing a process cycle, commonly expressed as an average of previous such periods.

**Tutoring** A computer program designed to provide self-directed education to a student or trainee.

**Tutoring system** A computer program designed to provide self-directed education to a student or trainee. (Also Intelligent Tutoring System).

**Twisted-pair wires** The typical copper wiring used for routine telephone service but adaptable for newer communication technologies.

**Type-checking** In computer programming, the act of checking that the types of values, such as integers, decimal numbers, and strings of characters, match throughout their use.

**Typology** A way of classifying things to make sense of them, for a certain purpose.

**Ubiquitous computing** A form of computing and human-computer interaction that seeks to embed computing power invisibly in all facets of life.

**Ultrasound** A common energy source derived from high-frequency sound waves.

**UMLS** See: Unified Medical Language System.

**UMLS Knowledge Sources** Components of the Unified Medical Language System that support its use and semantic breadth.

**UMLS Semantic Network** A knowledge source in the UMLS that provides a consistent categorization of all concepts represented in the Metathesaurus. Each Metathesaurus concept is assigned at least one semantic type from the Semantic Network.

**Unicode** Represents characters needed for foreign languages using up to 16 bits.

**Unified Medical Language System (UMLS) Project** A terminology system, developed under the direction of the National Library of Medicine, to produce a common structure that ties together the various vocabularies that have been created for biomedical domains.

**Unified Modeling Language (UML)** A standardized general-purpose modeling language developed for object-oriented software engineering that provides a set of graphic notation techniques to create visual models that depict the relationships between actors and activities in the program or process being modeled.

**Uniform resource identifier (URI)** The combination of a URN and URL, intended to provide persistent access to digital objects.

**Uniform resource locator (URL)** The address of an information resource on the World Wide Web.

**Uniform resource name (URN)** A name for a Web page, intended to be more persistent than a URL, which often changes over time as domains evolve or Web sites are reorganized.

**Unique health identifier (UHI)** A government-provided number that is assigned to an individual for purposes of keeping track of their health information.

**Universal Serial Bus(USB)** A connection technology for attaching peripheral devices to a computer, providing fast data exchange.

**Unobtrusive measures** Measures made using the records accrued as part of the routine use of the information resource, including, for example, user log files.

**Unstructured interview** An interview where there are no predetermined questions.

**Unsupervised machine learning** A machine learning approach that learns patterns from the data without labeled training sets.

**URAC** An organization that accredits the quality of information from various sources, including health-related Web sites.

**Usability** The quality of being able to provide good service to one who wishes to use a product.

**Usability testing** A class of methods for collecting empirical data of representative users performing representative tasks; considered the gold standard in usability evaluation methods.

**User authentication** The process of identifying a user of an information resource, and verifying that the user is allowed to access the services of that resource. A standard user authentication method is to collect and verify a username and password.

**User-centered design** An iterative process in which designers focus on the users and their needs in each phase of the design process. UCD calls for involving users throughout the design process via a variety of research and design techniques to increase the likelihood that the product will be highly usable by its intended users.

**User-interface layer** The architectural layer of a software environment that handles the interface with users.

**Utility** In decision making, a number that represents the value of a specific outcome to a decision maker (see, for example, quality-adjusted life-years).

**Validity check** A set of procedures applied to data entered into an EHR intended to detect or prevent the entry of erroneous data; e.g., range checks and pattern checks.

**Value-based reimbursement** In health care, an alternative to traditional fee-for-service reimbursement, aimed at rewarding quality rather than quantity of services.

**Variable** Quantity measured in a study. Variables can be measured at the nominal, ordinal, interval, or ratio levels.

**Vector mathematics** In the context of information retrieval, mathematical systems for measuring and comparing vector representations of documents and their contents.

**Vector-space model** A method of full-text indexing in which documents can be conceptualized as vectors of terms, with retrieval based on the cosine similarity of the angle between the query and document vectors.

**Vendor-neutral archives (VNA)** A technology in which images (and potentially any file of clinical relevance) is stored (archived) in a standard format with a standard interface (e.g., DICOM), such that they can be accessed in a vendor-neutral manner by other systems.

**Vertically integrated** Refers to an organizational structure in which a variety of products or services are offered within a single chain of command; contrasted with horizontal integration in which a single type of product is offered in different geographical markets. A hospital that offers a variety of services from obstetrics to geriatrics would be “vertically integrated.” A diagnostic imaging organization with multiple sites would be “horizontally integrated”.

**Veterinary informatics** The application of biomedical informatics methods and techniques to problems derived from the field of veterinary medicine. Viewed as a subarea of clinical informatics.

**Video-display terminal (VDT)** A device for displaying input signals as characters on a screen, typically a computer monitor.

**View** In a database-management system, a logical submodel of the contents and structure of a database used to support one or a subset of applications.

**View schemas** An application-specific description of a view that supports that program's activities with respect to some general database for which there are multiple views.

**Virtual address** A technique in memory management such that each address referenced by the CPU goes through an address mapping from the virtual address of the program to a physical address in main memory.

**Virtual medical record** A standard model of the data elements found in EHR systems. The virtual medical record approach assumes that, even if particular EHR implementations adopt nonstandard data dictionaries and disparate ways for storing clinical data, mapping the contents of each EHR to a canonical model greatly simplifies interoperability with CDS Systems and other applications that may need to access the data.

**Virtual memory** A scheme by which users can access information stored in auxiliary memory as though it were in main memory. Virtual memory addresses are automatically translated into actual addresses by the hardware.

**Virtual patient** A digital representation of a patient encounter that can range from a simple review of clinical findings to a realistic graphical view of a person who can converse and can be examined for various clinical symptoms and laboratory tests.

**Virtual Private Network (VPN)** A private communications network, usually used within a company or organization, or by several different companies or organizations, communicating over a public network. VPN message traffic is carried on public networking infrastructure (e.g., the Internet) using standard (often insecure) protocols.

**Virtual reality** A collection of interface methods that simulate reality more closely than does the standard display monitor, generally with a response to user maneuvers that heighten the sense of being connected to the simulation.

**Virtual world** A three-dimensional representation of an environment such as a hospital, a clinic or a home-care location. The represented space usually includes a virtual patient, and interactive equipment and supplies that can be used to examine and care for the patient. Some virtual worlds are multi-user and allow multiple learners to manifest themselves as characters in the virtual world for interaction with each other and the patient.

**Virus/worm** A software program that is written for malicious purposes to spread from one machine to another and to do some kind of damage. Such programs are generally self-replicating, which has led to the comparison with biological viruses.

**Visual-analog scale** A method for valuing health outcomes, wherein a person simply rates the quality of life with a health outcome on a scale from 0 to 100.

**Vocabulary** A dictionary containing the terminology of a subject field.

**Volatile** A characteristic of a computer's memory, in that contents are changed when the next program runs and are not retained when power is turned off.

**Volume rendering** A method whereby a computer program projects a two-dimensional

image directly from a three-dimensional voxel array by casting rays from the eye of the observer through the volume array to the image plane.

**vonNeuman machine** A computer architecture that comprises a single processing unit, computer memory, and a memory bus.

**Voxel** A volume element, or small cubic area of a three-dimensional digital image (see pixel).

**Washington DC Principles for Free Access to Science** An organization of non-profit publishers that aims to balance wide access with the need to maintain sustainable revenue models.

**Wearables** In the context of mobile health, wearables refer to a range of electronic devices that can be incorporated into clothing or worn on the body, such as smartwatches, activity trackers, and physiological sensors, that are used to collect health-related data and provide health interventions. Also referred to as wearable devices or wearable technologies.

**Web browser** A computer program used to access and display information resources on the World Wide Web.

**Web catalog** Web pages containing mainly links to other Web pages and sites.

**Web Services Discovery Language (WSDL)** An XML-based language used to describe the attributes of a web service, such as a SOAP service.

**Web-based technologies** Computer capabilities that rely on the architecture principles of the Internet for accessing data from remote servers.

**Weblogs/blogs** A type of Web site that provides discussion or information on various topics.

**WebMD** An American company that provides web-based health information services.

**Whole Slide Digitization** The process of capturing an entire specimen on a slide into a digital image. Compared with capturing images of a single field of view from a microscope, this captures the entire specimen, and can be millions of pixels on a side. This allows subsequent or remote review of the specimen without requiring capture of individual fields.

**Wide-area networks (WANs)** A network that connects computers owned by independent institutions and distributed over long distances.

**Wi-Fi** A common wireless networking technology (IEEE 802.11x.) that uses radio waves to provide high-speed connections to the Internet and local networks.

**Word** In computer memory, a sequence of bits that can be accessed as a unit.

**Word sense disambiguation (WSD)** The process of determining the correct sense of a word in a given context.

**Word senses** The possible meanings of a term.

**Word size** The number of bits that define a word in a given computer.

**Workstation** A powerful desktop computer system designed to support a single user. Workstations provide specialized hardware and software to facilitate the problem-solving and information-processing tasks of professionals in their domains of expertise.

**World Intellectual Property Organization (WIPO)** An international organization, headquartered in Geneva and dedicated to promoting the use and protection of intellectual property.

**World Wide Web (WWW or Web)** An application implemented on the Internet in which multimedia information resources are made accessible by any of a number of protocols, the most common of which is the HyperText Transfer Protocol (HTTP).

**Worm** A self-replicating computer program, similar to a computer virus; a worm is self-contained and does not need to be part of another program to propagate itself.

**xAPI** Experience Application Programming Interface goes beyond interoperability standards, such as SCORM, and supports col-

lection of data about the learner's experience while using the learning object.

**XML** A metalanguage that allows users to define their own customized markup languages. See Extensible Markup Language.

**X-ray crystallography** A technique in crystallography in which the pattern produced by the diffraction of x-rays through the closely spaced lattice of atoms in a crystal is recorded and then analyzed to reveal the nature of that lattice, generally leading to an understanding of the material and molecular structure of a substance.
